Third Method.—The eye-piece is fixed in the axis, and the segments are symmetrically displaced from the axis each by an amount equal to half the angle measured.

Of these methods Bessel generally employed the first because of its simplicity, notwithstanding that it involved a resetting of the right ascension and declination of the axis of the tube with each reversal of the segments. The chief objections to the method are that, as one star is in the axis of the telescope and the other displaced from it, the images are not both in focus of the eye-piece,[2] and the rays from the two stars do not make the same angle with the optical axis of each segment. Thus the two images under measurement are not defined with equal sharpness and symmetry. The second method is free from the objection of non-coincidence in focus of the images, but is more troublesome in practice from the necessity for frequent readjustment of the position of the eye-piece. The third method is the most symmetrical of all, both in observation and reduction; but it was not employed by Bessel, on the ground that it involved the determination of the errors of two screws instead of one. On the other hand it is not necessary to reset the telescope after each reversal of the segments.[3]

[2] The distances of the optical centres of the segments from the eye-piece are in this method as 1 : secant of the angle under measurement. In Bessel's heliometer this would amount to a difference of $\frac{15}{1000}$th of an inch when an angle of 1° is measured. For two degrees the difference would amount to nearly $\frac{1}{16}$th of an inch. Bessel confined his measures to distances considerably less than 1°.

[3] In criticizing Bessel's choice of methods, and considering the loss of time involved in each, it must be remembered that Fraunhofer provided no means of

When Bessel ordered the Königsberg heliometer, he was anxious to have the segments made to move in cylindrical slides, of which the radius should be equal to the focal length of the object-glass. Fraunhofer, however, did not execute this wish, on the ground that the mechanical difficulties were too great.

Wichmann states (*Königsb. Beobach.*, xxx. p. 4) that Bessel had indicated, by notes in his handbooks, the following points which should be kept in mind in the construction of future heliometers:—(1) The segments should move in cylindrical slides;[1] (2) the screw should be protected from dust;[2] (3) the zero of the position circle should not be so liable to change;[3] (4) the distance of the optical centres of the segments should not change in different position angles or otherwise;[4] (5) the points of the micrometer screws should rest on ivory plates;[5] (6) there should be an apparatus for changing the screen.[6]

The elder Struve, in describing the Pulkowa heliometer,[7] made by Merz in 1839 on the model of Bessel's heliometer, submits the following suggestions for its improvement:[8]—(1) to give automatically to the two segments simultaneous equal and opposite movement;[9] and (2) to make the tube of brass instead of wood; to attach the heliometer head firmly to this tube; to place the eye-piece permanently in the axis of the telescope; and to fix a strong cradle on the end of the declination axis, in which the tube, with the attached head and eye-piece, could rotate on its axis.

Both suggestions are important. The first is originally the idea of Dollond (fig. 29); its advantages were overlooked by his son (description of fig. 30), and it seems to have been quite forgotten till resuggested by Struve. But the method is not available if the separation is to be measured by screws; it is found, in that case, that the direction of the final motion of turning of the screw must always be such as to produce motion of the segment against gravity, otherwise the "loss of time" is apt to be variable. Thus the simple connexion of the two screws by cog-wheels to give them automatic opposite motion is not an available method unless the separation of the segments is independently measured by scales.

Struve's second suggestion has been adopted in nearly all succeeding heliometers. It permits complete rotation of the tube and measurement of all angles in reversed positions of the circle; the handles that move the slides can be brought down to the eye-end, inside the tube, and consequently made to rotate with it; and the position circle may be placed at the end of the cradle next the eye-end where it is convenient of access. Struve also points out that by attaching a fine scale to the focussing slide of the eye-piece, and knowing the coefficient of expansion of the brass tube, the means would be provided for determining the absolute change of the focal length of the object-glass at any time by the simple process of focussing on a double star. This, with a knowledge of the temperature of the screw or scale and its coefficient of expansion, would enable the change of screw value to be determined at any instant. Or, if we suppose the temperature of the instrument to be the same in all its parts, the changed scale value becomes simply a function of the reading of the focal scale.

Bonn heliometer.

It is probable that the Bonn heliometer was in course of construction before these suggestions of Struve were published or discussed, since its construction resembles that of the Königsberg and Pulkowa instruments. Its dimensions are similar to those of the former instrument. Bessel, having been consulted by the celebrated statesman Sir Robert Peel, on behalf of the Radcliffe trustees, as to what instrument, added to the Radcliffe Observatory, would probably most promote the advancement of astronomy, strongly advised the selection of a heliometer. The order for the instrument was given to the Repsolds in 1840, but "various circumstances, for which the makers are not responsible, contributed to delay the completion of the instrument, which was not delivered before the winter of 1848."[10] The building to receive it was commenced in March 1849 and completed in the end of the same year. This splendid instrument has a superb object-glass of $7\frac{1}{2}$ inches aperture and 126 inches focal length. The makers availed themselves of Bessel's suggestion to make the segments move in cylindrical slides, and of Struve's to have the head attached to a brass tube; the eye-piece is set permanently in the axis, and the whole rotates in a cradle attached to the declination axis. They provided a splendid, rigidly mounted, equatorial stand, fitted with every luxury in the way of slow motion, and scales for measuring the displacement of the segments were read by powerful micrometers from the eye-end.[11] It is somewhat curious that, though Struve's second suggestion was adopted, his first was overlooked by the makers. But it is still more curious that it was not afterwards carried out, for the communication of automatic symmetrical motion to both segments only involves a simple alteration previously described. But, as it came from the hands of the makers in 1849, the Oxford heliometer was incomparably the most powerful and perfect instrument in the world for the highest order of micrometric research. It so remained, unrivalled in every respect, till 1873; it remains still, optically, the most powerful heliometer in the world; and, with a few alterations, it might almost rival the most recent instruments in practical convenience and accuracy. These alterations, all of which could be made without great difficulty, are the following:—

(*a*) Beyond the automatic symmetrical motion above-described, the instrument should be fitted with means for adjusting the screens from the eye-end (see footnote [6] in last column).

(*b*) The arrangement of the scales should be changed. At present both scales are read separately by separate micrometers, each relative to a separate fiducial line. What the observer requires is the difference of the readings of the two scales, and this can obviously be most quickly and accurately obtained if the edges of the two scales are brought together, and both are read, relatively to each other, by the same micrometer.

(*c*) The unsatisfactory motion in position angle should be replaced by the action of a pinion (attached to the cradle) in the teeth of a wheel (attached to the tube).[12]

(*d*) The position circle should be read by telescopes or microscopes attached to the cradle, and accessible from the eye-end.

(*e*) It would add greatly to the rapidity of work and the ease of the observer if a small declination circle were attached to the cross-head, capable of being read from the eye-end.

As the transit of Venus of 1874 approached, preparations were set on foot by the German Government in good time; a commission of the most celebrated astronomers was appointed, and it was resolved that the heliometer should be the instrument chiefly relied on. The four long-neglected small heliometers made by Fraunhofer were brought into requisition. Fundamental alterations were made upon them:—their wooden tubes were replaced by tubes of metal; means of measuring the focal point were provided; symmetrical motion was given to the slides; scales on each slide were provided instead of screws for measuring the separation of the segments, and both scales were read by the same micrometer microscope; a metallic thermometer was added to determine the temperature of the scales. These small instruments have since done admirable work in the hands of Schur, Hartwig, Kustner, and Elkin.

Russian heliometers.

The Russian Government ordered three new heliometers (each of 4 inches aperture and 5 feet focal length) from the Repsolds, and the design for their construction was superintended by Struve, Auwers,

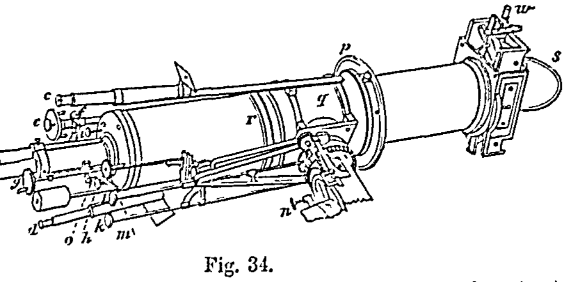

Fig. 34.

and Winnecke, the last-named making the necessary experiments at Carlsruhe. Fig. 34 represents the type of instrument which re-

reading the screws or even the heads from the eye-end. Bessel's practice was to unclamp in declination, lower and read off the head, and then restore the telescope to its former declination reading, the clockwork meanwhile following the stars in right ascension. The setting of both lenses symmetrically would, under such circumstances, be very tedious.

1 This most important improvement would permit any two stars under measurement each to be viewed in the optical axis of each segment. The optical centres of the segments would also remain at the same distance from the eye-piece at all angles of separation. Thus, in measuring the largest as well as the smallest angles, the images of both stars would be equally symmetrical and equally well in focus. Modern heliometers made with cylindrical slides measure angles over two degrees, the images remaining as sharp and perfect as when the smallest angles are measured.

2 Bessel found, in course of time, that the original corrections for the errors of his screw were no longer applicable. He considered that the changes were due to wear, which would be much lessened if the screws were protected from dust.

3 The tube, being of wood, was probably liable to warp and twist in a very uncertain way.

4 We have been unable to find any published drawing showing how the segments are fitted in their cells.

5 We have been unable to ascertain the reasons which led Bessel to choose *ivory* planes for the end-bearings of his screws. He actually introduced them in the Königsberg heliometer in 1810, and they were renewed in 1848 and 1850.

6 A screen of wire gauze, placed in front of the segment through which the fainter star is viewed, was employed by Bessel to equalize the brilliancy of the images under observation. An arrangement, afterwards described, has been fitted in modern heliometers for placing the screen in front of either segment by a handle at the eye-end.

7 This heliometer resembles Bessel's, except that its foot is a solid block of granite instead of the ill-conceived wooden structure that supported his instrument. The object-glass is of 7·4 inches aperture and 123 inches focus.

8 *Description de l'Observatoire central de Pulkowa*, p. 208.

9 Steinheil applied such motion to a double-image micrometer made for Struve. This instrument suggested to Struve the above-mentioned idea of employing a similar motion for the heliometer.

10 Manuel Johnson, M.A., Radcliffe observer, *Astronomical Observations made at the Radcliffe Observatory, Oxford, in the year* 1850, Introduction, p. iii.

11 The illumination of these scales is interesting as being the first application of electricity to the illumination of astronomical instruments. Thin platinum wire was rendered incandescent by a voltaic current; a small Swan light and condenser would probably now be found more satisfactory.

12 This has been recently carried out by Stone, the present Radcliffe observer, on Gill's suggestion.

sulted from their labours. The brass tube, strengthened at the bearing points by strong truly-turned collars, rotates in the cast-iron cradle q attached to the declination axis. a is the eye-piece fixed in that axis, b the micrometer for reading both scales.

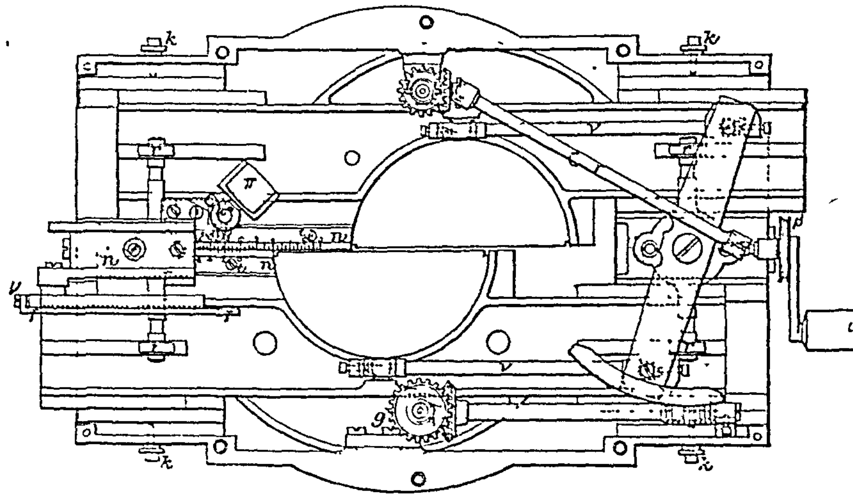

Fig. 35.

c, d are telescopes for reading the position circle p, e the handle for quick motion in position angle, f the slow motion in position angle, g the handle for changing the separation of the segments by acting on the bevel-wheel g' (fig. 35). h is a milled head connected by a rod with h' (fig. 35), for the purpose of interposing at pleasure the prism π in the axis of the reading micrometer; this enables the observer to view the graduations on the face of the metallic thermometer $\tau\tau$ (composed of a rod of brass and a rod of zinc). i is a milled head connected with the wheel $i'i'$ (fig. 35), and affords the means of placing the screen s (fig. 34), counterpoised by w over either half of the object-glass. k clamps the telescope in declination, n clamps it in right ascension, and the handles m and l provide slow motion in declination and right ascension respectively

The details of the interior mechanism of the "head" will be almost evident from fig. 35 without description. The screw, turned by the wheels at g', acts in a toothed arc, whence, as shown in the figure, equal and opposite motion is communicated to the slides by the jointed rods v, v. The slides are kept firmly down to their bearings by the rollers r, r, r, r, attached to axes which are, in the middle, very strong springs. Side-shake is prevented by the screws and pieces k, k, k, k. The scales are at n, n; they are fastened only at the middle, and are kept down by the brass pieces t, t.

Lord Lindsay's heliometer. A similar heliometer was made by the Repsolds to the order of Lord Lindsay for his Mauritius expedition in 1874. It differed only from the three Russian instruments in having a mounting by the Cookes in which the declination circle reads from the eye-end.[1] This instrument was afterwards most generously lent by Lord Lindsay to Gill for his expedition to Ascension in 1877.[2]

These four Repsold heliometers proved to be excellent instruments, easy and convenient in use, and yielding results of very high accuracy in measuring distances. Their slow motion in position angle, however, was not all that could be desired. When small movements were communicated to the handle e (fig. 34) by the tangent screw f, acting on a small toothed wheel clamped to the rod connected with the driving pinion, there was apt to be a torsion of the rod rather than an immediate action. Thus the slow motion would take place by jerks instead of with the necessary smoothness and certainty. When the heliometer part of Lord Lindsay's heliometer was acquired by Gill in 1879, he changed the manner of imparting the motion in question. A square toothed racked wheel was applied to the tube at r (fig. 34). This wheel is acted on by a tangent screw whose bearings are attached to the cradle; the screw is turned by means of a handle supported by bearings attached to the cradle, and coming within convenient reach of the observer's hand. The tube turns smoothly in the racked wheel, or can be clamped to it at the will of the observer. This alteration and the new equatorial mounting have been admirably made by Grubb; the result is completely successful. The instrument so altered has been in constant use at the Cape Observatory since March 1881 in determining the parallax of the more interesting southern stars.

Yale College heliometer. Still more recently the Repsolds have completed a new heliometer for Yale College, New Haven, United States. The object-glass is of 6 inches aperture and 98 inches focal length. The mounting, the tube, objective-cell, slides, &c., are all of steel.[3] The instrument is shown in fig. 36. The circles for position angle and declination are read by micrometer microscopes illuminated by the lamp L; the scales are illuminated by the lamp l. T is part of the tube proper, and turns with the head. The tube V, on the contrary, is attached to the cradle, and merely forms a support for the finder Q, the handles at f and p, and the moving ring P. The latter gives quick motion in position angle; the handles at p clamp and give slow motion in position angle, those at f clamp and give slow motion in right ascension and declination. a is the eye-piece, b the handle for moving the segments, c the micrometer microscope for reading the scales and scale micrometer, d the micrometer readers of the position and declination circles, e the handle for rotating the large wheel E which carries the screens. The hour circle is also read by microscopes, and the instrument can be used in both positions (tube preceding and

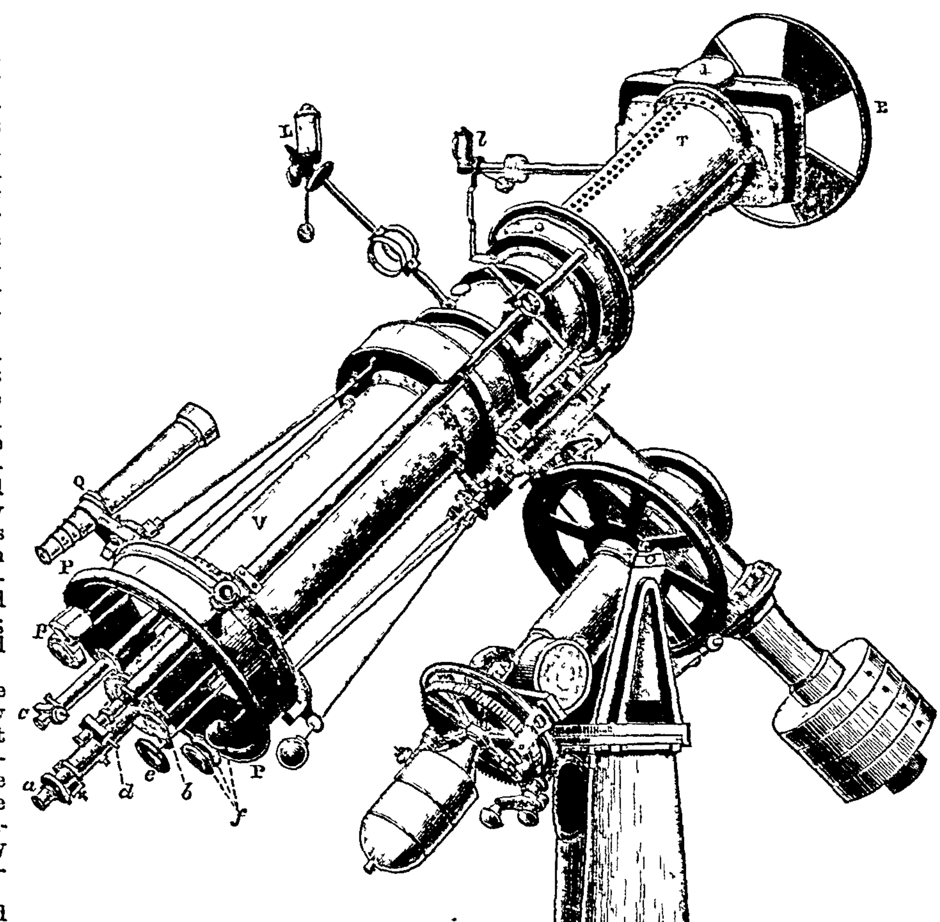

Fig. 36.

[2] *Mem. Royal Astronomical Society*, vol. xlvi pp. 1-172.

[3] The primary object was to have the object-glass mounted in steel cells, which more nearly correspond in expansion with glass. It became then desirable to make the head of steel for sake of uniformity of material, and the advantages of steel in lightness and rigidity for the tube then became evident.

following) for the elimination of the effect of flexure on the position angles.

There is very little left to criticize in this instrument. It embraces the results of all knowledge and experience on the subject to the present time. In one point, however, modern heliometers have a disadvantage compared with the older forms. A great advance in accuracy was, no doubt, made when the screw was abandoned as a means both of moving and measuring the displacement of the slides.[1] But it is obviously much quicker to read and record the indication of one screw-head than to bisect two or four scale-divisions and enter the corresponding readings. Auwers, in his researches on the parallax of 61 Cygni,[2] was able, with the Königsberg heliometer, to make forty pointings in about an hour; it is quick work to make sixteen pointings (reading two divisions on each scale at each pointing) with the modern heliometer in the same time, when attention is paid to the desirable reversals of the segments and of the position circle and the resettings in right ascension and declination. Now time during opportunities of good definition (or otherwise)[3] is too precious to be sacrificed, if it can be saved even by ten-fold labour afterwards. Carrington[4] has suggested the possible use of photography to record the readings of astronomical circles, and since his day "Swan lights" and "sensitive dry plates" seems to have brought his suggestion within the range of practice. A special microscope, fitted with an aplanatic photographic objective and a well-contrived carrier, might be made automatically to expose a different part of a narrow dry plate, by mere pressure or turning of a button after each bisection. Each plate might easily record the sixteen bisections which constitute a complete measure of two pairs of stars (as in a parallax determination). As it is only necessary to photograph two divisions of each scale, the photographic enlargement of these divisions need only be limited by the sensitiveness of the plates and the power of the illumination to produce a picture in a conveniently short space of time. The plates employed at night could be conveniently developed the following day and measured with a special apparatus at any convenient time and with almost any desired accuracy. Were such a system reduced to practice it would at least double, perhaps treble, an observer's possible output of work.

Reversing prism.

Gill has introduced a powerful auxiliary to the accuracy of heliometer measures in the shape of a reversing prism placed in front of the eye-piece, between the latter and the observer's eye. If measures are made by placing the image of a star in the centre of the disk of a planet, the observer may have a tendency to do so systematically in error from some acquired habit or from natural astigmatism of the eye. But by rotating the prism 90° the image is presented entirely reversed to the eye, so that in the mean of measures made in two such positions personal error is eliminated. Similarly the prism may be used for the study and elimination of personal errors depending on the angle made by a double star with the vertical. The best plan of mounting such a prism has been found to be the following. l', l^2 (fig. 37) are the eye lens and field lens respectively of a Merz positive eye-piece. In this construction the lenses are much closer together and the diaphragm for the eye is much farther from the lenses than in Ramsden's eye-piece. The prism p is fitted accurately into brass slides (care has to be taken in the construction to place the prism so that an object in the centre of the field will so remain when the eye-piece is rotated in its adapter). There is a collar, clamped by the screw at S, which is so adjusted that the eye-piece is in focus when pushed home, in its adapter, to this collar. The prism and eye-piece are then rotated together in the adapter.

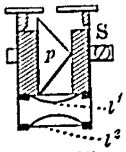

Fig. 37.

Micrometers which Involve the Employment of the Diurnal Motion.

Advantage is often taken of the diurnal motion to measure the relative positions of stars. The varieties of reticules and scales that have been employed are far too numerous even for mention in detail. The following are the means and methods by which most work has been done, and they are typical of all the others. In the focus of his meridian telescope Lacaille had a brass diaphragm in which was cut a hole, having parallel, sharp, straight edges of the shape shown in fig. 38. The longer diagonal of the rhomboid so formed was at right angles, and the shorter parallel, to the diurnal motion. The method of observation consisted in noting the instant of ingress and egress of each star which presented itself. The mean of the times thus noted for each star gave the time of its transit over the imaginary line ab, whilst the difference between the instant of ingress and that of egress (converted into arc by the known approximate declination) gave the length of the chord traversed by the star parallel to the imaginary line cd. Hence (the dimensions of the rhomboid being known) the difference of the star's declination from the line cd became known (the observer was of course careful to note whether the star passed to north or south of cd). Thus every star that crossed the field was observed, all their right ascensions were referred to the clock-time of passing ab, and all their declinations to that of cd; hence their mutual differences of right ascension and declination were known. In this way, in the short space of ten months, Lacaille observed nearly ten thousand stars at the Cape of Good Hope in the years 1751–52.[5] — Lacaille's rhomboid.

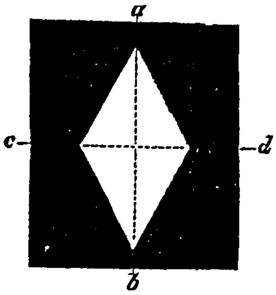

Fig. 38.

Ring micrometer. Fraunhofer's ring micrometer consists of a ring of steel, very truly turned, mounted in a hole cut in a circular disk of glass. The ring is placed in the focus of a telescope, and viewed by a positive eye-piece. The observer notes the instants when the two objects enter and emerge from each side of the ring. The only data required for computing the difference of right ascension and declination of the two objects are the times above mentioned, the diameter of the ring, and *the approximate declination of one of the objects*. The latter is always known. The methods of determining the former and of reducing the observations are to be found in every work on practical astronomy. The ring micrometer has been largely used in observing comets.

Argelander's scale. Argelander, in making his famous survey of the northern heavens,[6] employed a semicircle of glass, the straight edge of which (truly ground) crosses the centre of the field of view at right angles to the diurnal motion of the stars. Differences of right ascension were directly observed at this edge, whilst differences of declination were noted by strong dark lines drawn at right angles to the edge at each 10′ of arc. A telescope of 3 inches aperture with a magnifying power of 10 diameters commanded a field of 3° 20′ in declination. One observer was placed at the telescope, another at the clock. The telescope observer marked the instant when the star touched the glass edge, by calling sharply the word "eight" or "nine," &c., which also indicated the magnitude; the same observer also noted and recorded the reading of the declination scale (where the star crossed it), without removing his eye from the telescope. The clock observer wrote down the magnitude called out by the telescope observer, and the instant by the clock when the word was given. The two records were then compared after the observations of the night were over. In this way Schönfeld and Krueger (Argelander's assistants) observed and catalogued about three hundred thousand stars. The probable error of an observation is about ±0·7 sec. in right ascension and ±0′·4 in declination.

Bond's mica declinometer. Bond[7] employed a very similar arrangement, differing only from Argelander's in having the scale cut on a sheet of transparent mica $\frac{1}{1000}$th of an inch in thickness. Very oblique illumination was employed, and the divisions and figures were seen bright upon a dark background. The range of declination was limited to 10′, the scale was divided to 10″, the right ascensions were observed by chronographic registration, and the great refractor of the Cambridge U. S. Observatory (with an aperture of 15 inches and power of 140) was employed. The probable errors in right ascension and declination were found to be ±0·06 sec. in right ascension and ±0″·6 in declination—results of marvellous accuracy considering the amount of work accomplished in a short time and the faintness (eleven to twelve magnitudes) of the stars observed.

Peters's zones. We were on the point of criticizing Bond's programme as somewhat too ambitious for realization without cooperation (it would take about twenty-six thousand hours of observing to carry out the scheme for the northern hemisphere alone) when we received from Peters of Clinton, U. S., the first twenty maps of a series which will include the whole of the sky between declination +30° and −30°. If we consider that all the stars in these maps of the eleventh magnitude or brighter have been observed by a method similar to Bond's, that the enormous additional labour of frequent revision has been undertaken, and all stars visible with a power of 80 in a telescope of 13 inches aperture (about fourteenth magnitude) have been filled in

---

1 Screws, as Auwers's discussion of Bessel's observations ("Parallaxe von 61 Cygni," *Abhandlungen der Konigl. Akad. der Wissenschaften zu Berlin*, 1868) has shown, are apt to wear and change their errors. It is, besides, undesirable to apply force and friction to a delicate standard of measure.

2 *Astron. Nachrichten*, No. 1416.

3 For example, in determining the diurnal parallax of a planet the most favourable conditions are limited on the one hand by the uncertainties of refraction at large zenith distances, and on the other by the small parallax factors of small zenith distances. It would probably be best to secure all the observations between 50° and 60° ZD, and this would only be possible with special facilities for reading the scales.

by alignment, *and that all this results from the unaided labour of a single observer*, we find that our ideas of *the possible* have to be modified, when such a man undertakes a work with persistent unity of purpose for more than twenty years (1860–83).

Berlin declinograph. There is an ingenious mode of registering differences of declination that has been in use at the Berlin Observatory since 1879, and is described by Dr Knarre in the *Zeitschrift für Instrumentenkunde* for July 1881. The instrument is called a declinograph. It has a web moved in declination by a quick-acting screw; the same screw carries a travelling pricker or point. The observer having bisected a star by the wire has simply to compress an india-rubber ball connected by a flexible tube with a thin metal box made on the principle of the vacuum chamber of an aneroid barometer. The expansion of this box so produced brings a sheet of paper in contact with two prickers, one the movable pricker before mentioned, the other a fixed pricker. The action of the vacuum box also automatically shifts the paper (a long roll) by a small quantity at each observation, so that successive observations are recorded in regular order. To obtain the observed differences of declination it is then only necessary to measure with a glass scale (divided for the special telescope to 10″) the distance of each record of the moving pricker from the fixed pricker. It is found, with this declinograph on the Berlin equatorial, that the observed declinations have only a probable error of $\pm 0''\cdot 9$. It is obvious that by using a chronograph in conjunction with this instrument both right ascensions and declinations could be recorded with great accuracy and rapidity.

Miscellaneous Micrometers.

Parallel glass micrometer. Clausen in 1841 (*Ast. Nach.*, No. 414) proposed a form of micrometer consisting of a divided plate of parallel glass placed within the cone of rays from the object-glass at right angles to the telescope axis. One half of this plane remains fixed, the other half is movable. When the inclination of the movable half with respect to the axis of the telescope is changed by rotation about an axis at right angles to the plane of division, two images are produced. The amount of separation is very small, and depends on the thickness of the glass, the index of refraction, and the focal length of the telescope. Secchi (*Comptes Rendus*, xli., 1855, p. 906) gives an account of some experiments with a similar micrometer; and Porro (*Comptes Rendus*, xli. p. 1058) claims the original invention and construction of such a micrometer in 1842. Clausen, however, has undoubted priority. Helmholtz in his "Ophthalmometer" has employed Clausen's principle, but arranges the plates so that both move symmetrically in opposite directions with respect to the telescope axis. Should Clausen's micrometer be employed as an astronomical instrument it would be well to adopt the improvement of Helmholtz.

Ghost micrometer. Burton and Grubb (*Monthly Notices*, vol. xli. p. 59), after calling attention to Lamont's paper (*Jahrbuch der K. S. b. München*, p. 187) and Littrow's paper (*Proc. of Vienna Acad. of Sciences*, vol. xx. p. 253) on a like subject, proceed to describe a most ingenious form of "Ghost Micrometer," in which the *image* of a fine line or lines ruled in (or rather cut through) a silver film deposited on glass is formed at the common focus of an object-glass and eye-piece of a telescope. A faint light being thrown on the outside of the silvered plate, there appear bright lines in the field of view. We have not had an opportunity of testing this, nor Grubb's more recent models; but, should it be found possible to produce such images satisfactorily, without distortion and with an apparatus convenient and rigid in form, such micrometers will probably supersede the filar micrometer. Their absolute freedom from diffraction, the perfect control of the illumination and thickness of the lines, and the accuracy with which it will be possible to construct scales for zone observations will be important features of the new method.

For the use of micrometers in connexion with the microscope, see p. 277 of the present volume. (D. GI.)

MICRONESIA. The term "Micronesia" embraces that region of the Pacific north of the great Melanesian islands, where, either perhaps from a greater or more rapid subsidence, or from the decreasing activity northwards of the coral builders, the islands become, generally speaking, smaller and fewer, and finally cease. Accordingly, excepting the Marianas or Ladrones, which are of volcanic origin, and a few isolated instances of elevation in the Carolines, the Micronesian islands, though many of the groups cover a vast area, are almost without exception very small low coral (atoll) formations. Besides the LADRONE and CAROLINE ISLANDS (*q.v.*) Micronesia includes the Marshall and Gilbert groups, and some geographers include the Anson group, a number of small widely-scattered islets to the west of Hawaii, the Magellan group farther west, and the Bonin Islands north of the Ladrones.[1]

North-easterly winds prevail during the winter months over the Marshalls, Ladrones, and Carolines, except in the extreme west, while between May and September the influence of the monsoon causes unsettled weather from the west, with heavy gales. In the Gilberts the south-east trade-wind brings fine weather at this season.

The ethnological features of Micronesia are much more definite than the geographical, for its populations form one great branch of the fair Polynesian race, distinguished from the other by well-marked differences in appearance, language, and institutions. Its ethnological relations are not thoroughly understood. The proximity of Japan and the Philippines on the west and of the Papuan and South Polynesian islands on the south and south-east suggests, what in fact we find, a combination of elements in different degrees of fusion. In some places the oblique Mongolian eye is noticed, and (along with certain Indo-Chinese customs) there is often a scantiness of beard and general "Malay" look which increases westwards, and seems to imply relations with the archipelago subsequent to the departure thence of the pure Polynesians. In the Gilberts the traces of Polynesian (Samoan) influences are evident, and are confirmed by tradition. Among the Carolines and the Marshalls darker and more savage communities are found, suggesting a Melanesian element, which is further traceable in the Ebon (Marshall) and other languages.

Each of the four groups, from long isolation, has developed peculiarities of its own. The most advanced were the "Chamorros" of the Ladrones, owing to the greater natural resources of the islands, and perhaps more frequent contact with influences from the west; but as a separate people they no longer exist, having been nearly exterminated by the Spaniards in the 17th century. Next in advancement come the Carolines. The general type is a well-proportioned rather slightly built figure, with small and regular features; head high and well-proportioned, but forehead rather retreating, and narrow at the temples; cheek bones and chin slightly prominent; colour somewhat darker than the Polynesians, the Marshalls being darker and more vigorous than the Carolines, while the Gilbert type is still darker and coarser. The upper class greatly surpasses the common people in physique and intelligence.

There is a peculiar division of society into septs or clans, the membership of which constitutes the closest tie. Persons of the same sept must not intermarry, and when two islands or communities meet in war the members of one sept, however widely separated by distance of space or time, will not injure or fight with each other. Each community is usually composed (but there are local differences) of—(1) an upper class of chiefs, from among whom the head (*tamol* or *iros*) is chosen; (2) a lower but still noble class; and (3) common people, mostly without rights of property. These last are only allowed one wife. Assemblies of the chiefs everywhere limit the kingly authority. In the Marshalls the sovereign has lost his control over many of the atolls, and in the Gilberts the above distinctions have nearly disappeared; the headship has lapsed, and, especially in the southern islands, the man of largest substance is the most powerful, and sometimes establishes a local supremacy. Here and there are traces, as in Tonga, of a spiritual sovereign, the descendants probably of a conquered dynasty. Succession is through the female side, which assures to women a certain position,

[1] These islands, which contain a mixed immigrant population, are claimed, and have been recently surveyed, by Japan. But they were annexed to England by Captain Beechey in 1827. (See Von Kittlitz, *Denkwürdigkeiten einer Reise nach . . . . Mikronesien*, &c., vol. ii.)

and leads besides to some curious results (see paper by Kubary in *Das Ausland*, 1880, No. 27). The upper class are the keepers of traditions, boat-builders, leaders of expeditions; tattooing is generally done by them, the amount increasing with a man's rank; the custom here still has definite religious associations. Both sexes are tattooed. The people are singularly amiable and well disposed, but will repay ill usage with treachery. The women (although chastity is not expected before marriage) are somewhat more moral than the Polynesians, and are treated with respect, as are the aged. The natives are polite and hospitable to strangers (except on the poorer and ruder islands), bright and intelligent, active traders, expert cultivators and fishermen. They have a hand-loom from which beautiful fabrics of banana, hibiscus, and other fibres are produced. The Marshall Islanders are the boldest and most skilful navigators in the Pacific. Their voyages of many months' duration, in great canoes sailing with outrigger to windward, well-provisioned, and depending on the skies for fresh water, help to show how the Pacific was colonized. They have a sort of chart, *medo*, of small sticks tied together, representing the positions of islands and the directions of the winds and currents. A two-edged weapon, of which the blade is of sharks' teeth, and a defensive armour of braided sennit, are also peculiar to the islands; a large adze, made of the *Tridacna gigas*, was formerly used in the Carolines, probably by the old builder race.

The languages of Micronesia, though grammatically alike, differ widely in their vocabularies. They have the chief characteristics of the Polynesian, with Malay affinities, and peculiarities such as the use of suffixes and inseparable pronouns and, as in Tagal, of the infix to denote changes in the verb; in the west groups there is a tendency to closed syllables and double consonants, and a use of the palatals *ch*, *j*, *sh*, the dental *th*, and *s* (the last perhaps only in foreign words), which is alien to the Polynesian. These letters are wanting in the Gilbert language, which differs considerably from all the others, and has much greater affinities with the Polynesian.

The religious myths are generally identifiable with the Polynesian, but a belief in the gods proper is overshadowed by a general deification of ancestors, who are supposed from time to time to occupy certain blocks of stone, set up near the family dwelling, and surrounded by circles of smaller ones. These stones are anointed with oil, and worshipped with prayer and offerings, and are also used for purposes of divination, in which, and in various omens, there is a general belief. In the Marshalls, in place of these stones, certain palm trees are similarly enclosed. The spirits also sometimes inhabit certain birds or fishes, which are then *tabu*, as food, to the family; but they will help to catch them for others. All this closely recalls the *karwars* or ancestral images of New Guinea. Temples are very rare, though these blocks of coral are sometimes surrounded by a roofless enclosure opening to the west. The bodies of the dead, and sometimes even of the sick, are despatched to sea westwards, with certain rites; those of the chiefs, however, are buried, for the order has something essentially divine about it; their bodies therefore are sacred, and their spirits naturally assume the position above described. Such a belief greatly strengthens the king's authority, for the spirits of his ancestors are necessarily more powerful than any other spirits. Thus too it comes that the chiefs, and all belonging to them, are tabu as regards the common people. There are various other subjects and occasions of tabu, but the institution has not the oppressive and all-pervading character which it has in Polynesia. Its action is often economical or charitable, *e.g.*, the ripening cocoa-nuts are tabu as long as the bread-fruit lasts, thus securing the former for future use; or it is put on after a death, and the nuts thus saved are given to the family—a kindness to them, and a mark of respect for the dead.

The flora of the Gilbert and Marshall groups is of the usual oceanic character, with close Indo-Malay affinities. It is much poorer than that of the Carolines,[1] with its Moluccan and Philippine elements, and this again is surpassed by that of the Ladrones. In the Gilberts the scattered woods of cocoa-palm and *Pandanus* have little undergrowth, while the south Marshalls, being within the belt of constant precipitation, have a dense growth of (mostly) low trees and shrubs, with here and there a tropical luxuriance and variety unusual on atolls. The *Pandanus* grows wild profusely, and is of exceptional importance, being the chief staple of food, so that the cocoa-nut, which, however, flourishes chiefly in the Gilberts, is used mainly to produce oil for exportation. The bread-fruit grows chiefly in the south Marshalls. The taro (*Arum cordifolium* and others) is cultivated laboriously, deep trenches being cut in the solid rock for its irrigation, but this and other plants of cultivation, and indeed the vegetation generally, fall off in number and quality northwards. Various vegetables are grown on soil imported for the purpose. Marine plants are rare. Wilkes found on Makin Island, Gilbert group, a "fruit resembling the gooseberry," called "teiparu," from which a preserve is made. This seems very like the tipari or Cape gooseberry of India (*Physalis peruviana*). And their *karaku*, a drink made from the sap of the flower-stalk of the cocoa-palm (unfermented before the arrival of Europeans), recalls the arrack of southern Asia.

The fauna, like the flora, becomes poorer eastwards, birds being much more numerous on the high islands than on the atolls, where the few are chiefly aquatic. On Bonabe (Puynipet) out of twenty-nine species eleven are sea birds, and of the remaining eighteen seven are peculiar to the island. From the Pelews fifty-six species are recorded (twelve peculiar), and from the neighbouring Mackenzie group (Ulithi) twenty (six peculiar). Yet curiously no species is recorded common to these two groups and peculiar to them. The common fowl is found everywhere, wild or tame, and in some places is kept for its feathers only. The rat and a *Pteropus* are the only indigenous land mammals. The Indian crocodile is found as far east as the Pelews. There are five or six lizards, including a *Gecko* and *Ablepharus*. Insects are numerous, but of few kinds. Scorpions and centipedes are common, but are said to be harmless.

The houses in the Gilberts and Marshalls (much less elaborate than in the Carolines) consist merely of a thatched roof resting on posts or on blocks of coral about 3 feet high, with a floor at that level, which is reached from an opening in the centre. On this the principal people sleep, and it serves as a storehouse inaccessible to rats, which infest all the islands.

The Marshall archipelago consists of two nearly parallel chains of atolls, from 100 to 300 miles apart, the west known as Ralik, the east as Ratak. They lie between 4° 30′ and 12° N., and between 165° 15′ and 172° 15′ E., and run about N.N.W. and S.S.E. They were discovered in 1529 by Saavedra, who, observing the fine tattooing of the inhabitants (the first allusion to the practice in the Pacific), called them Los Pintados. Among modern voyagers Wallis first visited them in 1767; Captains Marshall and Gilbert reached them in 1788, and Kotzebue (1816) explored them more thoroughly. Each group contains fifteen or sixteen atolls, which range from 2 to 50 miles in circumference. An anomalous feature is reported on some of them, viz., that the greater proportion of land, or at all events of soil, is not found as usual on the windward side of the lagoon, for the prevailing north-east wind sweeps, it is said, the materials of which the soil of such islands is composed across to the lee side. Jaluit Island is the commercial emporium of the whole region. There is a curious tradition on Ebon Island of the Darwinian fact that the atoll once formed the barrier reef of an island now sunk beneath the lagoon. The population of Ratak is about 6000, of Ralik 4000; there is little intercourse between the two groups.

The Gilbert archipelago, discovered by Byron in 1765, is geographically a south continuation of the Marshalls, the channel separating them being 50 leagues wide. It lies between 2° 40′ S. and 3° 20′ N., and between 172° 30′ and 177° 15′ E., and contains sixteen atolls, not including two hilly islands, Banaba and Nawodo, which lie 5° to 6° to the west. Several have good anchorages inside the lagoon, with entrances on the lee side. On some the lee or west reef is wanting, owing to the abrading force of the west storms. During these large trees are washed ashore, their roots containing pieces of fine basalt, of which implements are made. There is a far larger proportion of land to submerged reef and lagoon than in the Marshalls, the land sometimes rising 20 feet above the sea, whereas in the Marshalls the average level of the reef rock is less than a foot above the surface; but, though the supply of fresh water is exceptionally great, in fact enough for the luxury of a bath, the soil (especially in the south) is very much less productive. Yet the population, about 50,000, is exceptionally dense. The usual scattered houses are replaced by compact rows of roofs which, shaded by cocoa-palm, and each with its boat-shed below, line the shore. Their numbers are unchecked either by the constant practice of abortion or by fighting, to which they are much addicted, their weapons being more formidable than those of their neighbours. This exceptional vigour may be due to the decidedly hybrid character of the race. Hawaiian missionaries, under American superintendence, have laboured here since 1857.

MICROPHONE. See TELEPHONE.

[1] About 180 species have been observed on Kusaie, one-fourth of all the plants being ferns.

MICROSCOPE

THE microscope is an optical instrument for the examination of minute objects or parts of objects, which enlarges the visual pictures formed upon the retina of the observer by the rays proceeding from them.

Microscopes are distinguished as *simple* or *compound*. In the former, the rays which enter the eye of the observer come from an object brought near to it after refraction through either a single lens or a combination of lenses acting as a single lens,—its action as a "magnifier" depending on its enabling the eye to form a distinct image of the object at a much shorter distance than would otherwise be possible. The latter consists of at least two lenses, so placed relatively to the object, to the eye, and to one another that an enlarged image of the object, formed by the lens placed nearest to it (the "object-glass"), is looked at through the lens nearest the eye (the "eye-glass"), which acts as a simple microscope in "magnifying" it; so that the compound microscope may be described as a simple microscope used to look at an enlarged image of the object, instead of at the object itself.

History of the Simple Microscope.—Any solid or liquid transparent medium of lenticular form, having either one convex and one flat surface or two convex surfaces whose axes are coincident, may serve as a "magnifier,"—what is essential being that it shall have the power of so refracting the rays which pass through it as to cause widely diverging rays to become either parallel or but slightly divergent. Thus if a minute object be placed on a slip of glass, and a single drop of water be carefully placed upon it, the drop will act as a magnifier in virtue of the convexity of its upper surface; so that when the eye is brought sufficiently near it (the glass being of course held horizontally, so as not to distort the spherical curvature of the drop) the object will be seen much enlarged. And if a small hole be made in a thin plate of metal, and a minute drop of water be inserted in it, this drop, having two convex surfaces, will serve as a still more powerful magnifier. There is reason to believe that the magnifying power of transparent media with convex surfaces was very early known. A convex lens of rock-crystal was found by Layard among the ruins of the palace of Nimrud. And it is pretty certain that, after the invention of glass, hollow spheres blown of that material and filled with water were commonly used as magnifiers (comp. vol. xiv. p. 577). The perfection of gem-cutting shown in ancient gems, especially in those of very minute size, could not have been attained without the use of such aids to the visual power; and there can be little doubt that the artificers who could execute these wonderful works could also shape and polish the magnifiers best suited for their own or others' use. Though it is impossible to say when convex lenses of glass were first made by grinding, it is quite certain that they were first generally used to assist ordinary vision as "spectacles," the use of which can be traced back nearly six centuries; and not only were spectacle-makers the first to produce glass magnifiers (or simple microscopes), but by them also the telescope and the compound microscope were first invented. There seems no reason to believe, however, that lenses of very high magnifying power (or short focus) were produced until a demand for them had been created by the introduction of the compound microscope, in which such lenses are required as "object-glasses"; and the difficulty of working lenses of high curvature with the requisite accuracy led in the first instance to the employment of globules made by fusing the ends of threads of spun glass. It was in this way that Robert Hooke shaped the minutest of the lenses with which he made many of the numerous discoveries recorded in his *Micrographia*; and the same method was employed by the Italian microscopist Father Di Torre. It seems to have been Leeuwenhoek that first succeeded in grinding and polishing lenses of such short focus and perfect figure as to render the simple microscope a better instrument for most purposes than any compound microscope then constructed,—its inferiority in magnifying power being more than counterbalanced by the superior clearness of the retinal picture. And, in despair of any such modification in the compound form as should remove the optical defects which seemed inherent in its plan of construction, scientific opticians and microscopic observers alike gave their chief attention for a considerable period to the improvement of the simple microscope. In order that the nature of these improvements may be understood, the principle of its action must be first explained.

The normal human eye has a considerable power of self-adjustment, by which its focal length is so varied that it forms equally distinct pictures of objects brought within ordinary reading distance (say 10 inches) and of objects whose distance is many times that length,—the size of the visual picture of any object diminishing, however, with the increase in the distance to which it is removed, and the amount of detail distinguishable in it following the same proportion. Thus a man who looks across the street at a placard posted on the opposite wall may very distinctly see its general form and the arrangement of its heading, and may be able to read what is set forth in its largest type, whilst unable to separate the lines, still more to read the words, of what is set forth below. But by crossing the street so as to bring his eye nearer the picture he finds himself able to read the smaller type as easily as he before read the larger,—the visual picture on his retina having been magnified, say 10 times in linear dimension, by the reduction of the distance of his eye from 40 feet to 4. Similarly, if he holds a page of excessively minute type at arm's length (say 40 inches) from his eye, he may be unable to read it, not because his eye does not form a distinct retinal picture of the page at that distance, but because the details of that picture are too minute for him to distinguish them. But if he brings the page from 40 inches to 10 inches distance, he may be able to read it without difficulty,—the retinal picture being enlarged four times linear (or sixteen times superficial) by this approximation. Now the rays that enter the eye from each point of a remote object diverge so little as to be virtually parallel; but the divergence increases with the approximation of the object to the eye, and at 10 inches the angle of their divergence is as wide as permits the ordinary eye to bring them to a focus on the retina. When the object is approximated more closely, an automatic contraction of the pupil takes place, so that the most diverging rays of each pencil are cut off, and a distinct picture may be formed (though not without a feeling of strain) when the object is (say) from 5 to 8 inches distant,—giving still greater minuteness of visual detail in conformity with the increase of size. A further magnifying power may be obtained without the interposition of any lens, by looking at an object, at 2 or 3 inches distance, through a pin-hole in a card; for by thus cutting off the more divergent rays of each pencil, so as to admit only those which can be made to converge to a focus on the retina at that distance, a distinct and detailed picture may be obtained, though at the expense of a great loss of light. Moreover,

although an ordinary eye does not form a distinct picture of an object at less than from 10 to 6 inches distance, a "myopic" or "short-sighted" eye (whose greater refractive power enables it to bring rays of wider divergence to a focus on the retina) may form an equally distinct picture of an object at from 5 to 3 inches distance; and, as the linear dimensions of that picture will be double that of the preceding, the object will be "magnified" in that proportion, and its details more clearly seen.

The effect of the interposition of a convex lens between the eye and an object nearly approximated to it primarily consists in its reduction in the divergence of the rays of the pencils which issue from its several points, so that they enter the eye at the moderate divergence which they would have if the object were at the ordinary nearest limit of distinct vision. And, since the shorter the focus of the lens the more closely may the object be approximated to the eye, the retinal picture is enlarged, causing the object to appear magnified in the same proportion. Not only, however, are the component rays of each pencil brought from divergence into convergence, but the course of the pencils themselves is changed, so that they enter the eye under an angle corresponding to that under which they would have arrived from a larger object situated at a greater distance; and thus, as the picture formed upon the retina by the small object *ab*, fig. 1, corresponds in all

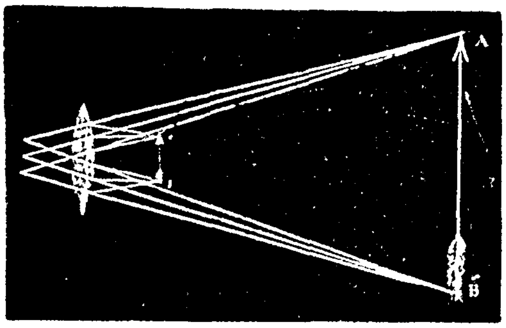

FIG. 1.—Action of Simple Microscope.

respects with that which would have been made by the same object AB of several times its linear dimension viewed at the nearest ordinary limit of distinct vision, the object is seen (by the formation of a "virtual image") on a magnified scale.

It is obvious that the "magnifying power" of any convex lens so used is measured by the ratio between the dimensions of the retinal picture formed with its assistance and those of the picture formed by the unaided eye. Thus, if by the use of a convex lens having 1 inch focal length we can form a distinct retinal image of an object at only an inch distance, this image will have ten times the linear dimensions of that formed by the same object at a distance of 10 inches, but will be only eight times as large as the picture formed when the object can be seen by ordinary vision at 8 inches distance, and only four times as large as the picture of the same object formed by a myopic eye at a distance of 4 inches. It is usual to estimate the magnifying power of single lenses (or of combinations that are used as such) by the number of times that their focal length is contained in 10 inches,—that of 1 inch focus being thus taken as ten times, that of $\frac{1}{10}$ inch as one hundred times, and so on. But the rule is obviously arbitrary, as the actual magnifying power varies in each individual with the nearest limit of distinct vision. Thus for the myopic who can see an object clearly at 4 inches distance, the magnifying powers of a 1 inch and $\frac{1}{10}$ inch lens will be only 4 and 40 respectively. The amplifying power of every single convex lens, however, is impaired (1) by that inability to bring to the same focus the rays which fall upon the central and the marginal parts of its surface which is called "spherical aberration," and (2) by that dispersion of the rays of different wave-lengths, in virtue of their different refrangibilities, which produces coloured fringes around the points and lines of the visual picture, and is therefore called "chromatic aberration" (see LIGHT). These aberrations increase with the "angle of aperture" given to the lens, that is, with the proportion between the diameter of its actual "opening" and the focal distance of the object; and thus, when a single lens of very short focus is used in order to gain a high magnifying power, such a reduction of its aperture by a perforated diaphragm or "stop" becomes necessary (in order, by excluding the peripheral rays, to obtain tolerable "definition" with freedom from false colour) that the amount of light admitted to the eye is so small as only to allow the most transparent objects to be thus viewed, and these only very imperfectly. In order to remedy this drawback, it was proposed by Sir D. Brewster to use instead of glass, in the construction of simple microscopes, such transparent minerals as have high refractive with low dispersive power; in which case the same optical effect could be obtained with lenses of much lower curvature, and the aperture might be proportionately enlarged. This combination of qualities is found in the diamond, whose index of refraction bears such a proportion to that of glass that a diamond lens having a radius of curvature of 8 would give the same magnifying power as a glass lens whose radius of curvature is 3, while the "longitudinal aberration" (or distance between the foci of central and of marginal rays) would be in a diamond lens only one-ninth of that of a glass lens having the same power and aperture. Putting aside, however, the costliness of the material and the difficulty of working it, a source of imperfection arises from a frequent want of homogeneousness in the diamond crystal, which has proved sufficient to make a lens worked from it give a double or even a triple image. Similar attempts made by Mr Pritchard with sapphire proved more successful; and, as a sapphire lens having a radius of curvature of 5 has the same focus and gives the same magnifying power as a crown-glass lens having a radius of 3, it was found to bear a much larger aperture without serious impairment by either spherical or chromatic aberration. As the sapphire, however, possesses the property of double refraction, the duplication of the markings of the object in their retinal image constitutes a very serious drawback to the utility of lenses constructed of this mineral; for, though the double refraction may be reduced almost to nothing by turning the convex side of the lens towards the object, yet, as this is the worst position in regard to spherical aberration, more is lost than is gained. Fortunately, however, for biological investigators working with simple microscopes, the introduction of the Wollaston doublet superseded the necessity of any further attempts at turning costly jewels to account as high-power magnifiers.

Wollaston Doublet.—This consists of a combination of two plano-convex lenses, whose focal lengths (as directed by Dr Wollaston) should be as 3 to 1, with their plane sides turned towards the object,—the smaller lens being placed lowest, and the upper lens at a distance of one and a half times its focal length above it. This construction, however, has been subsequently improved—(1) by the introduction of a perforated diaphragm between the lenses; (2) by a more effective adjustment of the distance between the two lenses, which seems to be most satisfactory when it equals the difference of their respective focal lengths, allowance being made for their thickness; and (3) by the division of the power of the lower lens (when a shorter focus than $\frac{1}{10}$ inch is required) into two, so as to form a "triplet." When combinations of this kind are well

constructed, spherical aberration is almost wholly got rid of, and chromatic dispersion is so slight that the angle of aperture may be considerably enlarged without much sacrifice of distinctness. Such "doublets" and "triplets," having been brought into use in England while the compound microscope still retained its original imperfections, proved very serviceable to such as were at that time prosecuting minute biological investigations: for example, the admirable researches of Dr Sharpey on ciliary action in animals (1830–35) and Mr Henry Slack's beautiful dissections of the elementary tissues of plants, as well as his excellent observations on vegetable cyclosis (1831), were made by their means. No one, however, would now use Wollaston "doublets" or "triplets" of high power in place of a compound achromatic microscope; and for the simple microscopes of low power that are useful either for dissecting or for picking out minute specimens (such as diatoms) other constructions are preferable, as giving a larger field and more light. As a hand-magnifier the "Coddington" lens—which is a sphere of glass with a deep groove ground out of its equatorial portion—has many advantages.[1] By making this groove sufficiently deep, both spherical and chromatic aberrations can be rendered almost insensible; and, as the rays falling on any part of the spherical surface can only pass to the eye either through or near the centre, the action of every part of that surface is the same, so that the image of the object will be equally distinct (when properly focussed) whether its parts lie nearer to the axis of the sphere or more remote from it, or the axis be itself turned to one side or the other. Again, it was mathematically shown by Sir John Herschel in 1821 that by the combination of a meniscus with a double convex lens—the four surfaces of these lenses having certain proportionate curvatures—spherical aberration could be entirely extinguished for rays parallel to the axis, the combination being thus an "aplanatic" doublet, while another combination, which he termed a "periscopic" doublet, gives a remarkable range of oblique vision with low powers, and almost entirely extinguishes chromatic aberration, although at the expense of residual spherical aberration. These combinations have been mounted both as hand-magnifiers and as single microscopes, for both which purposes they are much superior to single lenses of the same magnifying power. But such combinations have been greatly improved by the introduction of concaves of flint glass, so as to render them achromatic as well as aplanatic; and nothing, according to the writer's experience, can now be used with greater advantage for all the purposes answered either by the simple microscope or the hand-magnifier than Browning's "platyscopic" lenses or the "achromatic doublets" of Steinheil of Munich. Each of these combinations gives a large flat field, with plenty of light, admirable definition, and freedom from false colour.

At the period when "doublets" of very short focus were used in order to obtain high magnifying power, it was requisite to mount these on such a stand as would enable the focal adjustment to be made, and would admit the use of a special illuminating apparatus with great exactness. But now that comparatively low powers only are employed the ordinary rack-and-pinion movement is quite sufficient for their focal adjustment, and nothing more is required for the illumination of the object than a concave mirror beneath the stage when it is transparent, and a condensing lens above when it is opaque. The various patterns of simple microscope now made by different makers vary in their construction, chiefly in regard to portability, the size of their stages, and the mode in which "rests" or supports to the hands are provided. These, in Continental instruments, are very commonly attached to the stage; but, unless the stage itself and the pillar to which it is fixed are extremely massive, the resting of the hands on the supports is apt to depress the stage in a degree that affects the focal adjustment; and where portability is not an object it seems better that the hand-supports should be independent of the stage. For a laboratory microscope, the pattern represented in fig. 2 has been found very convenient,—the framework being of mahogany or other hard wood, the stage

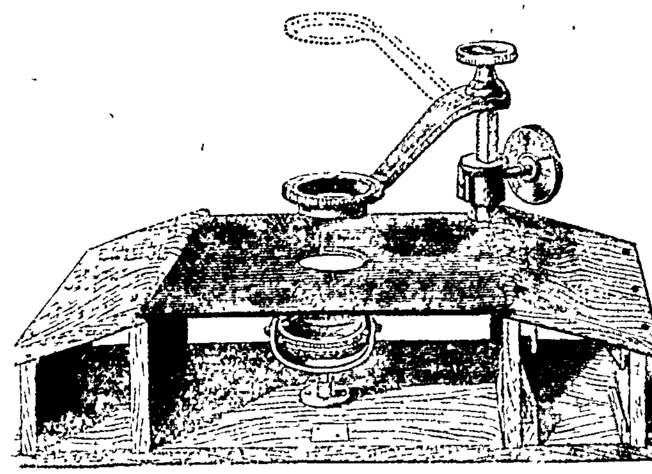

FIG. 2.—Laboratory Dissecting Microscope.

being large enough to admit a dissection or carry a water-trough of considerable size, and the bent arm that carries the "powers" being made capable of reversion, so as to permit the use of lenses of very long as well as of very short focus. As it is desirable that the stage should not be acted on chemically by sea-water, acids, or other reagents, it may be made either of a square of plate-glass or of a plate of ebonite with an aperture in the middle; and either of these may be made to slide in grooves in the side supports, so that one may be substituted for the other. The arm may be easily made (if desired) to carry the body of a compound microscope, so as to apply it to the examination of objects dissected or otherwise prepared under the simple microscope, without transferring them to another instrument. A portable form of simple microscope is shown in fig. 30.

Compound Microscope.—The placing of two convex lenses in such relative positions that one should magnify an enlarged image of a small near object formed by the other naturally soon followed the invention of the telescope, and seems to have first occurred to Hans Zansz or his son Zacharias Zansz, spectacle-makers at Middelburg in Holland, about 1590. One of their compound microscopes, which they presented to Prince Maurice, was in the year 1617 in the possession of Cornelius Drebell of Alkmaar, who then resided in London as mathematician to king James I. In order to make clear the successive stages by which the rude and imperfect microscope of that period has, after remaining for two centuries unimproved in any essential particular, been developed within the last half-century into one of the most important instruments of scientific research that the combination of theoretical acumen and manipulative skill has ever produced, it is necessary to explain the principle of its construction, and to show wherein lay the imperfection of its earlier form.

In its simplest construction, as already stated, the compound microscope consists of only two lenses,—the "object-glass" CD, fig. 3, which receives the light-rays direct from the object AB placed near it, and forms an enlarged but reversed image A′B′ at a greater distance on the other side, and the "eye-glass" LM, which receives the rays that diverge from the several points of this image as if they proceeded from the points of an actual object occupying the position and enlarged to the dimensions A′B′, and brings these to the eye at E, so altering their course as to

[1] It is difficult to understand how the name of Coddington came to be attached to the grooved sphere, seeing that he neither was nor claimed to be the inventor of it. Dr Wollaston's first "doublet" consisted of a pair of plano-convex lenses with their plane surfaces opposed to each other, and a diaphragm with central aperture placed between them. Sir D. Brewster showed that this construction is most advantageous when the two lenses are hemispheres, and the central aperture between their two plane surfaces is filled up by a transparent cement having the same refractive index as glass. And from this the transition is obvious to the grooved sphere, which had been made for Sir D. Brewster long before the high commendation it received from Mr Coddington brought it into general repute.

act as a simple microscope in magnifying that image to the observer. It was early found useful, however, to interpose another lens FF, fig. 4 (the "field-glass"), between the object-glass and the image formed by it, for the purpose of giving such a slight convergence to the pencil of rays as shall reduce the dimensions of the image, and thus allow a larger part of it to come within the range of the eye-

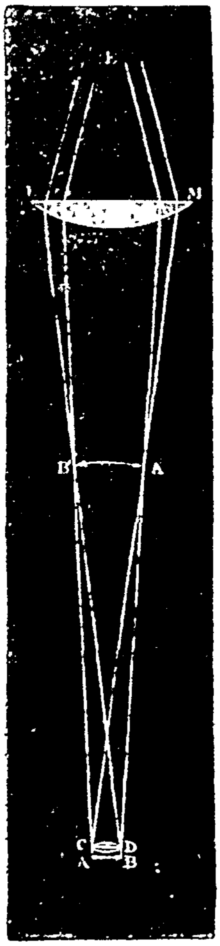

FIG. 3.—Diagram of Simplest Form of Compound Microscope.

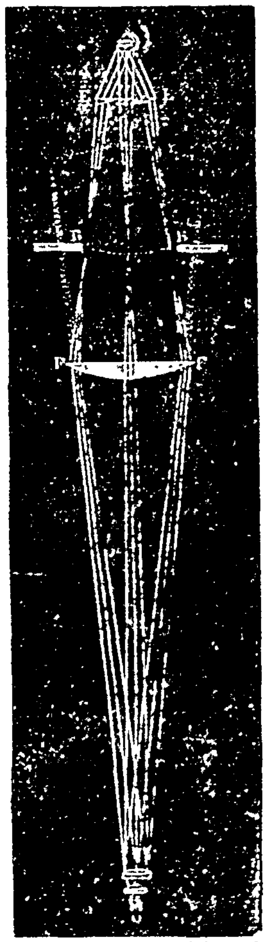

FIG. 4.—Diagram of Complete Compound Microscope.

glass, so that more of the object can be seen at once. And it was soon perceived that the eye-glass and the field-glass might be advantageously combined into an "eye-piece," in which a perforated diaphragm might be inserted at the focal plane of the image (*i.e.*, in the focus of the eye-glass), so as, by cutting off the peripheral portion of the field of view, to limit it to what can be seen with tolerable distinctness.

It is obvious that the magnifying power of such an instrument would depend (1) on the proportion between the size of the image formed at BB and that of the actual object, and (2) upon the magnifying power of the eye-glass. And further the proportion which the size of the image bears to that of the object depends upon two factors,—(1) the focal length of the object-glass, and (2) the distance between the object-glass and the plane BB occupied by the image it forms. If we diminish the focal length of the object-glass, the object must be brought nearer to it, so that, while the distance of the image on the other side remains unchanged, that distance comes to bear a larger proportion to the distance of the object, and the size of the image is augmented in a corresponding ratio. On the other hand, the object-glass remaining unchanged, the distance at which it forms the image of the object can be increased by a lengthening of the tube of the microscope; and, as this involves a shortening of the distance between the object-glass and the object, the proportion which the former bears to the latter is augmented, and the image is correspondingly enlarged. Thus an increase in the magnifying power of the compound microscope may be gained in three modes, which may be used either separately or in double or triple combination,—viz., (1) shortening the focus of the object-glass, (2) lengthening the tube of the microscope, and (3) increasing the magnifying power of the eye-glass by shortening its focus. This, it may be remarked, also lengthens the distance of the image from the object-glass, by bringing the focal plane BB nearer the eye-glass. The second of these methods was not unfrequently used in the older microscopes, which were sometimes made to draw out like telescopes, so as to increase the amplifying power of their object-glasses. But, whilst very inconvenient to the observer, such a lengthening of the one distance involved such a shortening of the other as greatly impaired the distinctness of the image by increasing the aberrations of the object-glass, so that this method came to be generally abandoned for one of the other two.

When lenses of from 1 to 4 inches focus were used as object-glasses, and their apertures were restricted by a stop to the central part of each, tolerably distinct images were given of the larger structural arrangements of such objects as sections of wood or the more transparent wings of insects,—which images would bear a further moderate enlargement by the eye-glass without any serious deterioration either by want of definition or the introduction of colour-fringes. But when lenses of less than 1 inch focus were employed in order to obtain a higher magnifying power, the greater obliquity of the rays so greatly increased their aberrations that defective definition and the introduction of false colours went far to nullify any advantage obtainable from the higher amplification; while the limitation of the aperture required to keep these aberrations within even moderate limits occasioned such a loss of light as most seriously to detract from the value of the picture. On the other hand, the use of deeper eye-pieces to enlarge the images formed by the object-glasses not only brought out more strongly all the defects of those images, but introduced a new set of errors of their own, so that very little was gained by that mode of amplification. Hence many of the best of the older microscopists (notably LEEUWENHOEK, *q.v.*) made some of their most valuable discoveries by the use of the simple microscope; and the amount of excellent work thus done surprises every one who studies the history of microscopic inquiry. This was still more the case, as already stated, when the use of single lenses of very short focus was superseded by the introduction of the Wollaston doublet. And the substitution of these doublets for the single lenses of object-glasses, while the single lens of the eye-glass was replaced by a Herschel's aplanatic doublet, and the field-glass was a convex lens whose two curves had the proportion of 1 : 6 (the form of least spherical aberration), constituted the greatest improvement of which the instrument seemed capable in pre-achromatic times.[1]

It has been only within the last sixty years (1820–30) that the microscope has undergone the important improvement which had been worked out by Dollond in the refracting telescope more than sixty years previously,—namely, the correction of the chromatic aberration of its objectives by the combination of concave lenses of flint-

[1] This combination was made in the first microscope of which the writer became possessed, about the year 1830; and he well recollects the great superiority to any compound microscope of the old construction which was proved by its power of separating the lines on the *Menelaus* scale, and of bringing into view the details of the structure of animalcules, with a clearness that only an achromatized object-glass could surpass.

glass with convex lenses of crown, while their spherical aberration is corrected by the combination (as in Herschel's aplanatic doublet) of convex and concave surfaces of different curvatures. The minute size and high curvature of the lenses required as microscopic objectives were long considered as altogether precluding the possibility of success in the production of such combinations, more especially as the conditions they would have to meet differ altogether from those under which telescopic object-glasses are employed. For the rays from distant objects fall upon the latter with virtual parallelism; and the higher the power required the longer is the focus given to them, and the smaller is the deflexion of the rays. In the microscope, on the other hand, the object is so closely approximated to the objective that the rays which proceed to it from the latter have always a very considerable divergence; and the deflexion to which they are subjected increases with that reduction of the focal length of the objective which is the necessary condition of the increase of its magnifying power. And thus, although the telescopic "triplet" worked out by Dollond (consisting of a double-concave of flint glass, interposed between two double-convex lenses of crown) can be so constructed as to be not only completely aplanatic (or free from spherical aberration) but almost completely achromatic (or free from chromatic aberration), this construction is only suitable for microscopic objectives of long focus and small angular aperture, the rays falling on which have but a very moderate divergence. And though, as will presently appear, some of the early attempts at the achromatization of the microscope were made in this direction, it was soon abandoned for other plans of construction, which were found to be alike theoretically and practically superior.

It seems to have been by Professor Amici, then of Modena, about 1812, that the first attempts were made at the achromatization of microscopic objectives; but, these attempts not proving successful, he turned his attention to the production of a reflecting microscope, which was a decided improvement upon the non-achromatized compound microscopes then in use. In the year 1820, however, the subject was taken up by Selligues and Chevalier of Paris, who adopted the plan of superposing three or four combinations, each consisting of a double-convex of crown cemented to a plano-concave of flint. The back combination (that nearest to the eye) was of somewhat lower power than those placed in front of it, but these last were all of the same focus, and no attempt was made by these opticians to vary the construction of the several pairs thus united, so as to make them correct each others' aberrations. Hence, although a considerable magnifying power could be thus obtained, with an almost complete extinction of chromatic aberration, the aperture of these objectives could not be greatly widened without the impairment of the distinctness of the image by a "coma" proceeding from uncorrected spherical aberration.

In ignorance, it would appear, of what was being done by the Paris opticians, and at the instigation of Dr Goring (a scientific amateur), Mr Tulley—well known in London as an able constructor of telescopic objectives—began, about the year 1824, to work object-glasses for the microscope on the telescopic plan. After many trials[1] he succeeded, in 1825, in producing a triplet of $\frac{9}{10}$ inch focus, admitting a pencil of 18°, which was so well corrected as to perform very satisfactorily with an eye-piece giving a magnifying power of 120 diameters. He afterwards made a similar triplet of shorter focus, which, when placed in front of the previous one, increased the angle of the transmitted pencil to 38°, and bore an eye-piece giving a magnifying power of 300 diameters. These triplets are said by Mr Ross to have never been exceeded by any similar combinations for accurate correction throughout the field.

Having come into possession, at the end of 1826, of an objective of Chevalier's construction, Mr J. J. Lister carefully examined its properties, and compared them with those of Tulley's triplets; and this comparison having led him to institute further experiments he obtained results which were at first so conflicting that they must have proved utterly bewildering to a less acute mind,[2] but which finally led him to the enunciation of the principle on which all the best microscopic objectives are now constructed. For he discovered that the performance of such composite objectives greatly depends upon the relative position of their component combinations,—the effect of the flint plano-concave upon the spherical aberration produced by the double-convex of crown varying remarkably according to the distance of the luminous point from the front of the objective. If the radiant is at a considerable distance, the rays proceeding from it have their spherical error under-corrected; but, as the source of light is brought nearer to the glass, the flint lens produces greater proportionate effect, and the under-correction diminishes, until at length a point is reached where it disappears entirely, the rays being all brought to one point at the conjugate focus of the lens. This, then, is one aplanatic focus. If, however, the luminous point is brought still nearer to the glass, the influence of the flint continues for a time to increase, and the opposite condition of over-correction shows itself. But, on still further approximation of the radiant, the flint comes to operate with less effect, the excess of correction diminishes and at a point still nearer to the glass vanishes, and a second aplanatic focus appears. From this point onwards under-correction takes the place of over-correction, and increases till the object touches the surface of the glass. As every such doublet, therefore, has two aplanatic foci for all points between which it is over-corrected, while for all points beyond it is under-corrected, the optician is enabled to combine two or more doublets with perfect security against spherical error. This will be entirely avoided if the rays be received by the front glass from its shorter aplanatic focus, and transmitted through the back glass in the direction of its longer aplanatic pencil. By the approximation of the two doublets over-correction will be reduced, while their separation will produce under-correction; and thus, by merely varying the distance between two such combinations, the correction of the spherical error may be either increased or diminished according to a definite rule. Slight defects in one glass may thus be remedied by simply altering its position in relation to the other,—an alteration which may be made with very little disturbance of the colour-correction. This important principle was developed and illustrated by Mr Lister in a memoir read to the Royal Society on January 21, 1830, *On some Properties in Achromatic Object-glasses, applicable to the Improvement of the Microscope*; and it was by working on the lines there laid down, that the three London opticians Ross,[3] Powell, and James Smith soon pro-

[1] It is due to Mr Joseph J. Lister to mention that Tulley's final success with this low power seems to have been attained by working on a suggestion given him by that gentleman. See *Monthly Microscopical Journal*, vol. iii. (1870), p. 134.

[2] Thus he found that, while each of Chevalier's doublet combinations, when used singly, presented a "bur" or "coma" outwards, this coma, instead of being exaggerated by the combination of two of these doublets, was much diminished. On the other hand, while two of Tulley's triplets, each of which performed admirably by itself, were used together, the images of all objects not in the centre presented a strong bur inwards with an under-correction of colour.

[3] In 1837 Mr Lister gave Mr Ross a projection for an objective of $\frac{1}{8}$ inch focus, in which a triple front was combined with two doublets. The great superiority of this lens, admirably executed by Mr Ross, caused him to adopt its plan as the standard one for high powers; and it is still in general use,—the back lens also being sometimes made as a triplet.

duced microscopic objectives that surpassed any then constructed on the Continent, while the subsequent adoption of the same principles by French and German opticians, as also by Professor Amici of Florence, soon raised their objectives to a corresponding level.

It has proved more advantageous in practice to make the several components of an achromatic objective correct each others' aberrations than to attempt to render each perfect in itself; and the mode in which this is accomplished will vary with the focus and angular aperture given to each combination. Thus, while a single "telescopic triplet" answers very well for the lowest power usually made (4 inches focus), and the same plan may be used—though at the sacrifice of angular aperture—for objectives of 3 inches, 2 inches, and even 1 inch focus, the best performance of these powers requires the combination of two doublets. And, while this last system also serves for objectives of ⅔ inch and ½ inch of low angle, a third component is required for giving to these objectives the aperture that renders them most serviceable, as well as for all higher powers. Instead of combining three achromatic doublets, however, many makers prefer placing in front a plano-convex of crown, and adding a third lens of crown to the doublet at the back, still using a doublet in the middle,—the whole combination thus consisting of six lenses, four of crown and two of flint. Further, Mr Wenham has shown that the whole colour-correction may be effected in the middle by interposing a double concave of dense flint between two double-convex lenses of crown,—the back lens, as well as the front, being then a plano-convex of crown, making five lenses in all. This plan of construction, though suitable to objectives of moderate angular aperture, and advantageous in regard to comparative simplicity and economy of construction, does not seem so well adapted for objectives to which the largest attainable aperture is to be given,—these being usually constructed with a triplet in front, a doublet in the middle, and a triplet at the back, so as to consist of eight separate lenses. And the first-class constructors of achromatic objectives in the United States usually place in front of these, in their highest powers, a single plano-convex of crown, by the addition of which a greater working distance can be obtained. But, as every such addition increases the liability to error from imperfections in the centring and grinding of the lenses (as well as loss of light by the partial reflexion of oblique rays from their surfaces), it is obvious that the most exact workmanship, involving a proportionate costliness, is required to bring out the full effect of such complex construction. And where angular aperture is regarded as the quality of primary importance it will be usually found preferable to have recourse to objectives constructed on either the "water" or the "oil" immersion system, to be presently described.

The great increase thus attained in the perfection of the corrections of microscopic objectives for both spherical and chromatic aberration of course rendered it possible to make a corresponding increase in their angular aperture. The minute scales of the wings of butterflies and other insects were naturally among the objects much examined; and it was soon perceived that certain lines and other markings became clearly discernible on these scales with objectives of what was then considered large angle which were utterly undistinguishable with non-achromatized microscopes (however high their magnifying power), and very imperfectly shown under achromatic objectives of small angle. Hence these scales came to be used as "test-objects," for judging of the "definition" and "resolving power" of microscopic objectives,—the former property consisting in the clearness, sharpness, and freedom from false colour of the microscopic images of boundary lines, and depending on the accuracy with which the aberrations are corrected, while the latter term designates that power of separating very closely approximated markings which is now known to be a "function" of aperture. The insect-scales formerly most valued for these purposes were those of the *Morpho menelaus* (fig. 5) and the similarly lined scales of the *Polyommatus argus* (azure-blue), the "battledoor" scales of the same butterfly (fig. 6), the ribbed scales of the *Lepisma saccharina* (sugar-louse), and the minute and peculiarly marked scales of the *Lepidocyrtus curvicollis* (fig. 7), commonly known as the *Podura*. The writer recollects the time when the satisfactory "resolution" of the first three of these tests was considered a sufficient proof of the goodness of even high-power objectives, and when the *Podura*-markings, if visible at all, could only be distinguished as striæ. The further opening-out of the aperture, however, enabled these striæ to be resolved into rows of "exclamation marks"; and, while there is still some uncertainty as to the precise structure of which these markings are the optical expression, practical opticians are generally agreed that the *Podura*-scale is very useful as a test for definition, with even the highest objectives, though it only serves as a test for a very moderate degree of resolving power. For the latter purpose it has been completely superseded by the closely approximated markings of the silicified envelopes of certain diatoms (which, however, show themselves in very different aspects according to the conditions under which they are viewed, figs. 8–11), and also by lines artificially ruled on glass, as in Nobert's "test-plate," the number of lines in the nineteen bands of which is stated by M. Nobert to range from 1000 to 10,000 to a Paris line, while Dr Royston Pigott gives the numbers in an English inch as 11,529 to the inch in the first band, and 112,595 in the nineteenth. This last dimension (as will afterwards appear) approaches the minimum distance at which such markings are theoretically separable by any magnifying power of the microscope.

The enlargement of the angle of aperture of microscopic objectives and the greater completeness of their corrections, which were obtained in the first instance by the adoption of Mr Lister's principles, and were demonstrated by the resolution of the test-objects then in use, soon rendered sensible an imperfection in their performance under certain circumstances, which had previously passed unnoticed; and the

important discovery was made by Mr Andrew Ross that a very decided difference exists in the precision of the image according as the object is viewed with or without a covering of thin glass, as also according as this cover is thin or thick.[1] As this difference increases in proportion to the widening of the aperture, it would obviously be a

source of great error and embarrassment if a means could not be found for its rectification. Its optical source, however, having been found by Mr Ross to lie in the "negative aberration" which is produced in the rays proceeding from the object to the front glass of the objective by the interposition of the plane-glass cover, and which increases with its thickness, his practical ability enabled him at the same time to indicate the remedy, which consists in under-correcting the front lens and over-correcting the two posterior combinations, and in making the distance between the former and the latter capable of adjustment by means of a screw-collar, as shown in fig. 12. For when the front pair is approximated most nearly to the next, and its distance from the object is increased, its excess of positive aberration is more strongly exerted upon the other two pairs than it is in the contrary conditions, and thus neutralizes the negative aberration produced by the interposition of the covering-glass. This correction is not needed for objectives of low or medium power and small angle of aperture; but it should always be provided when the angle exceeds 50°,—unless (as is now generally done

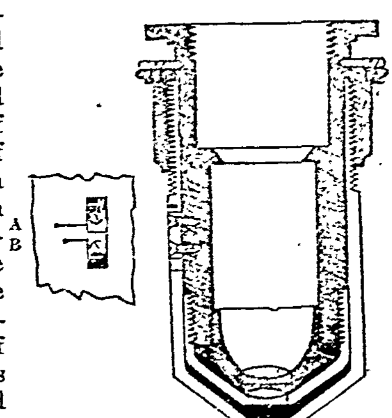

Fig. 12.—Section of Adjusting Achromatic Object-Glass. A, uncovered; B, covered.

in the case of objectives constructed for students' use) the maker adjusts them originally, not for uncovered objects, but for objects covered with glass of a standard thickness, say 0·005 or 0·004 inch. A departure from that standard to the extent of one or two thousandths of an inch in either direction, though extremely injurious to the performance of objectives whose aperture is 125° or more, scarcely makes itself perceptible in those of 90° or 100°. And the same may be said in regard to the immersion-objectives next to be described, which are peculiarly suitable to the purposes of minute histological research.

Immersion System.—It was long since pointed out by Professor Amici that the introduction of a drop of water between the front surface of the objective and either the object itself or its covering-glass would diminish the loss of light resulting from the passage of the rays from the object or its covering-glass into air, and from air into the front glass of the objective. It was obvious to him, moreover, that when the rays enter the object-glass from water, instead of from air, both its refractive and its dispersive action will be so greatly changed as to need an important constructive modification to meet the new condition. This modification seems never to have been successfully effected by Amici himself; but his idea was taken up by the two eminent Paris opticians, MM. Hartnack and Nachet, who showed that the application of what is now known as the "immersion system" to objectives of short focus and large angular aperture is attended, not merely with the advantages expected by Professor Amici, but with others on which he did not reckon. As the loss of light by the reflexion of a portion of the incident rays increases with the obliquity of their incidence, and as the proportional loss is far smaller when the oblique rays pass into glass from water than when they enter it from air, the advantage of increasing the angular aperture is more fully experienced with "immersion" than with "dry" objectives,—just as Professor Amici anticipated. But, further, the immersion system allows of a greater working distance between the objective and the object than can be attained with a dry or air objective having the same angular aperture; and this increase affords not only a greater freedom of manipulation, but also a greater range of "penetration" or "focal depth." Further, the observer is rendered so much less dependent upon the exactness of his cover-correction that it is found that water-immersion objectives of high power and considerable angular aperture, extremely well adapted for the ordinary purposes of scientific investigation, can be constructed without it,—a small departure from the standard thickness of covering-glass to which such objectives are adjusted by the maker having scarcely any effect upon the distinctness of the image. It is now the practice of several makers to supply two fronts to objectives of $\frac{1}{10}$ or $\frac{1}{12}$ inch focus, one of them fitting the objective for use "dry" (that is, in air), whilst the substitution of the other converts it into a water-immersion objective. And in the objectives constructed on Mr Wenham's system no change in the front glass is needed, all that is necessary for making them work as immersion-lenses being a yet closer approximation of the front lens to the second combination, which can be made by the screw-collar.

Within the last few years, however, the immersion system has undergone a still further and most important development, by the adoption of a method originally suggested by Mr Wenham (though never carried out by him), and independently suggested by Mr Stephenson to Professor Abbe of Jena, under whose direction it was first worked out by Zeiss (the very able optician of Jena), who has been followed by Powell and Lealand of London, as well as by several other constructors of achromatic objec-

[1] *Trans. Soc. Arts*, vol. li.

tives both in England and elsewhere, with complete success. This method consists in the replacement of the water previously interposed between the covering-glass and the front glass of the objective by a liquid having the same refractive and dispersive powers as crown-glass, so that the rays issuing at any angle from the upper plane surface of the covering-glass shall enter the plane front of the objective, without any deflexion from their straight course, and without any sensible loss by reflexion,—even the most oblique rays that proceed from the object keeping their direction unchanged until they meet the back or convex surface of the front lens of the objective. It is obvious that all the advantages derivable from the system of water-immersion will be still more thoroughly attained by this system of "homogeneous" immersion, provided that a fluid can be obtained which meets its requirements. After a long course of experiments, Professor Abbe found that oil of cedar wood so nearly corresponds with crown-glass, alike in refractive and in dispersive power, as to serve the purpose extremely well, except when it is desired to take special advantage of the most divergent or marginal rays, oil of fennel being then preferable. There are, however, strong objections to the use of these essential oils in the ordinary work of research; and it seems not unlikely that a solution of some one or more saline substances will be found more suitable. In addition to the benefit conferred by the water-immersion system, and more completely attained with the homogeneous, it may be specially pointed out that, as no correction for the thickness of the covering-glass is here required, the microscopist can feel assured that he has such a view of his object as only the most perfect correction of an air-objective can afford. This is a matter of no small importance, for while, in looking at a known object, the practised microscopist can so adjust his air-objective to the thickness of its covering-glass as to bring out its best performance, he cannot be sure, in regard to an unknown object, what appearances it ought to present, and may be led by imperfect cover-correction to an erroneous conception of its structure.

It has been recently argued that, as the slightest variation in the refractive index of either the immersion fluid or the covering-glass, a change of eye-pieces, or the least alteration in the length of the body—in a word, any circumstances differing in the slightest degree from those under which the objective was corrected—must affect the performance of homogeneous-immersion objectives of the highest class, they should still be made adjustable. The truth of this contention can, no doubt, be proved, not only theoretically, but practically,—the introduction of the adjustment enabling an experienced manipulator to attain the highest degree of perfection in the exhibition of many mounted objects, which cannot be so well shown with objectives in fixed settings. But it may well be questioned whether it is likely to do the same service in the hands of an ordinary working histologist, and whether the scientific investigator will not find it preferable, when using these objectives, to accept what their maker has fixed as their point of best performance. The principal source of error in his employment of them lies in the thickness of the optical section of the object; for the rays proceeding from its deeper plane, having to pass through a medium intervening between that plane and the cover-glass, whose refractive and dispersive indices differ from those of the glass and immersion-fluid, cannot be brought to so accurate a focus as those proceeding from the plane immediately beneath the cover-glass. The remedy for this, however, seems to lie rather in making the preparation as thin as possible than in the introduction of what is likely, in any but the most skilful and experienced hands, to prove a new source of error. Every one who has examined muscular fibre, for example, under a dry objective of very high power and large aperture, well knows that so great an alteration is produced in its aspect by the slightest change in either the focal adjustment or the cover-correction that it is impossible to say with certainty what are the appearances which give the most correct optical expression of its structure. This being a matter of judgment on the part of each observer, it seems obvious that the nearest approach to a correct view will be probably given by the focal adjustment of the best homogeneous immersion-objectives, in fixed settings, to the plane of the preparation immediately beneath the cover-glass (see *Jour. Roy. Micros. Soc.*, 1882, pp. 407, 854, 906).

In every particular in which the water-immersion system is superior to the dry, it is itself surpassed by the oil or other homogeneous system, the anticipations of those by whom it was suggested being thus fully realized. But the advantages already spoken of as derivable from the use of the "immersion system" are altogether surpassed by that which the theoretical studies of Professor Abbe have led him to assign to it, and of which he has practically demonstrated its possession. For he has shown (as will be explained below) that the interposition of either water or oil so greatly increases the real "aperture" of the objective that immersion-objectives may be constructed having a far greater virtual aperture than even the theoretical maximum (180°) of the angular aperture of an air-objective.

The same eminent physicist, working on the basis supplied by the mathematical investigations of Professor Helmholtz and himself on the undulatory theory of light, has further established an entirely new doctrine in regard to the production of highly magnified representations of closely approximated markings. All that has hitherto been said of the formation of images by the compound microscope relates to such as are produced, in accordance with the laws of refraction, by the alteration in direction which the light-rays undergo in their passage through the lenses interposed between the object and the eye. These dioptric images, when formed by lenses free from spherical and chromatic aberration, are geometrically correct pictures, truly representing the appearances which the objects themselves would present were they enlarged to the same scale and viewed under similar illumination. And we seem justified, therefore, in drawing from such microscopic images the same conclusions in regard to the objects they picture as we should draw from the direct vision of actual objects having the same dimensions. The principal source of error in such interpretations arises out of the "interference" to which the rays of light are subjected along the edges of the minute objects through which they pass, or along any such lines or margins in their inner part as are sufficiently opaque to throw a definite shadow. For every such shadow must be bordered, more or less obviously, by interference- or diffraction-spectra; and thus the images of strongly-lined objects with very transparent intermediate spaces may be so troubled or confused by these "diffraction-spectra" as to render it very doubtful what interpretation is to be put upon their appearances.

A good example of this kind is afforded by the scales of the gnat or mosquito, which are composed of a very delicate double membrane, strengthened by longitudinal ribs on both sides, those of the opposite sides uniting at the broad end of the scale, where they generally terminate as bristle-shaped appendages beyond the intermediate membrane. These are crossed by fine markings, which are probably ridge-like corrugations of the membrane, common to both sides of the scale. Between each pair of longitudinal ridges there may be seen, under certain adjustments of focus and illumination, three uniform parallel rows of beads, which have been supposed to represent a true structure in the membrane. By Dr Woodward (colonel in the United States army), however, it has been shown that this beaded appearance is merely the result of the "interferences" produced by the longitudinal and transverse lines of the scale. For the longitudinal diffraction-lines are clearly seen, alike in the microscopic image and in photographs (fig. 13), to extend into empty space beyond the contour of the scales, almost as far as the ends of the bristles in which the parallel ribs terminate; and they vary in number with the varying obliquity of illumination, so that in the same scale two, three, four, or even five rows of beads can be seen, and photographed at pleasure, in every intercostal space.[1]

Every microscopist who has worked much with high powers is well aware of the difficulty of distinguishing between real and spectral markings,—a difficulty which can only be overcome by training and experience. It seems,

[1] *Monthly Micros. Jour.*, vol. xv. (1876), p. 253.

however, to have been now fully ascertained by Professor Abbe that it is only through such diffraction-spectra that the microscope can make us acquainted with the minutest structural features of objects, since, according to the calculations of Professor Helmholtz and himself (based on the constants of the undulatory theory), no amount of magnifying power can separate dioptrically two lines, apertures, or markings of any kind, not more than $\frac{1}{2600}$ of an inch apart. The visual differentiation or "resolution" of lines or other markings whose distance lies

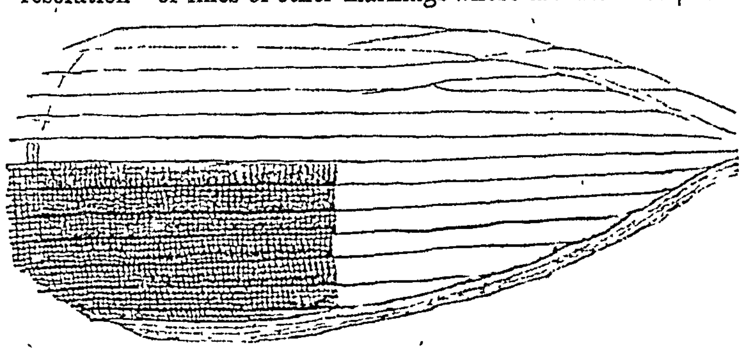

FIG. 13.—Scale of Gnat, showing Beaded Markings produced by Diffraction; from a Photograph by Colonel Dr Woodward.

within that limit is entirely the result of "interference,"—the objective receiving and transmitting, not only dioptric rays, but the inflected rays whose course has been altered in their passage through the object by the peculiar disposition of its particles, and combining these rays into a series of diffraction-spectra, the number and relative position of which bear a relation to the structural arrangement on which their production depends. If the objective be perfectly corrected, and all the diffraction-spectra lie within its field, these will be recombined by the eye-piece so as to form a secondary or "diffraction" image, lying in the same plane with the dioptric image, and coinciding with it, while filling up its outlines by supplying intermediate details. But where the markings (of whatever nature) are so closely approximated as to produce a wide dispersion of the interference-spectra, only a part of them may fall within the range of the objective; and the recombination of these by the eye-piece may produce a diffraction-image differing more or less completely (perhaps even totally) from the real structure; while, if they should lie entirely outside the field of the objective, no secondary or diffraction image will be produced. And thus, while the general form of such an object as a diatom-valve may be correctly given in a dioptric image, its surface may appear quite unmarked under an objective of small aperture, however great its magnifying power, though covered with regularly disposed markings when seen through an objective of wider aperture with perhaps only half the magnifying power.

It is obvious, however, that, while the dioptric image represents the actual object, the diffraction-image thus formed by the reunion of a portion of the interference pencils is only an optical expression of the result of their partial recombination, which may represent something entirely different from the real structure. For it has been proved experimentally, by placing finely-ruled gratings in the position of objects, and by limiting the apertures of objectives by diaphragms with variously disposed perforations, that the same arrangement of lines shall be presented to the eye by differently lined surfaces, and different arrangements by similarly lined surfaces, according to the numbers and relative positions of the reunited spectra. Hence it is clear that there must be an essential difference in character and trustworthiness between the images dioptrically formed of the general outlines and larger details of microscopic objects and those representations of their finer details which are given by the recombination of their diffraction-spectra,[1] and that the confidence to be placed in the latter class of representations will be greater in proportion to the completeness of the recombination of the separated interference-spectra, which, again, will be proportional (accurate correction of the aberrations being assumed) to the aperture of the objective.[2]

The combined advance of scientific theory and of practical skill in the application of it have now brought up the compound achromatic microscope to an optical perfection that renders it capable of actually doing almost everything of which, in the present state of optical theory, it can be regarded as capable. The resolution of Nobert's nineteenth band, having 112,595 lines to an inch, which was long regarded as the *crux* of microscopists, is now found so easy as to leave little room for doubt that, if a new test were obtainable having the *minimum visibile* of 118,000 lines to the inch, an oil-immersion objective would be found to resolve it. But the experience of the past makes it evident that, as no limit can be set to the advance of optical theory, results yet more remarkable may be still expected to arise, every such advance being turned to account by the practical skill which experience has now enabled the best constructors of achromatic objectives to attain.[3]

The progressive improvements thus effected in the construction of microscopic objectives have been accompanied by other improvements, alike in the optical and in the mechanical arrangements by which the best performance of these objectives can be secured; and it will be desirable now to describe in succession the most approved forms of the eye-piece, the objective, and the illuminating apparatus respectively, and then those of the instrument as a whole, pointing out the special adaptiveness of each to the requirements of different classes of scientific investigators.

Eye-Pieces.

It very early became obvious to those who were engaged in the achromatization of microscopic objectives that their best performance was obtained when the image given by them was further enlarged by the eye-piece known as the Huygenian, as having been devised by Huygens for his telescopes. It consists of two plano-convex lenses (EE and FF, fig. 4), with their plane sides towards the eye; these are placed at a distance equal to half the sum of their focal lengths,—or, to speak with more precision, at half the sum of the focal length of the eye-glass, and of the distance from the field-glass at which an image of the object-glass would be formed by it. A "stop" or diaphragm BB must be placed between the two lenses, in the visual focus of the eye-glass, which is, of course, the position wherein the image of the object will be formed by the rays brought into convergence by their passage through the field-glass. Huygens devised this arrangement merely to diminish the spherical aberration; but it was subsequently shown by Boscovich that the chromatic dispersion was also in great part corrected by it. Since the introduction of achromatic object-glasses for compound microscopes, it has been further shown that nearly all error may be avoided by a slight over-correction of these, so that the blue and red rays may be caused to enter the eye in a parallel direction (though not actually coincident), and thus to produce a colourless image. Thus let N, M, N (fig. 14) represent the two extreme rays of three pencils, which without the field-glass would form a blue image convex to the eye-glass at BB, and a red one at RR; then, by the intervention of the field-glass, a blue image concave to the eye-glass is formed at B'B', and a red

[1] Thus it is still a moot point whether the microscopic appearances seen in the siliceous valves of diatoms (figs. 8–11) are the optical representations of elevations, depressions, or perforations, or of internal molecular arrangements not involving any inequality of surface.

[2] This doctrine was first fully developed by Professor Abbe in the *Archiv für Mikrosk. Anatomie*, vol. ix. (1874), and is more fully expounded in his subsequent contributions to *Jour. Roy. Micros. Soc.* See also the papers of Mr Stephenson and Mr Crisp in that journal, and in the preceding *Monthly Microscopical Journal*.

[3] Any good workman can now make by the dozen such small-angled $\frac{1}{4}$ inch objectives as Mr A. Ross produced with much pains and labour fifty years ago. It was not until 1844 that, with the honourable emulation of surpassing what Professor Amici had then accomplished, he produced a $\frac{1}{12}$ inch of 135°, which, by taking advantage of some very heavy flint-glass he had, he afterwards increased to 170°.

one at R′R′. As the focus of the eye-glass is shorter for blue rays than for red rays by just the difference in the place of these images, their rays, after refraction by it, enter the eye in a parallel direction, and produce a picture free from false colour. If the object-glass had been rendered perfectly achromatic, the blue rays, after passing through the field-glass, would have been brought to a focus at *b*, and the red at *r*; so that an error would be produced, which would have been increased instead of being corrected by the eye-glass. Another advantage of a well-constructed Huygenian eye-piece is that the image produced by the meeting of the rays after passing through the field-glass is by it rendered concave towards the eye-glass instead of convex, so that every part of it may be in focus at the same time, and the field of view thereby rendered flat.[1]

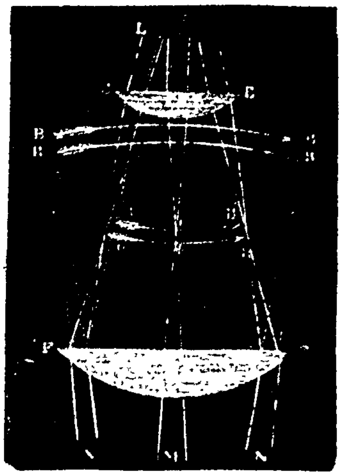

FIG. 14.—Section of Huygenian Eye-Piece, adapted to Over-Corrected Microscopic Objectives.

Two or more Huygenian eye-pieces, of different magnifying powers, known as A, B, C, &c., are usually supplied with a compound microscope. The utility of the higher powers will mainly depend upon the excellence of the objectives; for, when an achromatic combination of small aperture which is sufficiently well corrected to perform very tolerably with a "low" or "shallow" eye-piece is used with an eye-piece of higher magnifying power (commonly spoken of as a "deeper" one), the image may lose more in brightness and in definition than is gained by its amplification, while the image given by an objective of large angular aperture and very perfect correction shall sustain so little loss of light or of definition by "deep eye-piecing" that the increase of magnifying power shall be almost clear gain. Hence the modes in which different objectives of the same power, whose performance with shallow eye-pieces is nearly the same, are respectively affected by deep eye-pieces afford a good test of their respective merits, since any defect in the corrections is sure to be brought out by the higher amplification of the image, while a deficiency of aperture is manifested by the want of light. The working microscopist will generally find the A eye-piece most suitable, B being occasionally employed when a greater power is required to separate details, whilst C and others still deeper are useful for the purpose of testing the goodness of objectives, or for special investigations requiring the highest amplification with objectives of the finest quality. But he can commit no greater error than habitually to use deep eye-pieces for the purposes of scientific research, especially when (as in the study of living objects) long-continued and unintermitted observation is necessary. For the visual strain thus occasioned is exactly like that resulting from the habitual use of magnifying spectacles in reading, requiring the book to be held within 2 or 3 inches of the eye. And all experience shows that this feeling of strain cannot be disregarded, without the most injurious consequences to vision.

For viewing large flat objects, such as transverse sections of wood or of *Echinus* spines, under low magnifying powers, the eye-piece known as Kellner's may be employed with advantage. In this construction the field-glass, which is a double-convex lens, is placed in the focus of the eye-glass, without the interposition of a diaphragm; and the eye-glass is an achromatic combination of a plano-concave of flint with a double-convex of crown, which is slightly under-corrected, so as to neutralize the over-correction given to the objectives for use with Huygenian eye-pieces. A flat well-illuminated field of as much as 14 inches in diameter may thus be obtained, with very little loss of light; but, on the other hand, there is a certain impairment of defining power, which renders the Kellner eye-piece unsuitable for objects presenting minute structural details; and it is an additional objection that the smallest speck or smear upon the surface of the field-glass is made so unpleasantly obvious that the most careful cleansing of that surface is required every time that this eye-piece is used. Hence it is better fitted for the occasional display of objects of the character already specified than for the ordinary wants of the working microscopist.

Solid eye-pieces, consisting of cylinders of glass with convex ends, are sometimes used in place of the Huygenian, when high magnifying power is required for testing the performance of objectives. The lower surface, which has the lesser convexity, serves as a field-glass, while the image formed by this is magnified by the highly convex upper surface to which the eye is applied,—the advantage derivable from this construction lying in the abolition of the plane surfaces of the two lenses of the ordinary eye-piece.[2]

A "positive" or Ramsden's eye-piece—in which the field-glass, whose convex side is turned upwards, is placed so much nearer the eye-glass that the image formed by the objective lies below instead of above it—was formerly used for the purpose of micrometry,—a divided glass being fitted in the exact plane occupied by the image, so that its scale and that image are both magnified together by the lenses interposed between them and the eye. The same end, however, may be so readily attained with the Huygenian eye-piece that no essential advantage is gained by the use of that of Ramsden, the field of which is distinct only in its centre.

OBJECTIVES.

It has been seen that one of the principal points in the construction of microscopic objectives to which the attention of their makers has been constantly directed has been the enlargement of their "aperture,"—this term being understood to mean, not their absolute opening as expressed by linear measure, but their capacity for receiving and bringing to a remote conjugate focus the rays diverging from the several points of a near object. The aperture of an objective has been usually estimated by its "angle of aperture,"—that is, by the degree of divergence of the most extreme rays proceeding from the axial point of the object to the margin of the objective (fig. 15) which take part in the formation of the image. It is pointed out, however, by Professor Abbe that, in the case of single lenses used as objectives, their apertures are really proportional, not to their respective angles of aperture, but to the ratio between the actual diameter or clear opening of each to its focal distance, a ratio which is simply expressed by the sine of its semiangle. And in the case of combinations of lenses it can be demonstrated mathematically that their respective apertures are determinable—other conditions being the same—by the ratio of the diameters of their back lenses, so far as these are really utilized, to their respective focal lengths,—this ratio being expressed, as before, by the sine of the semiangle of aperture (sin u).

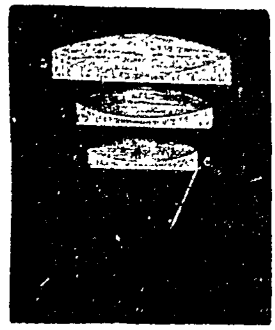

FIG. 15.—Section of Achromatic Object-Glass, composed of three pairs of (flint and crown) lenses. *abc* is its angle of aperture.

The difference between these two modes of comparison can be readily made obvious by reference to the theoretical maximum of 180°, which is attained by opening out the boundaries of the angle *abc* (fig. 15) until they come into the same straight line, the sine of the semiangle (90°) then becoming unity. For, while an objective having an angle of 60° would count by comparison of angles as having only one-third of the theoretical maximum, its real aperture would be half that maximum since the sine of its semiangle (30°) = ½. And, as the sines of angles beyond 60° increase very slowly, an objective of 120° angle will have as much as 87 per cent. of the theoretical maximum of aperture, although its angle is only two-thirds, or 66·6 per cent., of 180°. It hence becomes obvious that little is really gained in real aperture by the opening-out of the angle of microscopic objectives to its greatest practicable limit (which may be taken as 170°), while such extension—even if unattended with any loss either of definition or of colour-correction—necessarily involves a great reduction alike in the working distance and in the focal depth or penetration of the combination, as will be presently explained.

Numerical Aperture.—It has now been demonstrated by Professor Abbe that, independently of the advantages already specified as derivable from the application of the immersion system to objectives of short focus and wide aperture, the real aperture of an immersion objective is considerably greater than that of a dry or air objective of the same angle,—the comparative apertures of objectives working through different media being in the compound ratio of two factors, viz., the sines of their respective semiangles of aperture and the refractive indices of the "immersion" fluids. It is the product of these ($n \sin u$) that gives what is termed by Professor Abbe the "numerical aperture,"—which serves, therefore, as the only true standard of comparison, not only between dry or air and water or oil immersion lenses, but also between immersion lenses adapted to work respectively with water, oil, or any other interposed fluid. That the angle of aperture expressed by the same number of degrees must correspond with very different working apertures in dry, water immersion, and oil or homogeneous immersion objectives becomes evident when we consider what

[1] The reader may be referred to Mr Varley's investigation of the properties of the Huygenian eye-piece in the fifty-first volume of the *Transactions of the Society of Arts*; and to the article "Microscope," by Mr Ross, in the *Penny Cyclopædia*, reprinted, with additions, in the *English Cyclopædia*.

[2] These eye-pieces are much in vogue in the United States, where they are made of extremely short foci,—even to $\frac{1}{16}$ inch.

happens when divergent pencils of rays pass from one medium into another of higher refractive index. For such divergent pencils, proceeding from air into water or oil, will be closed together or compressed; so that the rays which, when an object is mounted in air, spread out over the whole hemisphere then form comparatively narrow pencils, and can thus be utilized by an immersion objective of smaller aperture than is required in a dry objective to admit the most diverging rays of air-pencils. It follows, therefore, that a given angle in a water or oil immersion objective represents a much larger aperture than does the same angle in an air-objective; and thus it comes to pass that by opening out the angle of immersion objectives they may be made to receive and utilize rays of much greater divergence than can possibly enter dry objectives of even maximum aperture.

The following table, abridged from that given by Professor Abbe for every 0·02 of numerical aperture from 0·50 up to the maximum of 1·52, brings this contrast into clear view:—

Numerical Aperture Table.

Numerical Aperture ($n \sin u = a$).	Angle of Aperture ($=2u$).			Illuminating Power (a^2).	Theoretical Resolving Power, in Lines to an Inch ($\lambda=0·5269\,\mu$ =line E).	Penetrating Power $\left(\frac{1}{a}\right)$.
	Dry Objectives ($n=1$).	Water-Immersion Objectives ($n=1·33$).	Homogeneous-Immersion Objectives ($n=1·52$).			
	° ′	° ′	° ′			
1·52	...	...	180 0	2·310	146,528	·658
1·42	...	...	138 12	2·016	136,888	·704
1·33	...	180 0	122 6	1·770	128,212	·752
1·26	...	142 39	111 59	1·588	121,464	·794
1·18	...	125 3	101 50	1·392	113,752	·847
1·12	...	114 44	94 56	1·254	107,968	·893
1·06	...	105 42	88 26	1·124	102,184	·943
1·00	180 0	97 31	82 17	1·000	96,400	1·000
0·94	140 6	89 56	76 24	·884	90,616	1 064
0·86	118 38	80 34	68 54	·740	82,904	1·163
0·80	106 16	73 58	63 31	·640	77,120	1·250
0·76	98 56	69 42	60 0	·578	73,264	1·316
0·70	88 51	63 31	54 50	·490	67,480	1·429
0·62	76 38	55 34	48 9	·384	59,768	1·613
0·56	68 6	49 48	43 14	·314	53,984	1·786
0·50	60 0	41 10	38 24	·250	48,200	2·000

Thus, taking as a standard of comparison a dry objective of the maximum theoretical angle of 180°, whose numerical aperture is the sine of 90°, or 1·00, we find this standard equalled by a water-immersion objective whose angle of aperture is no more than 97½°, and by an oil or homogeneous immersion objective of only 82°,—the numerical apertures of these, obtained by multiplying the sines of their respective semiangles by the refractive index of water or of oil, being 1·00 in each case. Each, therefore, will have as great a power of receiving and utilizing divergent rays as any dry objective can even theoretically possess.

But, as the actual angle of either a water or an oil immersion objective can be opened out to the same extent as that of an air or dry objective, it follows that the aperture of the former can be augmented far beyond even the theoretical maximum of the latter. Thus the numerical aperture of a water-immersion lens of the maximum angle of 180° is 1·33, or one-third greater than that of an air-lens of the same angle; and this aperture would be given by an oil-immersion objective of only 122°. Again, the numerical aperture of an oil-immersion objective having the theoretical maximum angle of 180° would be 1·52, or more than one-half greater than that of an air-lens of the same angle. And the numerical apertures corresponding to angles of 170°, which have been actually attained in both cases, fall very little short of the proportions just given.

So, again, an oil-immersion objective whose angle of aperture is only 60° has as high a numerical aperture (0·76) as a water-immersion objective of 69½°, or as a dry objective of 99°; and a dry objective of 140° has no greater a numerical aperture (0·94) than a water-immersion of 90° or an oil-immersion of 76½°.

This important doctrine may be best made practically intelligible by a comparison of the relative diameters of the back lenses of dry with those of water and oil immersion objectives of the same power, from an "air-angle" of 60° to an "oil-angle" of 180°,—these diameters expressing, in each case, the opening between the extreme pencil-forming rays at their issue from the posterior surface of the combination, to meet in its conjugate focus for the formation of the image, the relation of which opening in each case to the focal length of the combination is the real measure of its aperture (fig. 16). Thus the dry objective of 60° angle (5 in fig. 16) has its air-angle represented by $\sin u = \frac{1}{2} = 0·50$ numerical aperture. The dry objective of 97° (4) has its air-angle represented by $\sin u = \frac{3}{4} = 0·75$ numerical aperture. And the dry objective having the (theoretical) angle of 180° (3) has its air-angle represented by $\sin u = 1·00$ numerical aperture,—this corresponding to 96° water-angle and 82° oil-angle. But the water-immersion lens having the (theoretical) angle of 180° (2) has its water-angle represented by $n \sin u = 1·33$ numerical aperture. And the oil-immersion lens having the (theoretical) angle of 180° (1) has its oil-angle represented by $n \sin u = 1·52$ "numerical aperture."[1] These theoretical apertures for water and oil immersion lenses having been found as nearly attainable in practice as the theoretical maximum for dry objectives, such lenses can utilize rays from objects mounted in balsam or other dense media, which are entirely lost for the image (since they do not exist physically) when the same object is in air or is observed through a film of air. And this loss cannot be compensated by an increase of illumination; because the rays which are lost are different rays physically from those obtained by any illumination, however intense, through an aeriform medium.

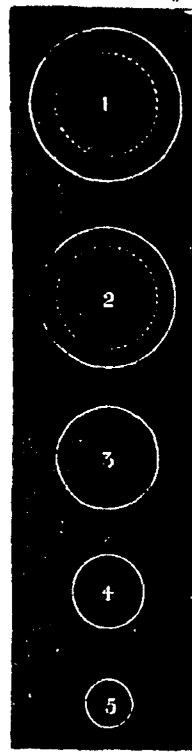

Fig. 16.—Relative Diameters of Back Lenses of Air, Water, and Oil Immersion Objectives.

It is by increasing the number of diffraction-spectra that the additional rays thus received by objectives of great numerical aperture impart to them an increased resolving power for lined and dotted objects,—the truth of the image formed by the recombination of these spectra being (as already shown) essentially dependent on the number of them that the objective may be capable of receiving.

But whilst the resolving power of microscopic objectives increases in the ratio of their respective numerical apertures, and whilst their illuminating power (dependent upon the quantity of light that passes through them) increases with the square of the numerical aperture, the case is reversed with another most important quality,—that of penetration or focal depth; for this diminishes as the numerical aperture increases, until nothing but what is precisely in the focal plane can be even discerned with objectives possessed of the highest resolving power. Thus, the penetrating power of an objective of 60° air-angle being expressed as 2·000, an extension of that angle to 76½° reduces it to 1·613, an extension to 89° reduces it to 1·429, and an extension to 99° reduces it to 1·316; further extension to 118½° reduces it to 1·163, while an objective whose air-angle is 140° has a penetrating power of only 1·064. So, again, the oil-immersion objective which has the numerical aperture of 1·00 corresponding to the theoretical air-angle of 180° has a penetrating power of 1·000; this is brought down to ·752 when its angle is so increased as to make its numerical aperture 1·33, equalling the theoretical maximum of a water-immersion objective, and is ·658 at the theoretical maximum (1·52) of an oil-objective.

Hence it is clear that, as some of the qualities to be sought in microscopic objectives are absolutely incompatible, a preference is to be accorded to objectives of greatest resolving power but very little penetration, or to those of moderate resolving power and great penetration, according to the uses to which they are to be applied; and some general principles will now be laid down in regard to this matter, based alike on science and experience.

In the first place, a marked distinction is to be drawn between those objectives of low or moderate power which are to be worked dioptrically and those of high power which are to be worked diffractively. The objects on which the former are to be for the most part used are either minute transparent bodies having solid forms which the observer should be able to take in as wholes (as in the case of *Polycystina*, the larger diatoms, *Infusoria*, &c.); or transparent sections, dissections, or injections, whose parts lie in different planes, the general relations of which he desires to study, while reserving their details for more special scrutiny; or opaque objects, whose structure can only be apprehended from the examination of their surfaces, when the inequalities of those surfaces are seen in their relations to each other. In all these cases it is desirable that microscopic vision should resemble ordinary vision as much as possible. If the eye were so constructed as to enable us to discern only those parts of an object that lie precisely in the plane to which we focus it, our visual conceptions of the forms and relations of these parts, and consequently of the object as a whole, would in general be very inadequate, and often erroneous. It is because, while focussing our eye successively on the several planes of the object, we can see the relation of each to what is nearer and more remote that we can readily acquire a visual conception of its shape as a whole, and that unmistakable perception of solid form which is given by the combination of the two dissimilar perspectives of near objects in binocular vision

[1] The dotted circles in the interior of 1 and 2, of the same diameter as 3, show the excess in the diameters of the back lenses of the water and oil objectives over that of the dry at their respective theoretical limits.

(p. 273) could not possibly be formed if our vision were strictly limited to the exact plane for which our eyes are focussed.

Hence it is obvious that, in the case of objectives of low and moderate amplification, focal depth or penetration is a quality for the want of which no other excellence can compensate,—the opening-out of their apertures being only advantageous in so far as it does not seriously interfere with their penetrating power. It is, no doubt, quite possible to construct a 1 inch objective with an aperture so large that, when the requisite amplification has been gained by deep eye-piecing, it shall resolve the lined "tests" ordinarily used for a ¼, or to construct an objective of 4/10 inch focus which shall in like manner do the ordinary work of a ⅛. But, as such objectives are thereby spoiled for their own proper work, the loss to the microscopist is but poorly compensated by his ability to resolve with them, under such deep eye-pieces as cannot be habitually used without serious risk to the eye-sight, the lined and dotted tests which can be much better shown under objectives of shorter focus and wider aperture, with eye-pieces of low amplification. For, whilst deep eye-pieces cannot be habitually employed for continuous observation, without putting a strain upon the eyes resembling that which results from the constant use of a magnifying glass, even the very highest objectives may be used continuously for long periods in combination with shallow eye-pieces, with scarcely any fatigue, and therefore (it is probable) without sensible injury.[1]

In estimating the goodness of a microscopic objective, five distinct qualities have to be separately considered:—(1) its working distance, or the actual interval between its front lens and the object on which it is focussed; (2) its penetrating power, or focal depth; (3) the flatness of its field; (4) its definition, or power of giving a distinct image of all well-marked features of an object, and especially of their boundary lines; and (5) its resolving power, by which it separates closely approximated lines, dots, or striæ.

1. The "working distance" of an objective has no fixed relation to its focal length,—the latter being estimated by its equality in power with a single lens of given radius of curvature (such as 1 inch, ¼ inch, 1/12 inch, &c.), while the former varies with the mode in which the combination is constructed and with the aperture given to it. For low and moderate powers, ranging up to 4/10 inch focus, good working distance is especially important, alike because it is closely related to penetrating power, and also because it facilitates the use of side-illumination for opaque objects. And in such objectives of high power as are to be used, not for the resolution of lined or dotted tests, but for the observation of living and moving objects of extreme minuteness, good working distance is no less important, on account of its relation to focal depth. In the case of those objectives, on the other hand, in which resolving power is made the first consideration, it is only needful that the working distance shall be such as to permit the interposition of a thin glass cover; and this, although necessarily diminished with the widening of the aperture, can be always obtained by the adoption of the immersion system.

2. The "penetrating power" or "focal depth" of an objective may be defined as consisting in the vertical range through which the parts of an object not precisely in the focal plane may be seen with sufficient distinctness to enable their relations with what lies exactly in that plane to be clearly traced out,—just as would be done by ordinary vision if the object were itself enlarged to the dimensions of its microscopic image. The close relation between this quality and the preceding becomes obvious when it is considered that the longer the working distance of an objective the less will the distinctness of the image it forms be affected by any given alteration (say the 1/10000 of an inch) in its focal adjustment. Consequently, of two objectives having the same magnifying power but different working distances, that one will have the most focal depth whose working distance is the greater. On the other hand, as the penetrating power of an objective is reduced in direct accordance with the increase of its numerical aperture, it must be sacrificed wherever the highest resolving power is to be attained. Hence, as already remarked, this attribute will be very differently valued by different observers, according to the work on which they are respectively engaged. For the general purposes of biological research, not only with low or moderate (for the reasons already stated), but also with high powers, a considerable amount of focal depth is essential. It is impossible, for example, to follow satisfactorily the movements of an *Amœba*, or to study the "cyclosis" in the cell of a *Vallisneria*, or to trace the distribution of a nerve-thread, with an objective in which focal depth is so completely sacrificed to aperture that nothing can be discerned save what is precisely in the focal plane, since, instead of passing gradationally from one focal plane to another, as the observer can do with an objective of good penetration, he can only get a succession of "dissolving views," with an interval of "chaos" between each pair. When, on the other hand, it is desired to scrutinize with the greatest precision such minute details as are presented in one and the same focal plane (as, for example, those of the thinnest possible film of tissue spread out between a glass slide and its covering glass), the microscopist will prefer an objective in which focal depth is subordinated to aperture, for the sake of the resolving power which he can thus command. And it will often happen in biological research that it is advantageous thus to bring objectives of the latter class to bear upon objects which could not have been detected in the first instance save by objectives of much inferior resolving power but greater focal depth.

[1] Hence, for work of this kind, the shallower eye-pieces and longer tubes of English microscopes are to be preferred to the deeper eye-pieces and shorter tubes of the ordinary Continental model, the shallowest eye-pieces of the latter being usually equal in power to the ordinary B eye-pieces of the former.

3. The "flatness of the field" afforded by the objective is a condition of great importance to the advantageous use of the microscope, since the extent of the area clearly seen at one time practically depends upon it. Many objectives are so constructed that, even when the object is perfectly flat, the foci of the central and peripheral parts of the field are so different that, when the adjustment is made for one, the other is more or less indistinct. Hence, when the central part of the area is in focus, no more information is gained respecting the peripheral than if the latter had been altogether stopped out. With a really good objective, not only should the image be distinct over the whole field at once, but the marginal portion should be as free from colour as the central. As imperfection in this respect is often masked by the contraction of the aperture of the diaphragm in the eye-piece, the relative merits of two objectives, as regards flatness of field, should always be tested under an eye-piece giving a large aperture.

4. The "defining power" of an objective, which depends upon the completeness of its corrections for spherical and for chromatic aberration, and upon the accurate centring of its component lenses, is an attribute essential to its satisfactory performance, whatever may be its other qualities,—its importance in scientific research being such that no superiority in resolving power can compensate for the want of it; and, though it is possible to obtain perfect correction for spherical aberration up to the highest practicable limit of angle, yet the difficulty of securing it increases rapidly with the augmentation of aperture, the want of it being made perceptible, especially when deep eye-pieces are put on, by the blurring of clearly-marked lines or edges, and by general "fog." Perfect colour-correction, on the other hand, is not possible for dry lenses of the widest angle, on account of the irrationality of the secondary spectrum; but this may be neutralized by the use of the immersion system. As already stated, what has to be aimed at in the construction of microscopic objectives is not absolute colour-correction, but a slight degree of over-correction, which, by compensating the chromatic dispersion of the Huygenian eye-piece, shall produce an image free from false colour. As this can be secured far more easily in the construction of objectives of moderate than in those of very wide aperture, the cost of the former is proportionally small,—an additional reason for the preference to be given to them on other grounds, in regard to all save very special kinds of microscopic work.

5. "Resolving power," being that by which very minute and closely approximated markings—whether lines, striæ, dots, or apertures—can be separately discerned, is a function which is only of primary importance in objectives whose amplifying power specially fits them for the study of objects of this class. It appears from the mathematical researches of Professor Abbe that the maximum resolving power (with a theoretical angle of 180°) would be capable of separating 146,528 lines to the inch; but he considers the limit of visual resolution depending on the power of the eye to be about 1/113000 of an inch; and this limit seems to have been nearly reached. To make such a separation distinctly perceptible, an amplification of at least 3000 linear would be requisite; and this can only be obtained either by the use of an objective of very high power (such as 1/25 inch focus) in combination with a low or medium eye-piece or by putting a very deep eye-piece upon an objective of lower power (such as a ⅛ inch),—the former method, for the reasons already given, being decidedly preferable. For the resolution of less closely approximated markings objectives of 1/20, 1/10, 1/12, and ⅛ inch answer very well; and the resolving power which they require may be obtained without any excessive widening of the aperture. For the loss of resolving power consequent upon the contraction of the angle of a water-immersion objective to 128⅓° is only one-tenth of the theoretical maximum 128,212; while a reduction to 105⅔° only lowers the number of separable lines to 102,184 to the inch,—thus diminishing the resolving power by little more than one-fifth, while the working distance and focal depth of the combination are greatly increased, and perfect definition is more certainly attainable. The ⅛ inch is (according to the writer's experience, which is confirmed by the theoretical deductions of Professor Abbe) the lowest objective in which resolving power should be made the primary qualification,—the ⅙, ⅕, ¼, and 4/10 inch being specially suited to kinds of biological work in which this is far less important than focal depth and dioptric precision. This view is strengthened by the very important consideration that the resolving power given by wide aperture cannot be utilized, except by a method of illumination that causes light to pass through

the object at an obliquity corresponding to that at which the most divergent rays enter the objective. Now, although in the case of objects whose markings are only superficial such obliquity may not be productive of false appearances (though even this is scarcely conceivable), it must have that effect when the object is thick enough to have an internal structure; and the experience of all biological observers who have carried out the most delicate and difficult investigations is in accord, not only as to the advantage of direct illumination, but as to the deceptiveness of the appearances given by oblique, and the consequent danger of error in any inferences drawn from the latter. Thus, for example, the admirable researches of Strassburger, Fleming, Klein, and others upon the changes which take place in cell-nuclei during their subdivision can only be followed and verified (as the writer can personally testify) by examination of these objects under axial illumination, with objectives of an angle so moderate as to possess focal depth enough to follow the wonderful differentiation of component parts brought out by staining processes through their whole thickness.

The most perfect objectives for the ordinary purposes of scientific research, therefore, will be obviously those which combine exact definition and flatness of field with the widest aperture that can be given without an inconvenient reduction of working distance and loss of the degree of focal depth suitable to the work on which they are respectively to be employed. These last attributes are especially needed in the study of living and moving objects; and, in the case of these, dry objectives are decidedly preferable to immersion, since the shifting of the slide which is requisite to enable the movement of the object to be followed is very apt to produce disarrangement of the interposed drop. And, owing to the solvent power which the essential oils employed for homogeneous immersion have for the ordinary cements and varnishes, such care is necessary in the use of objectives constructed to work with them as can only be given when the observer desires to make a very minute and critical examination of a securely-mounted object.

The following table expresses the magnifying powers of objectives constructed on the English scale of inches and parts of an inch, with the 10 inch body and the A and B eye-pieces usually supplied by English makers, and also specifies the angle of aperture which, in the writer's judgment, is most suitable for each. He has the satisfaction of finding that his opinions on this latter point, which are based on long experience in the microscopic study of a wider range of animal and vegetable objects than has fallen within the purview of most of his contemporaries, are in accordance with the conclusions drawn by Professor Abbe from his profound investigations into the theory of microscopic vision,[1] which have been carried into practical accomplishment in the excellent productions of Mr Zeiss.

Focal Length.	Angular Aperture.	Magnifying Power.		Focal Length.	Angular Aperture.	Magnifying Power.

½ „	45	100	150	$\frac{1}{16}$ „	170	800	1200
$\frac{4}{10}$ „	70	125	187				

For ordinary biological work, the ⅕, $\frac{1}{10}$, and $\frac{1}{12}$ objectives, with angles of from 100° to 120°, will be found to answer extremely well if constructed on the water-immersion system.

Each of these powers should be tested upon objects most suited to determine its capacity for the particular kind of work on which it is to be employed; and, in such testing, the application of deeper eye-pieces than can be habitually employed with advantage will often serve to bring out marked differences between two objectives which seem to work almost equally well under those ordinarily used,—defects in definition or colour-correction, and want of light, which might otherwise have escaped notice, being thus made apparent. No single object is of such general utility for these purposes as a large well-marked *Podura* scale; for the eye which has been trained to the use of a particular specimen of it will soon learn to recognize by its means the qualities of any objective between 1 inch and ⅕ inch focus; and it may be safely asserted that the objective which most clearly and sharply exhibits its characteristic markings is the best for the ordinary work of the histologist.

For the special attribute of resolving power, on the other hand, tests of an entirely different order are required; and these are furnished, as already stated, either by the more "difficult" diatoms, or by the highest numbers of Nobert's ruled test-plate. The diatom-valve at present most in use as a test for resolving power is the *Amphipleura pellucida*, the lines on which were long supposed to be more closely approximated than those of Nobert's nineteenth band, being affirmed by Mr Sollitt to range from 120 to 130 in $\frac{1}{1000}$ of an inch. But the admirable photographs of this valve obtained by Colonel Dr Woodward have confirmed the conclusion long previously expressed by the writer, that this estimate was far too high, being based on the "spurious lineation" produced by diffraction, and show that the striæ on the largest valves do not exceed 91, while those on the smallest are never more numerous than 100, in $\frac{1}{1000}$ of an inch. The same admirable manipulator has also obtained excellent photographs of another very difficult test-diatom, *Surirella gemma*, from which it appears that its transverse striæ count longitudinally at the rate of 72,000 to the inch, whilst the beaded appearances into which these may be resolved count transversely at the rate of 84,000 to the inch. Thus it appears that the complete resolution of these "vexatious" diatoms does not require by any means the maximum of aperture, but is probably dependent at least as much on the perfection of the corrections and the effectiveness of the illumination.

It must be understood that there is no intention in these remarks to undervalue the efforts which have been perseveringly made by the ablest constructors of microscopic objectives in the direction of enlargement of aperture. For these efforts, besides increasing the resolving power of the instrument, have done the great service of producing a vast improvement in the quality of those objectives of moderate aperture which are most valuable to the scientific biologist; and the microscopist who wishes his *armamentum* to be complete will provide himself with objectives of those different qualities, as well as different powers, which shall best suit his particular requirements.[2]

Illuminating Apparatus.

Every improvement in the optical performance of the compound achromatic microscope has called forth a corresponding improvement in the illumination of the objects viewed by it, since it soon came to be apparent that without such improvement the full advantage of the increased defining and resolving powers of the objectives could not be obtained. For the illumination of transparent objects examined by light transmitted through them under low powers of moderate angle a converging pencil of rays reflected upon their under surface by a concave mirror is generally sufficient,—a "condenser" being only needed when the imperfect transparency of the object requires the transmission of more light through it. And the microscopist engaged in ordinary biological studies, who works on very transparent objects with objectives of ⅕ or ⅙ inch focus, or $\frac{1}{12}$ inch immersion, will find that the small concave mirror of short focus with which the Continental models are furnished (see fig. 28) will generally prove sufficient for his needs. This mirror is usually hung at such a distance beneath the stage that parallel rays falling on it are brought to a focus in the object as it lies on a slip of glass resting on the stage; and thus, when the instrument is used by day, the light of a bright cloud (which is preferable to any other) gives a well-illuminated field, even with the powers last-mentioned. But when lamplight is used its divergent rays are not brought to a focus in the object by a mirror that is fixed as just stated; and the distance of the mirror beneath the stage should be made capable of increase (which is easily done by attaching it to a lengthening bar), so as to obtain the requisite focal convergence. Still the best effects of objectives of less than ¼ inch focus cannot be secured without the aid of an achromatic condenser, interposed between the mirror and the object, so as to bring a larger body of rays to a more exact convergence.

When objectives of still higher power are employed, the employment of such a condenser becomes indispensable; and when the highest powers are being used by lamplight, it is desirable to dispense with the mirror altogether, and to place the flame exactly in the optic axis of the microscope. The condenser should be an achromatic combination, corrected for the ordinary thickness of the glass slip on which the object lies, and capable of being so adjusted as to focus the illuminating pencil in the object.

As it is often found desirable that an object should be illuminated by central rays alone, or that the quantity of light transmitted through it should be reduced (for bringing into view delicate details of structure which are invisible when the object is flooded with light), every microscope should be provided with some means of cutting off the outer rays of the illuminating cone. The "diaphragm-plate" ordinarily used for this purpose is a disk of black metal, pivoted to the under side of the stage, and perforated with a graduated series of apertures of different diameters, any one of which can be brought, by the rotation of the disk, exactly into the optic axis of the microscope. But the required effect can be much more advantageously obtained by the "iris-diaphragm," in which a number of converging plates of metal are made so to slide over each other by the motion of a lever or screw that the aperture is either enlarged or diminished, while always remaining practically circular as well as central; and in this manner a continuous

[1] See his paper on "The Relation of Aperture and Power in the Microscope," in *Jour. Roy. Micros. Soc.*, 1882, pp. 300, 460.

[2] See the remarks of Mr Dallinger,—whose experience in the application of the highest powers to the study of the minutest living objects is probably greater than that of any living observer,—in *Jour. Roy. Micros. Soc.*, December 1882, p. 853.

view of the object is obtained, with a gradational modification of the light. Another method, commonly adopted in German microscopes, is to place a draw-tube in the optic axis between the stage and the mirror, and to drop into the top of this tube one of a set of "stops" perforated with apertures of different sizes; this allows a gradational effect to be obtained by raising or lowering the tube, so as to place the stop nearer to or more remote from the object; but it is not nearly so convenient as the iris-diaphragm; and the effect of the stop is not nearly so good when it is removed to some distance beneath the object as when it is very near to the under surface of the glass object-slide. When an achromatic condenser is used, either a diaphragm-plate or an iris-diaphragm should be placed below its back lens, so as to cut off any required proportion of the outer rays that form its illuminating cone.

Such an arrangement, while suiting all the ordinary requirements of the microscopist who uses the highest powers of his instrument for the purposes of biological investigation (as, for example, in the study of *Bacteria* or of the reproduction of the *Monadina*), does not serve to bring into effective use the special resolving power possessed by objectives of large aperture. It has long been known that for the discernment of very closely approximated markings oblique illumination is advantageous,—an objective which exhibits such a diatom-valve as *Pleurosigma angulatum* with a smooth unmarked surface when illuminated by the central rays of the achromatic condenser making its characteristic markings (figs. 8–11) distinctly visible when the central rays of the condenser are kept back by a stop, and the object is illuminated by its convergent marginal rays only. And it has also been practically known for some time that the resolution of lined or dotted tests can be often effected by mirror illumination alone, if the mirror be so mounted as to be able to reflect rays through the object at such obliquity to the optic axis of the microscope as to reach the margin of a wide-angled objective. But it has only been since Professor Abbe's researches have given the true theory of "resolution" that the special advantage of oblique illumination has been fully comprehended, and that the best means have been devised for using it effectively. Two different systems have now come into use, each of which has its special advantages.

One consists in the attachment of the illuminating apparatus (mirror and achromatic condenser) to a "swinging tail-piece" (see fig. 32), which, moving radially upon a pivot whose axis intersects the optic axis at right angles in the plane of the object, can transmit the illuminating pencil through it at any degree of obliquity that the construction of the stage allows. The direction of this pencil being of course limited to one azimuth, it is requisite, in order to bring out its full resolving effect, that the object should be made to rotate, by making the stage that carries it revolve round the optic axis, so that the oblique pencil may impinge upon the lines or other markings of the object in every direction successively. It will then be found that the appearances presented by the same object often vary considerably,—one set of lines being shown when the object lies in one azimuth, and another when its azimuth has been changed by rotation through 60°, 90°, or some other angle. Various contrivances have also been devised for throwing very oblique illuminating pencils on the object by means of prisms placed beneath the stage.

Illumination of at least equal obliquity to that afforded by the swinging tail-piece may now, however, be obtained by the use of condensers specially constructed to give a divergence of 170° to the rays which they transmit when used immersionally, by bringing their flat tops into approximation to the under side of the glass slide on which the object is mounted, with the interposition of a film of water or (preferably) of glycerin. By using a central stop, marginal rays alone may be allowed to pass; and these will be transmitted through the object in every azimuth at the same time. But diaphragms with apertures limiting the transmitted rays to one part of the periphery may be so fixed in a tube beneath the condenser as to be easily made to rotate, thus sending its oblique pencils through the object in every azimuth in succession. And where this rotation of the diaphragm brings out two sets of lines at a certain angular interval a diaphragm with two marginal openings at a corresponding angular distance will enable both to be seen at once. Numerous arrangements of this kind have been devised by those who devote their special attention to the resolution of difficult diatom-tests; but they are of little or no use to those who use the microscope for biological research.

For the illumination of the surfaces of opaque objects which must be seen by reflected light the means employed will vary with the focal length of the objective employed. For large bright objects viewed under a low magnifying power good ordinary daylight is sufficient; but if the surface of the object is dull, reflecting but little light, the aid of a bull's-eye or large bi-convex lens must be employed in order to give it sufficient brilliance. This aid will always be required by lamplight; and by a proper adjustment of the relative distances of the lamp and the object the rays from the lamp may be made either to spread themselves over a wide area or to converge upon a small spot. The former is the method suitable to large objects viewed under a low magnifying power; the latter to the illumination of small objects which are to be examined under objectives of (say) 1 inch or ⅔ inch focus. Another method which may be conveniently had recourse to when the microscope is provided with a swinging tail-piece is to turn this on its pivot until the concave mirror is brought above the stage, so that rays which it gathers either from natural or artificial sources may be reflected downwards upon the surface of the object.

The illumination of an opaque object to be seen with a higher power than the ⅔ or ½ inch objectives was formerly provided for by a concave speculum (termed a Lieberkuhn after its inventor), with a perforation in the centre for the passage of the rays to the objective to which it is fitted,—the curvature of the speculum being so adapted to the focus of the objective which carries it that, when the latter is duly adjusted, the rays reflected upwards around the object from the mirror to the speculum shall converge strongly on the object. The various disadvantages of this mode of illumination, however, have caused it to be now generally superseded by other arrangements. For powers between 1½ inch and $\frac{1}{10}$ inch, and even for a ¼ or ⅕ inch of small angle and good working distance, nothing is so convenient as the parabolic speculum or side-illuminator (F, fig. 17) invented by the late Richard Beck. This is attached to a spring-clip that slides on the tubes of low-power objectives, so that its distance from the object and the direction of its reflected pencil are readily adjusted; and for use with higher powers it may be either mounted on a separate arm attached to some part of the stand of the microscope, or may be hung in the manner shown in fig. 17 from an "adapter" A interposed between the objective and the body. By rotating the collar B and making use of the joints C, C, the lengthening rod D, and the ball and socket E, any position may be given to the speculum F that may best suit the objective with which it is used.

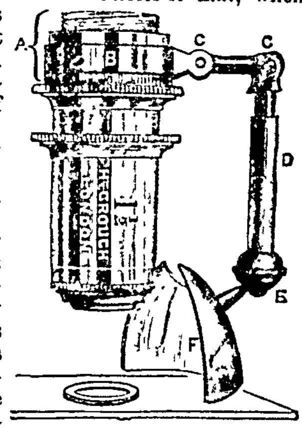

Fig 17.—Beck's Parabolic Side-Illuminator, with Crouch's Adapter.

When, however, it is desired to illuminate objects to be seen under objectives of high power and very short working distance, side illumination of any kind becomes difficult, though not absolutely impossible;[1] and various modes have been devised for the illumination of the object by means of light sent down upon it, through the objective, from above. This is done in the vertical illuminator of Messrs Beck (fig. 18)—the original idea of which was first given by the American Professor H. L. Smith—by a disk of thin glass B, *b*, attached to a milled head by which its angular position may be adjusted, and introduced by a slot A, *e* into the interior of an adapter that is interposed between the objective C, *d* and the nose *c* of the body. The light which enters at the lateral aperture A, *a*, falling upon the oblique surface of the disk C, *b*, is reflected downwards, and is concentrated by the lenses of the objective upon the object beneath. The lateral aperture may be provided with a diaphragm, with openings of different sizes, for diminishing the false light to which this method is liable; or a screen with a small aperture may be placed between the lamp and the

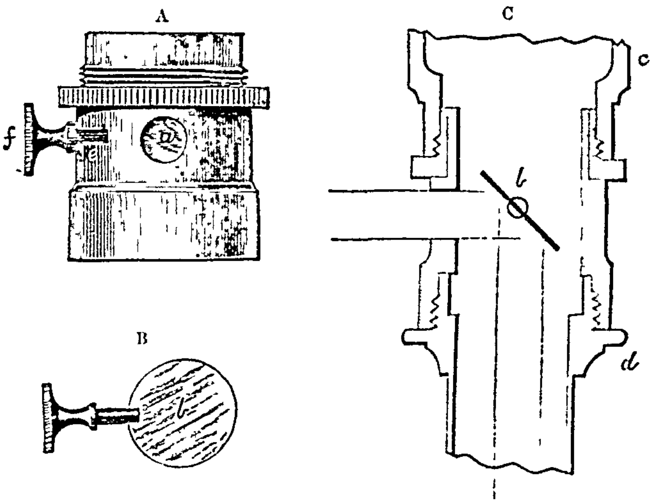

Fig. 18.—Beck's Vertical Illuminator.

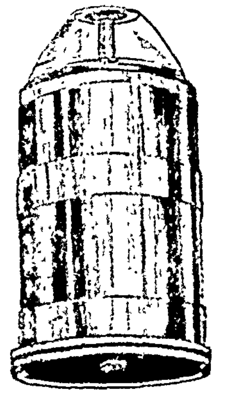
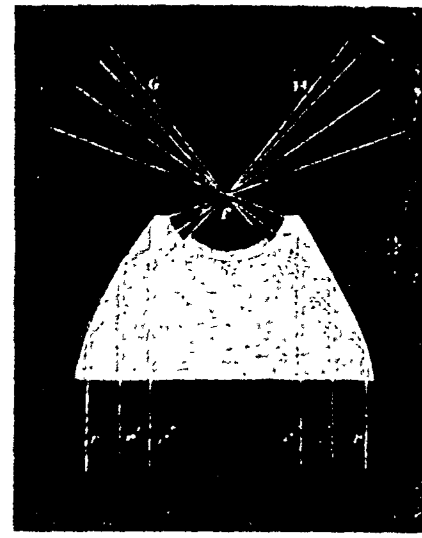
[1] See a method devised by Mr James Smith, in *Jour. R. Micr. Soc.*, vol. iii., N. S., 1880, p. 898.

illuminator, at any distance that is found to produce the best effects. In using this illuminator, the lamp should be placed at a distance of about 8 inches from the aperture; and, when the proper adjustments have been made, the image of the flame should be seen upon the object. The illumination of the entire field, or the direction of the light more or less to either side of it, can easily be managed by the interposition of a small condensing lens placed at about the distance of its own focus from the lamp. The objects viewed by this mode of illumination with dry-front objectives are best uncovered, since, if they are covered with thin glass, so large a proportion of the light sent down upon them is reflected from the cover (especially when objectives of large angle of aperture are employed) that very little is seen of the objects beneath, unless their reflective power is very high. With immersion objectives, however, covered objects may be used. Another method of vertical illumination long since devised by Mr Tolles has recently been brought into notice by Professor W. A. Rogers of Boston (U. S.). It consists in the introduction of a small rectangular prism at a short distance behind the front combination of the objective, so that parallel rays entering its vertical surface pass on between its parallel horizontal surfaces until they meet the inclined surface, by which they are reflected downwards. In passing through the front combination of the objective, they are deflected towards its axis; but, as their angle of convergence is less than the angle of divergence of the rays proceeding from the object, the reflected rays will not meet in the focal point of the lens, but will be so distributed as to illuminate a sufficient area. By altering the extent to which the prism is pushed in, or by lifting or depressing its outer end by means of a milled-head screw, the field of illumination can be regulated. The working of this prism with immersion-objectives is stated by Mr Tolles to be peculiarly satisfactory.

Black-Ground Illumination.—There are certain classes of objects which, though sufficiently transparent to be seen with light transmitted through them, are best viewed when illuminated by rays of such obliquity as not to pass directly into the objective,—such a proportion of these rays being retained by the object as to render it self-luminous, when, all direct light being cut off, the general field is perfectly dark. This method is particularly effective in the case of such delicate mineral structures as the siliceous tests of *Polycystina* and the "frustules" of *Diatomaceæ*. And it is one advantage of this kind of illumination that it brings out with considerable effect the solid forms of objects suited to it, even when they are viewed monocularly. Two modes of providing this illumination are in use, each of which has its special advantages. One consists in placing a central stop either upon or immediately beneath a condenser of wide aperture, which shall cut off all rays save those that, after passing through the object (as in fig. 20), diverge at an angle greater than that of the objective used; so that, while the ground is darkened, the object is seen brightly standing out upon it. But if the divergence of the rays is but moderate (say 60°), and the angle of the objective is large (say 90°), the most divergent rays of the condenser will enter the marginal portion of the objective, and, the field not being darkened, the black-ground effect will not be produced. This method has the great convenience of allowing black-ground illumination to be substituted for the ordinary illumination under different powers, without any other change in the apparatus than the turning of a diaphragm-plate fitted with stops of different sizes suitable to the several apertures of the objectives; and the modern achromatic condensers of wide aperture can be thus used with objectives of 120° angle.

An excellent black-ground illumination is also given by the parabolic illuminator (fig. 19), originally worked out as a silvered speculum by Mr Wenham, but now made as a paraboloid of glass that reflects to its focus the rays which fall upon its internal surface. A diagrammatic section of this instrument, showing the course of the rays through it, is given in fig. 20, the shaded portion representing the paraboloid. The parallel rays r, r', r'', entering its lower surface perpendicularly, pass on until they meet its parabolic surface, on which they fall at such an angle as to be totally reflected by it, and are all directed towards its focus F. The top of the paraboloid being ground out into a spherical curve of which F is the centre, the rays in emerging from it undergo no refraction, since each falls perpendicularly upon the part of the surface through which it passes. A stop placed at S prevents any of the rays reflected upwards by the mirror from passing to the object, which, being placed at F, is illuminated by the rays reflected into it from all sides of the paraboloid. Those rays which pass through it diverge again at various angles; and if the least of these, GFH, be greater than the angle of aperture of the object-glass, none of them can enter it. The stop is attached to a stem of wire, which passes vertically through the paraboloid and terminates in a knob beneath, as shown in fig. 19; and by means of this it may be pushed upwards, so as to cut off the less divergent rays in their passage towards the object, thus giving a black-ground illumination with objectives of an angle of aperture much wider than GFH. In using the paraboloid for delicate objects, the rays which are made to enter it should be parallel; consequently the plane mirror should always be employed; and when, instead of the parallel rays of daylight, we are obliged to use the diverging rays of a lamp, these should be rendered as parallel as possible, previously to their reflexion from the mirror, by the interposition of the "bull's-eye" so adjusted as to produce this effect. There are many cases, however,





Figs. 19, 20.—Wenham's Parabolic Illuminator.

in which the stronger light of the concave mirror is preferable. When it is desired that the light should fall on the object from one side only, the circular opening at the bottom of the wide tube that carries the paraboloid may be fitted with a diaphragm adapted to cover all but a certain portion of it; and, by giving rotation to this diaphragm, rays of great obliquity may be made to fall upon the object from every azimuth in succession.

In order to adapt this paraboloid to objectives of very wide angle of aperture, a special modification of it, originally devised by Mr Wenham, has been latterly reintroduced under the designation of "immersion-paraboloid," with most excellent effect. This consists in making the top of the paraboloid flat instead of concave, and in interposing a film of glycerin between its surface and the under surface of the glass slide carrying the object. Only rays of such extreme obliquity are allowed to pass into the slide as would be totally reflected from its under surface if they fell upon it through air; and, as these illuminate the object without passing into the objective, it can be thus examined under even the highest powers.

Binocular Microscopes.

Stereoscopic Binoculars.—The admirable invention of the stereoscope by Professor Wheatstone has led to a general appreciation of the value of the conjoint use of both eyes, in conveying to the mind a conception of the solid forms of objects such as the use of either eye singly does not generate with the like certainty or effectiveness (see Stereoscope). This conception is the product of the mental combination of the dissimilar perspective projections which our right and left retinæ receive of any object that is sufficiently near the eyes for the formation of two images that are sensibly dissimilar. Now it is obvious that a similar difference must exist between the two perspective projections of any object in relief that are formed by the right and left halves of a microscopic objective and that this difference must increase with the angular aperture of the objective. And the fact of this difference may be easily made apparent experimentally, by adapting a semicircular "stop" to any objective of from 20° to 30° angle in such a manner that it can be turned so as to cover either its right or its left half; for not only will the two images of any projecting object formed by the rays transmitted through the two uncovered halves be found sensibly different, but, if they be photographed or accurately drawn, the "pairing" of their pictures in the stereoscope will bring out the form of the object in vivid relief. What is needed, therefore, to give the true stereoscopic effect to a binocular microscope is a means of so bisecting the cone of rays transmitted by the objective that its two lateral halves shall be transmitted the one to the right and the other to the left eye, and that the two images shall be crossed (the image formed by the right half of the objective being sent to the left eye, and that formed by the left half of the objective being sent to the right eye) in order to neutralize the reversing effect of the microscope itself. If this crossing does not take place, the effect will be rendered "pseudoscopic," not "orthoscopic,"—its projections becoming depressions, and its depressions being brought out as prominences. It was from a want of due appreciation of this fact that the earlier attempts at constructing a stereoscopic binocular gave representations of objects placed under it, not in their true orthoscopic, but in their pseudoscopic aspect. This was the case, for example, with the binocular microscope first devised by

Professor Riddell of New Orleans in 1851, which separated the cone of rays by a pair of rectangular prisms so placed edge to edge above the objective that the rays passing through its right half were reflected horizontally to the right side, to be changed to the vertical direction and sent to the right eye by a lateral rectangular prism, while the rays from the left half of the objective were sent to the left eye in a similar manner. Professor Riddell describes the "conversion of relief" produced by this arrangement with the ordinary eye-piece as making a metal spherule appear "as a glass ball silvered on the under side, and a crystal of galena like an empty box." And to render the images "normal and natural" he found himself obliged to use erecting eye-pieces, which should produce a second reversal of the images that had been reversed in their first formation.[1] Subsequently, however, Professor Riddell devised and perfected another arrangement giving a true orthoscopic effect, which, after being long disregarded, has been latterly taken up and brought into use by Mr Stephenson. The cone of rays passing upwards from the objective meets a pair of prisms (A, A fig. 21) fixed immediately above its back lens, which divides it into two halves; each of these is subjected to internal reflexion from the inner side of the prism through which it passes; and the slight separation of the two prisms at their upper end gives to the two pencils B, B, on their emergence from the upper surfaces of the prisms, a divergence which directs them through two obliquely-placed bodies to their respective eye-pieces. By this internal reflexion a lateral reversal is produced, which neutralizes that of the ordinary microscopic image, so that, while each eye receives the image formed by its own half of the objective, the pairing of the two pictures produces a true orthoscopic effect.[2]

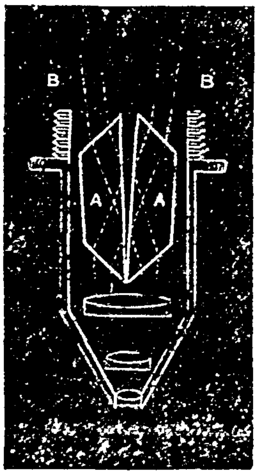


Fig. 21.—Riddell's Binocular Prisms.

About the same date MM. Nachet of Paris succeeded in devising a binocular that should give a true orthoscopic image, by placing above the object-glass an equiangular prism (P. fig. 22) with one of its surfaces parallel to its back lens, which, receiving the pencils *ab* forming the right half of the cone, internally reflects them obliquely upwards to the left, and in like manner reflects the pencils *a'b'* from the left half of the cone obliquely upwards to the right. These pencils, passing out of the left and right oblique faces of the prism at right angles (so as not to undergo either refraction or dispersion), enter right and left lateral prisms, also at right angles, and, after being internally reflected by these, pass out vertically, at right angles to their upper surfaces, through two parallel bodies (fig. 23), whose eye-pieces bring them to a focus in the right and left eyes respectively. The distance between these bodies may be adjusted to the varying distances between the axes of individual pairs of eyes, by adjusting screws at their base, which vary the distance of the lateral prisms from the central. This instrument gives a theoretically perfect representation of a microscopic object in relief, as it would appear if enlarged to the size of its image, and brought to within about 10 inches of the eye; and its chief practical defect is that, as the two bodies are parallel, instead of being slightly convergent, it cannot be continuously used without an uncomfortable strain. But, as its performance depends upon the accuracy of the seven plane surfaces of the three prisms, and on the correctness of their relations to each other, it is liable to considerable error from imperfections in its construction; and, as the instrument can only be used for its own special purpose, the observer must be provided with an ordinary single-bodied microscope for the examination of objects unsuited to the powers of the binocular. This last objection applies also to Professor Riddell's model.

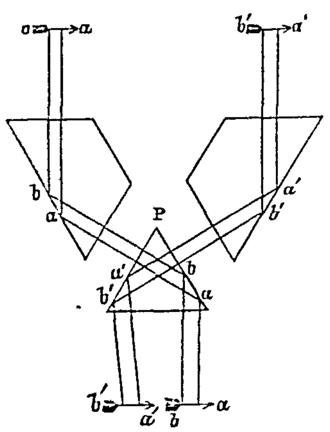

Fig. 22.—Nachet's Binocular Prisms.

It was for these reasons that Mr Wenham, fully impressed with the advantages of stereoscopic vision to the microscopist, set himself to devise a construction by which it might be obtained without the drawbacks inevitable in the working of Riddell's and Nachet's instruments; and he soon succeeded in accomplishing this on a plan which has proved not only convenient but practically satisfactory, notwithstanding its theoretical imperfection. Only the right half of the cone of rays proceeding upwards from the right half of the objective (*a*, fig. 24) is intercepted by a prism placed immediately over that half of its back lens, which, by two internal reflexions (as shown in fig. 25), sends its pencils obliquely upwards into the left-hand or secondary body L, whilst the pencils of the left half-cone pass uninterruptedly into the right-hand body R, and form an image that suffers no other deterioration than that which results from the halving of the angular aperture and the consequent loss of light. The moderate convergence of the two bodies (which, by varying the angles of the prism, may be made greater or less, so as to accord with the ordinary convergence of the optic axes in the individual observer) is much more generally suitable than the parallelism of MM. Nachet's earlier instrument; and the adjustment requisite for variation of distance between the eyes can be made by simply lengthening or shortening the bodies by drawing out or pushing in the diverging eye-pieces.

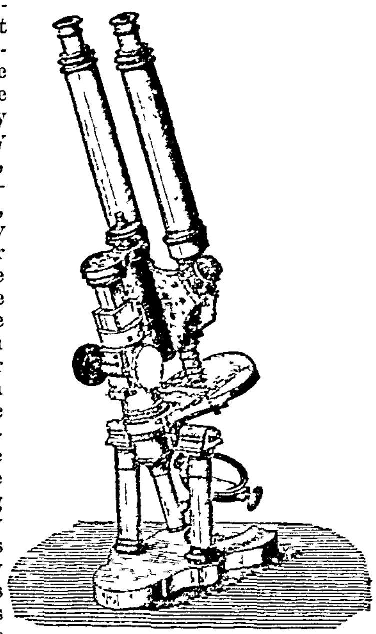

Fig. 23.—Nachet's Binocular Microscope.

It may be fairly objected to Mr Wenham's method (1) that, as the rays which pass through the prism and are obliquely reflected into the secondary body traverse a longer distance than those which pass on uninterruptedly into the principal body, the image formed by them will be somewhat larger than that which is formed by the other set, and (2) that the image formed by the rays which have been subjected to the action of the prism must be inferior in distinctness to that formed by the uninterrupted half of the cone of rays. But these objections are found to have no practical weight. For it is well known to those who have experimented upon the phenomena of stereoscopic vision (1) that a slight difference in the size of the two pictures is no bar to their perfect combination, and (2) that, if one of the pictures be good, the full effect of relief is given to the image, even though the other picture be faint and imperfect, provided that the outlines of the latter are sufficiently distinct to represent its perspective projection. Hence if, instead of the two equally half-good pictures which are obtainable by MM. Nachet's original construction, we had in Mr Wenham's one good and one indifferent picture, the latter would be decidedly preferable. But, in point of fact, the deterioration of the second picture in Mr Wenham's arrangement is less considerable than that of both pictures in the original arrangement of MM. Nachet; so that the optical performance of the Wenham binocular is in every way superior. It has, in addition, these further advantages over the preceding:—first, the greater comfort in using it (especially for some length of time together) which results from the convergence of the axes of the eyes at their usual angle for moderately near objects; second, that this binocular arrangement does not necessitate a special instrument, but may be applied to any microscope which is capable of carrying the weight of the secondary body,—the prism being so fixed in a movable frame that it may in a moment be taken out of the tube or replaced therein, so that when it has been removed the principal body acts in every respect as an ordinary microscope, the entire cone of rays passing uninterruptedly into it; and, third, that the simplicity of its construction renders its derangement almost impossible. Hence it is the one most generally preferred by microscopists who use the long-bodied English model.

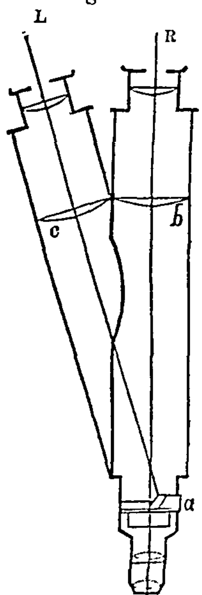

Fig. 24.—Wenham's Stereoscopic Binocular Microscope.

For short-bodied Continental microscopes, however, MM. Nachet

[1] See Silliman's *Journal*, vol. xv., 1853, p. 68; and *Quart. Jour. of Micros. Sci.*, vol. i., 1853, p. 236.
[2] *Quart. Jour. of Micros. Sci.*, vol. ii., 1854, p. 18.

have devised an arrangement of two prisms, based on Mr Wenham's fundamental idea of deflecting one half of the cone of rays into a secondary body, whilst the other half proceeds onwards without change of direction into the principal body. And it is an interesting feature in this construction that, by a simple change in the *position of the dividing prism, the true "orthoscopic" image may be* made, by a "conversion of relief," to become "pseudoscopic." [1]

The effect of stereoscopic projection may be attained, however, without a double body, by the insertion of a suitably constructed binocular eye-piece into the body of any ordinary monocular microscope. A plan of this kind was first successfully worked out by Mr Tolles (the very able optician of Boston, United States), who interposed a system of prisms similar to that devised by MM. Nachet (fig. 22), but on a much larger scale, between an "erector" (resembling that used in the eye-piece of a day telescope) and a pair of ordinary Huygenian eye-pieces, the central or dividing prism being placed at or near the plane of the secondary image formed by the erector, while the two eye-pieces are placed immediately above the lateral prisms,—the combination thus making that division in the pencils forming the secondary (erected) image which it makes in the Nachet binocular in the pencils emerging from the objective.

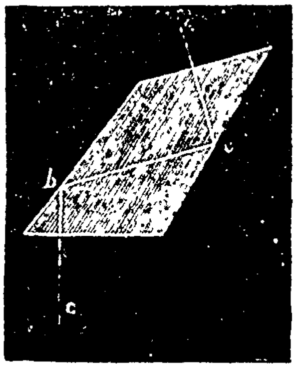

FIG. 25.—Wenham's Binocular Prism.

A stereoscopic eye-piece of a very different construction has been recently devised by Professor Abbe, who, making use, for the division between the two eye-pieces of the rays going to form the first image, of an arrangement of prisms essentially similar to that devised by Mr Wenham for his non-stereoscopic binocular (fig. 27), obtains either an orthoscopic or a pseudoscopic effect by placing on each eye-piece a cap with a semicircular diaphragm, so as to extinguish half of each of the cones of rays that form the two retinal images. While in one position of the diaphragms true stereoscopic or orthoscopic relief is given, it is sufficient to turn the diaphragms into the opposite position to obtain a pseudoscopic conversion.[2] It appears, however, that this arrangement, though possessing points of great interest in relation to the theory of binocular vision, is not likely to supersede the ordinary Wenham prism.

It must be obvious to every one who studies with sufficient attention the conditions under which true stereoscopic relief can be given that no combination of two dissimilar retinal perspectives can be satisfactory unless the visual pictures represent with tolerable distinctness the features of the object that lie in different focal planes. This is provided for, in ordinary vision, by the power of accommodation possessed by the eye, which, while focussed exactly to any one plane, can also include in its visual picture (within certain limits) what is either nearer or more remote. Now it seems probable that, as Professor Abbe has urged, this power of accommodation comes into play in microscopic stereoscopy, but there can be no question that the visual distinctness of the parts of an object lying within and beyond the focal plane, and therefore the completeness of the stereoscopic image, mainly depends upon the "focal depth" of the objective employed,—which, as already explained, is a function of its angular aperture. When, however, objectives of long focus and small aperture are employed in binocular microscopy, although each of the two perspective projections may be fairly distinct throughout, the effect of solid relief will be very inconsiderable, because the pictures are not sufficiently dissimilar to one another,—the case being exactly analogous to that of the stereoscopic combination of two photographic portraits taken at an angle of no more than a few degrees from each other. Still, with an objective of 1½ inches focus and an angular aperture of from 15° to 20°, a very distinct separation is made of the focal planes of transparent sections of structures having no great minuteness of detail,—such, especially, as injected preparations,—the solid forms of their capillary networks being presented to the mind's eye with a vividness that no monocular representation of them can afford. When a 1 inch objective of 20° or 25° is used, the stereoscopic effect becomes much more satisfactory; so that objects of moderate projection (such as many of the siliceous *Polycystina*, *Diatomaceæ*, &c.) can be seen in nearly their natural projection, and, if the focal adjustment is made for a medium plane, with tolerable distinctness both of their nearer and remoter parts. With a ⅔ inch of 30° or 35°, the stereoscopic relief becomes more pronounced; but the diminution of the focal depth prevents the several planes of objects in strong relief from being as distinctly seen at the same time. A ½ inch objective of about 40° of aperture, however, affords the most satisfactory results with suitable objects,—full stereoscopic relief being gained without exaggeration, so as to present, *e.g.*, the discoidal diatoms and the smaller *Polycystina* in their true forms, whilst their nearer and more remote parts are seen with sufficient distinctness to require only a very slight adjustment of the focus for their perfect definition. Still more minute objects may be well shown by $\frac{4}{10}$ths and ¼th objectives whose angular aperture does not exceed 50°; but it can be shown both theoretically and practically[3] that the dissimilarity of the two perspective projections of objects in relief formed by objectives of any angle much exceeding 40° is such as to exaggerate the stereoscopic effect; besides which, every enlargement of angular aperture so greatly diminishes the focal depth of the objectives that only those parts of the objects which lie very near the focal plane can be seen with distinctness sufficient for the formation of a good stereoscopic image. Hence, for the purposes of minute histological research, the stereoscopic binocular is (in the present writer's opinion) almost valueless; since, if any distinct perspective differentiation can be gained with objectives of the short focus and enlarged angle that are most suitable to such investigations, that differentiation will be so great as to produce a highly exaggerated stereoscopic effect. If such objectives be used binocularly at all, they must be so mounted that their back lenses are in very close proximity to the prism; and the (transparent) object must be illuminated by an achromatic condenser of sufficient aperture to send through it pencils of sufficient divergence to produce the secondary image.

In regard to the advantage derived from the use of the stereoscopic binocular, with the powers, and upon the objects, suitable to produce the true effect of solid form, the writer can unhesitatingly assert, as the result of a long and varied experience, that in no other way could he as certainly or as vividly image those forms to himself, and that in prolonged work upon such subjects he is conscious of a great saving of fatigue, which seems attributable not merely (perhaps not so much) to the conjoint use of both eyes as to the absence of the mental effort required for the interpretation of the microscopic picture, when the solid form of the object has to be ideally constructed from it (chiefly by means of the information obtainable through the focal adjustment), instead of being directly presented to the mind's eye.[4]

Non-Stereoscopic Binoculars.—The great comfort which is experienced by the microscopist in the conjoint use of both eyes has led to the invention of more than one arrangement by which this can be secured when those high powers are required which cannot be employed with the ordinary stereoscopic binocular. This is accomplished by Messrs Powell and Lealand by taking advantage of the fact that, when a pencil of rays falls obliquely upon the surface of a refracting medium, a part of it is reflected without entering that medium at all. In the place usually occupied by the Wenham prism they interpose an inclined plate of glass with parallel sides, through which one portion of the rays proceeding upwards from the whole aperture of the objective passes into the principal body with very little change in its course, whilst another portion is reflected from its surface into a rectangular prism so placed as to direct it obliquely upwards into the secondary body (fig. 26). Although there is a decided difference in brightness between the two images, that formed by the reflected rays being the fainter, yet there is marvellously little loss of definition in either, even when the $\frac{1}{25}$ inch objective is used. The disk and prism are fixed in a short tube, which can be readily substituted in any ordinary binocular microscope for the one containing the Wenham prism.

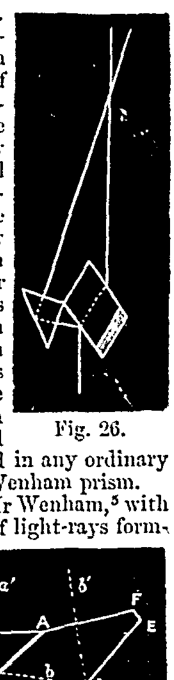

Fig. 26.

Other arrangements were devised long ago by Mr Wenham,[5] with a view to obtain a greater equality in the amount of light-rays forming the two pictures; and he has latterly carried one of these into practical effect, with the advantage that the compound prism of which it consists has so nearly the same shape and size as his ordinary stereoscopic prism as to be capable of being mounted in precisely the same manner, so that the one may be readily exchanged for the other. The axial ray *a*, proceeding upwards from the objective, enters the prism ABDEF (fig. 27) at right angles to its lower face, and passes on to *c*, where it meets the inclined face AB, at which this prism is nearly in contact with the oblique face of the right-angled

[4] A very elaborate investigation, by Professor Abbe, "On the Conditions of Orthoscopic and Pseudoscopic Effects in the Binocular Microscope," will be found in the *Jour. of the Roy. Micros. Soc.*, 2d ser., vol. i., 1881, p. 203.

[5] *Transactions of the Micros. Soc.*, N. S., vol. xiv., 1866, p. 105.

prism ABC. By internal reflexion from the former and external reflexion from the latter about half the beam b is reflected within the first prism in the direction cb, while the other half proceeds straight onwards through the second prism, in the direction ca', so as to pass into the principal body. The reflected half, meeting at d the oblique (silvered) surface DE of the first prism, is again reflected in the direction db', and, passing out of that prism perpendicularly to its surface AF, proceeds towards the secondary body. The two prisms must not be in absolute contact along the plane AB, since, if they were, Newton's rings would be formed; and much nicety is required in their adjustment, so that the two reflexions may be combined without any blurring of the image in the secondary body.

For the prolonged observation, under high powers, of objects not requiring the extreme of perfection in definition,—such, for example, as the study of the cyclosis in plants,—great advantage is gained from the conjoint use of both eyes by one of the above arrangements.

Mechanical Construction of the Microscope.

The optical arrangements on which the working of the compound achromatic microscope depends having now been explained, we have next to consider the mechanical provisions whereby they are brought to bear upon the different purposes which the instrument is destined to serve. Every complete microscope must possess, in addition to the lens or combination of lenses which affords its magnifying power, a stage whereon the object may securely rest, a concave mirror for the illumination of transparent objects from beneath, and a condensing-lens for the illumination of opaque objects from above.

1. Now, in whatever mode these may be connected with each other, it is essential that the optical part and the stage should be so disposed as either to be altogether free from tendency to vibration or to vibrate together; since it is obvious that any movement of one, in which the other does not partake, will be augmented to the eye of the observer in proportion to the magnifying power employed. In a badly-constructed instrument, even though placed upon a steady table resting upon the firm floor of a well-built house, when high powers are used, the object is seen to oscillate so rapidly at the slightest tremor—such as that caused by a person walking across the room, or by a carriage rolling by in the street—as to be frequently almost indistinguishable; whereas in a well-constructed instrument scarcely any perceptible effect will be produced by even greater disturbances. Hence, in the choice of a microscope, it should always be subjected to this test, and should be unhesitatingly rejected if the result be unfavourable. If the instrument should be found free from fault when thus tested with high powers, its steadiness with low powers may be assumed; but, on the other hand, though a microscope may give an image free from perceptible tremor when the lower powers only are employed, it may be quite unfit for use with the higher. The method still adopted by some makers, of supporting the body by its base alone, is the worst possible, especially for the long body of the large English model, since any vibration of its lower part is exaggerated at its ocular end. The firmer the support of the body along its length the less tremor will be seen in the microscopic image.

2. The next requisite is a capability of accurate adjustment to every variety of focal distance, without movement of the object. It is a principle universally recognized in the construction of good microscopes that the stage whereon the object is placed should be a fixture, the movement by which the focus is to be adjusted being given to the optical portion. This movement should be such as to allow free range from a minute fraction of an inch to three or four inches, with equal power of obtaining a delicate adjustment at any part. It should also be so accurate that the optic axis of the instrument should not be in the least altered by any movement in a vertical direction, so that, if an object be brought into the centre of the field with a low power, and a higher power be then substituted, the object should be found in the centre of its field, notwithstanding the great alteration in the focus. In this way much time may often be saved by employing a low power as a "finder" for an object to be examined by a higher one; and when an object is being viewed by a succession of powers little or no readjustment of its place on the stage should be required. A rack-and-pinion adjustment, if it be made to work both tightly and smoothly, answers sufficiently well for the focal adjustment, when objectives of low power only are employed. But for any lenses whose focus is less than half an inch a "fine adjustment," or "slow motion," by means of a screw-movement operating either on the object-glass alone or on the entire body (preferably on the latter), is of great value; and for the highest powers it is quite indispensable. It is essential that in this motion there should be no "lost time," and that its working should not produce any "twist" or displacement of the image. In some microscopes which are provided with a fine adjustment the rack-and-pinion movement is dispensed with, the "coarse adjustment" being given by merely sliding the body up and down in the socket which grasps it; but this plan is only admissible where, for the sake of extreme cheapness or portability, the instrument has to be reduced to the form of utmost simplicity, as in figs. 28, 29.

3. Scarcely less important than the preceding requisite, in the case of the compound microscope, especially with the long body of the ordinary English model, is the capability of being placed in either a vertical or a horizontal position, or at any angle with the horizon, without deranging the adjustment of its parts to each other, and without placing the eye-piece in such a position as to be inconvenient to the observer. It is certainly a matter of surprise that some microscopists, especially on the Continent, should still forego the advantages of the inclined position, these being attainable by a very small addition to the cost of the instrument; but the inconvenience of the vertical arrangement is much less when the body of the microscope is short, as in the ordinary Continental model; and there are many cases in which it is absolutely necessary that the stage should be horizontal. This position, however, can at any time be given to the stage of the inclining microscope, by bringing the optic axis of the instrument into the vertical direction. In ordinary cases, an inclination of the body at an angle of about 55° to the horizon will usually be found most convenient for unconstrained observation; and the instrument should be so constructed as, when thus inclined, to give to the stage such an elevation above the table that, when the hands are employed at it, the arms may rest conveniently upon the table. In this manner a degree of support is attained which gives such free play to the muscles of the hands that movements of the greatest nicety may be executed by them, and the fatigue of long-continued observation is greatly diminished. When the ordinary camera lucida[1] is used for drawing or measuring, it is requisite that the microscope should be placed horizontally. It ought, therefore, to be made capable of every such variety of position; and the stage must of course be provided with some means of holding the object, whenever it is itself placed in such a position that the object would slip down unless sustained.

4. The last principle on which we shall here dwell, as essential to the value of a microscope designed for ordinary work, is simplicity in the construction and adjustment of every part. Many ingenious mechanical devices have been invented and executed for the purpose of overcoming difficulties which are in themselves really trivial. A moderate amount of dexterity in the use of the hands is sufficient to render most of these superfluous; and without such dexterity no one, even with the most complete mechanical facilities, will ever become a good microscopist. There is, of course, a limit to this simplification; and no arrangement can be objected to on this score which gives advantages in the examination of difficult objects, or in the determination of doubtful questions, such as no simpler means can afford. The meaning of this distinction will become apparent if it be applied to the cases of the mechanical stage and the achromatic condenser. For, although the mechanical stage may be considered a valuable aid in observation, as facilitating the finding of a minute object, or the examination of the entire surface of a large one, yet it adds nothing to the clearness of our view of either; and its place may in great degree be supplied by the fingers of a good manipulator. On the other hand, the use of the achromatic condenser not only contributes very materially, but is absolutely indispensable, to the formation of a perfect image, in the case of many objects of a difficult class; the want of it cannot be compensated by the most dexterous use of the ordinary appliances; and consequently, although it may fairly be considered superfluous as regards a large proportion of the purposes to which the microscope is directed, whether for investigation or for display, yet as regards the particular objects just alluded to it is a no less necessary part of the instrument than the achromatic objective itself.

As a typical example of the simplest form of compound microscope that is suitable for scientific research,—which, with various modifications of detail, is the one generally employed on the Continent,—the *Microscope de dissection et d'observation* (fig. 28) of M. Nachet, especially as constructed for portability (figs. 29–31), seems particularly worthy of description. In its vertical form (fig. 28) the solid foot to which the mirror is pivoted gives support to the pillar F, to the top of which the stage P, having a diaphragm-plate beneath it, is firmly attached. On the top of this pillar the tubular stem A is fitted in such a manner that it may be removed by unscrewing the large milled head L,—though, when this is well screwed down, the stem stands quite firmly. This stem bears at its summit a short horizontal arm, which carries a strong vertical tube that firmly grasps the "body" of the microscope, while permitting this to be easily slid upwards or downwards, so as to make a "coarse adjustment" of the focus. The "fine adjustment" is made by turning the milled head V, which either presses down the outer tube of the stem, or allows it to be raised by the upward pressure of a strong spiral spring in its interior. By unscrewing the milled head L, the stem A with its arm and compound body can be detached from the pillar; and, a small light arm H holding either single lenses or doublets being slid into this, a convenient dissecting microscope is thus provided. The only drawback in the construction of this simple model is its not being provided with a joint for

[1] A camera lucida adapted for use with the vertical microscope has been devised by M. Nachet.

the inclination of the body; but this is introduced into the portable form of the instrument shown in fig. 29, the basal portion of which (fig. 30) can be used, like that of the preceding model, as a simple microscope, and, by a most ingenious construction, can be so folded as to lie flat in a shallow case (fig. 31) that holds also the upper part with the objectives of both the simple arm and the com-

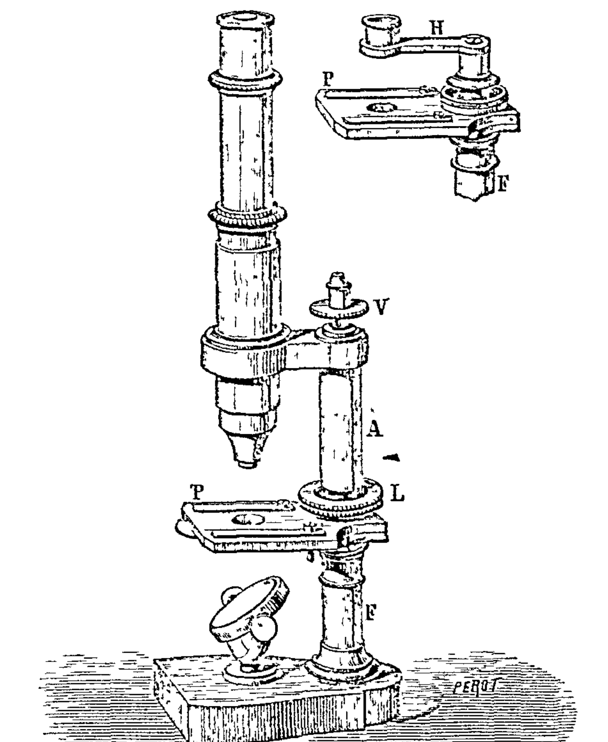

Fig. 28.—Nachet's Combined Simple and Compound Microscope.

pound body. M. Nachet now connects his objectives with the body of his microscopes, not by a screw, but by a cylindrical fitting held in place by the pressure of a spring-clip against a projecting shoulder. This method not only allows one objective to be removed and replaced by another much more readily than does the screw-fitting, but also renders the centring of different objectives more exactly conformable. It may be safely affirmed that a very large proportion of the microscopic work of the last half-century, which has given an entirely new aspect to biological science, has been done by instruments of this simple Continental type.

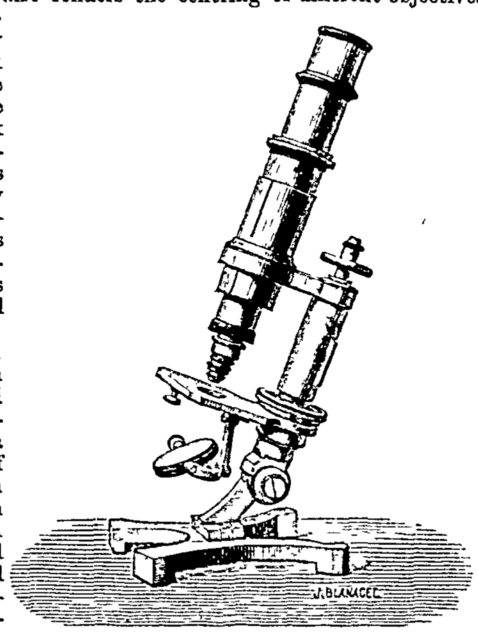

Fig. 29.—Nachet's Portable Compound Microscope.

A larger model, however, was from the first adopted by English opticians; and, as a typical example of the general plan of construction now most followed both in England and in the United States, the improved Jackson-Zentmayer microscope of Messrs Ross (fig. 32) may be appropriately selected. The tripod base of this instrument carries two pillars, between which is swung upon a horizontal axis (capable of being fixed in any position by a tightening screw) a solid "limb," with which all the other parts of the instrument are connected,—a plan of construction originally devised by Mr George Jackson. The binocular body, having at its lower end (as in fig. 24) an opening into which either of the Wenham prisms can be inserted, and at its top a rack movement for adjusting the eye-pieces to the distance between the eyes of the observer, is attached to a racked slide, which is so acted on by the large double milled

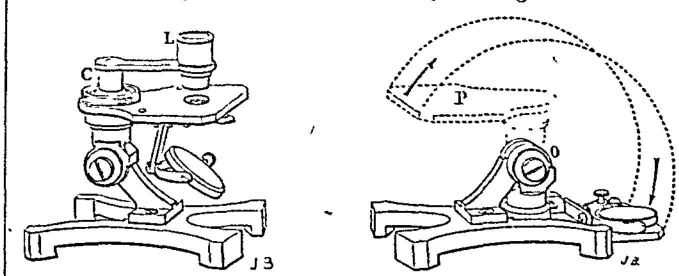

Fig. 30.—Nachet's Portable Dissecting Microscope; on the left as set up for use, on the right as having the stage P turned back upon the joint O, so as to lie flat on the bottom of the case.

head in the upper part of the limb as to give a "quick" upward or downward motion to the body; while the "slow" motion, or fine

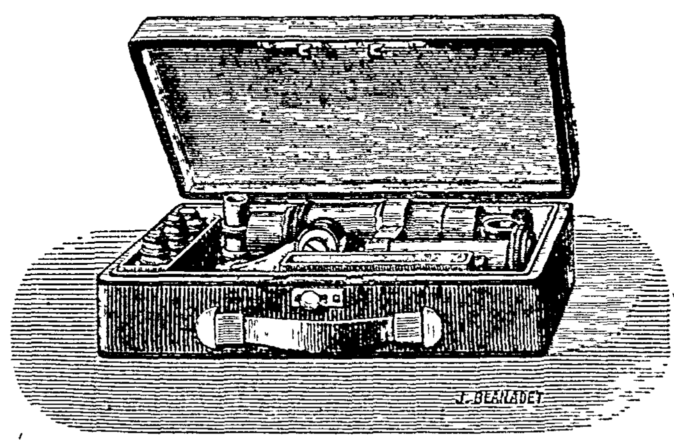

Fig. 31.—Nachet's Portable Compound and Dissecting Microscope, as packed in case.

adjustment, is given by means of the vertical micrometer screw at the back of the limb, which raises or lowers a second slide behind the rack.[1] The stage is supported upon a firm ring, which is immovably fixed, not to the limb, but to a strong conical pivot which passes through the limb, to be clamped by a screw-nut at its back,—the purpose of this being to allow the whole stage to be inclined to one side or the other at any angle, so that a solid object may be viewed sideways or from below, as well as from above. Upon this ring the stage rotates horizontally, its angular movement being measured by a graduated scale and vernier at its edge; and it can be fixed in any azimuth by a clamping-screw beneath. Rectangular movement is given to the traversing platform which carries the object by two milled heads on the right of the stage, the whole construction of which is adapted to allow light of extreme obliquity to be thrown upon the object from beneath. On the strong pivot by which the stage is

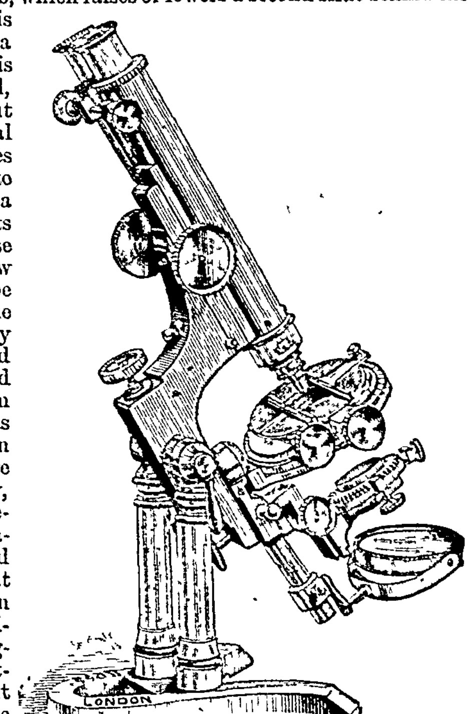

Fig. 32.—Ross's Jackson-Zentmayer Compound Microscope.

[1] In the older form of construction still retained by some makers the fine adjustment acts directly on the objective, the fitting of which is made to slide up and down within the nose of the body; but this plan is attended with many disadvantages.

attached to the limb (the axis of which passes through the point at which the object-plane is intersected by the optic axis of the body) is hung the swinging tail-piece invented by Mr Zentmayer of Philadelphia, which, carrying the whole illuminating apparatus, may be so set as to give to the axis of the illuminating pencil any required degree of obliquity. To the upper part of it is attached a rack-and-pinion movement carrying the "substage," which is provided with two milled-headed screws for centring it precisely with the microscope-body. Into this may be fitted the achromatic condenser, parabolic illuminator, polarizing prism, or any other kind of illuminating apparatus; whilst at its lower end it carries the mirror, the position of which may be varied by sliding its fitting up or down the "tail-piece," or by turning the arm which carries it to one side or the other; while, if direct illumination from a lamp should be preferred, it may be turned altogether aside. By swinging the tail-piece round above the stage, oblique light may be reflected from the mirror, through the condenser, upon the upper surfaces of objects. The condenser usually fitted to this instrument is of about $\frac{4}{10}$ inch focus, with a large back lens; behind which are placed an iris-diaphragm for reducing the light to the central rays, and a diaphragm-plate with apertures of the various forms most suited for the resolution of lined objects by oblique rays.

No instrument, in the writer's judgment, is better adapted than this for the highest purposes of microscopical research. It works admirably with every power from the lowest to the highest, and is capable of receiving any one of the numerous pieces of apparatus which have been devised for special researches of various kinds. The detailed description of these not being here admissible, it will be sufficient to indicate the polariscope and the spectroscope as the most important of these accessories.

Micrometry.

The microscopist has constant need of some means of taking exact measurements of the dimensions of the minute objects, or parts of objects, on the study of which he is engaged; and the accuracy of the operation will of course be proportioned to the correctness of the standard used, and the care with which it is applied.

The instruments employed in microscopic micrometry are of two kinds, the measurement being taken in one by the rotation of a fine screw with a divided milled head, whilst in the other a slip of glass ruled with lines at fixed distances gives a scale which forms a basis of computation. Each of these has its advantages and its disadvantages.

The stage-micrometer constructed by Frauenhofer was formerly much used by Continental microscopists, and has the advantage of indicating the actual dimensions of the objects to be measured; but it has the two special disadvantages that a sufficiently small value cannot be conveniently given to its divisions, and that any error in its construction and working is augmented by the whole magnifying power employed. This instrument has now, however, almost entirely given place to one of those to be next described.

The screw-micrometer ordinarily used in astronomical measurements (see Micrometer) can be adapted to the eye-piece of the microscope in a manner essentially the same as that in which it is applied to the telescope,—its two parallel threads—of which one is fixed and the other made to approach towards or recede from this by the turning of the screw—being placed in the focus of the eye-glass, and being therefore seen as lines crossing its field of view. The object is so focussed that its image is formed in the same plane; and, the latter being brought into such a position that one of its ends or margins lies in optical contact with the fixed line, the screw is turned so as to bring the movable line into the like coincidence with the other. But the distance between the lines, as given by the number of divisions of the micrometer, will here be the measurement, not of the object itself, but of its magnified image; and the value of these divisions, therefore, will depend upon the amplification given by the particular objective used. Thus, suppose each division of the micrometer to have an actual value of $\frac{1}{10000}$th of an inch, and the visual image to have one hundred times the linear dimensions of the object, the theoretical micrometric value of each division would be $\frac{1}{100}$th of $\frac{1}{10000}$th, or one-millionth, of an inch,—a degree of minuteness, however, not practically attainable. It is necessary, moreover, to determine the micrometric value of the divisions of the micrometer, not only for every objective, but for variations in the conditions under which that objective may be employed, as regards the length of the tube or "body" of the microscope, which is varied not only by the draw-tube, but also, in many cases, in the working of the fine adjustment or slow motion, and also, in the case of the large-angled powers furnished with adjustment for thickness of the covering-glass, for the degree of separation of the front- from the back-glasses of the objective, which makes a very sensible difference in its magnifying power. This determination is made by means of a divided glass stage-micrometer put in the place of the object, so that the lines ruled upon it at fixed intervals shall be projected upon the field of view. The stage-micrometer is usually ruled either to 1000ths of an inch or 100ths of a millimetre; and it is convenient that one of the divisions of its image should be made to coincide exactly with a certain number of divisions of the screw-micrometer. This may be done by lengthening the draw-tube, so as to increase the amplification of the scale until coincidence has been reached; and the exact amount of this lengthening should be noted,—as should also the precise position of the milled head of the slow motion (if it acts on the objective, instead of on the body as a whole), and of the adjusting screw-collar of the objective itself. Thus, if two lines of the stage-micrometer separated by 1000th of an inch be brought into coincidence with the two threads of the eye-piece micrometer, separated by forty divisions of the screw milled head, the value of each of those divisions is $\frac{1}{40000}$th of an inch. If the above conditions be precisely recorded for each objective used in micrometry, the micrometric value of the divisions remains the same for that objective, whenever it is employed under the same conditions.

The errors to which micrometers are subject arise (1) from inequalities in the ruling of the stage-micrometer, (2) from irregularities in the screw of the eye-piece micrometer, (3) from "lost time" in its working, and (4) from the thickness of its threads. In order to eliminate the first and second, it is well to determine the relation of the divisions of the two micrometers by the comparison of a considerable number of both; the third proceeds from an imperfection of workmanship which, if it shows itself sensibly, entirely destroys the value of the instrument, while the fourth can be rectified by the exercise of skill and judgment on the part of the observer. For, if the micrometer is so constructed as to read zero when one thread lies exactly upon the other, its divisions indicate the distance between the axes of these threads when separated; and the dimensions of any object (such as a blood-corpuscle) lying between their borders will obviously be too great by half the thickness of the two threads, that is, by the entire thickness of one thread. When, on the other hand, the measurement is being made (as of the distances of the striæ on diatoms) by the coincidence between certain lines on the object and the axes of the threads of the micrometer, the dimensions indicated by the divisions of the screw milled-head will be correct.

The costliness of a well-constructed screw-micrometer being a formidable obstacle to its general use, a simpler method (devised by Mr George Jackson) is more commonly adopted, which consists in the insertion of a ruled-glass scale into the focus of an ordinary Huygenian eye-piece, so that its lines are projected on the field of view. This scale (ruled, like an ordinary measure, with every fifth line long, and every tenth line double the length of the fifth) is fixed in a brass inner frame, that has a slight motion in the direction of its length within an outer frame; and this last, being introduced through a pair of slits into the eye-piece just above the diaphragm, and being made to occupy the centre of the field, is brought exactly into focus by unscrewing the eye-glass as far as may be requisite. When the image of the object to be measured is brought by the focal adjustment of the object-glass into the same plane, a small pushing-screw at the end of the micrometer (whose action is antagonized by a spring at the other end) is turned until one of the long divisions of the scale is brought into optical contact with one edge of the image of the object to be measured, and the number of divisions is then counted to its other edge,—the operation being exactly that of laying a rule across the real object if enlarged to the size of its image. The micrometric value of each division of this eye-piece scale must be carefully ascertained for each objective, as in the case of the screw-micrometer, the error arising from inequality of its divisions being eliminated as far as possible by taking an average of several. The principal point of inferiority in this form of micrometer is that, as its divisions cannot be made of nearly so small a value as those of the screw-micrometer, an estimate of fractional parts of them often becomes necessary, which is objectionable as involving an additional source of error. To meet this objection, Hartnack has introduced the diagonal scale used in mathematical instruments before the invention of the vernier.

Another mode of making micrometric measurements, which for some purposes has considerable advantages, is to employ a stage-micrometer in combination with some form of camera lucida attached to the eye-piece of the microscope, so that the image of its divisions may be projected upon the same surface as that on which the image of the object is thrown. By first using the ruled stage-micrometer, and marking on the paper the average distance of its lines as seen in the central part of the field, and then ruling the paper accordingly, the micrometric value of the divisions so projected may be exactly determined for the objective employed and the distance of the drawing-plane from the eye-piece,—so that, when the image of any object is projected under the same conditions, the dimensions of that image or of any parts of it can be exactly measured upon the divided scale previously projected, and the true dimensions of the object thus easily ascertained. If, for example, the lines of a stage-micrometer ruled to the thousandth of an inch should, when thus projected, fall at a distance of an inch apart, then the application of an ordinary scale of inches (divided into tenths) to the image of an object projected by the same objective

and on the same plane would give its real dimensions in thousandths of an inch, while the tenths of the inch scale would represent a real dimension of as many ten-thousandths. It is often desirable to make such measurements from careful tracings of the outlines of objects, rather than from the visual images,—this plan being especially advantageous when the exact dimensions of many similar objects have to be compared, as in the case of blood-corpuscles, precise measurements of which are not unfrequently required in judicial inquiries. It was by the use of this method that the late Mr Gulliver made his admirable series of measurements of the average and extreme dimensions of the blood-corpuscles of different animals. And more recently Mr Dallinger has shown,—by first making a very fine camera lucida tracing of *Bacterium termo* under an amplification of 2000 diameters, and measuring the breadth of its body in the mode above indicated (which gave it as $\frac{1}{20400}$th of an inch), and then by magnifying his tracing from five to ten diameters, and comparing, by means of the screw-micrometer, the breadth of the flagellum with that of the body (which last proved to be just ten times as great),—that, although the theoretical limit of resolving power for closely approximated lines is $\frac{1}{140523}$th of an inch, a semitransparent filament whose breadth is not greater than $\frac{1}{200000}$th of an inch may be clearly discerned, and even measured with a close approximation to accuracy (*Jour. of Royal Micros. Society*, vol. i., 1879, p, 169). (W. B. C.)

MIDAS, king of Phrygia, is one of those half-legendary heroes in whom religious legends have gathered round a real person. The name Midas the king, ΜΙΔΑΙ ϜΑΝΑΚΤΕΙ, occurs on a very ancient tomb in the valley of the Sangarius, the legendary seat of the Phrygian kingdom (*Iliad* iii. 189). The Phrygian monarchy was destroyed by the Cimmerians about 670 B.C., and the last king Midas committed suicide by drinking bull's blood. The name Midas became in Greek tradition the representative of this ancient dynasty, but all that is told of him is religious myth. He is a figure in the cycle of Cybele legends, the son of the goddess and her first priest. He is also closely connected with the cultus of Dionysus, like the two heroic personages Marsyas and Silenus. The Midas legend was known on Mount Bermius in Macedonia, and must at one time have existed in Greece; two cities Midea, in Argolis and in Bœotia, recall the Phrygian city Midæium.

See Herod. viii. 138; Xen., *Anab.*, i. 2, 13; Paus. i. 45, &c.

MIDDELBURG, in Holland, the ancient capital of the province of Zealand, situated in the middle of the island of Walcheren, is mentioned as early as 1153, and receives the title "town" in a charter granted it in 1227. It has all the characteristics of an old and worn-out place. The population (25,000 in 1739) had sunk to 12,000 or 13,000 by the beginning of the 19th century, and has only begun recently to increase again, being 15,939 in 1882. The dwelling-houses, which in 1739 were about 3800, are now but 3000, and of these about 600 are unoccupied. The vast warehouses and imposing mansions once belonging to wealthy families, which have either died out or left the place, call up the memory of that prosperity which Middelburg enjoyed before its extensive trade, with the East and West Indies, with England and Flanders, was ruined by the war with England and the French occupation. By the opening of the railway (1872) and of the ship canal (1873) to Flushing Middelburg was lifted out of its isolation, and, with the assistance of the chamber of commerce, manufacturing industries (iron, machinery, furniture, oil, cigars, &c.) were established; but the prosperity anticipated for Flushing, and consequently for Middelburg, remains unrealized. One of the chief sights of Middelburg is the splendid town-house, for the most part erected in 1512–13, with its front gable adorned with twenty-five statues of counts and countesses of Holland and Zealand; it contains the archives, and a most valuable antiquarian and historical collection. The abbey, begun in 1150, has frequently been the residence of royal visitors (Maximilian, Philip the Fair, Charles V., and so on down to Napoleon I., and William I., II., and III.); part of it is now an hotel, and part of it is occupied by the provincial authorities. The great hall of the building, in which the states of Zealand assemble, is adorned with beautiful tapestries by Jan de Maecht, representing the heroic feats of the men of Zealand in the contest with Spain. What was formerly the nave of the abbey church is now the New Church, and the ancient choir constitutes the Choir Church. The former contains a fine pulpit resting on an eagle, the monument of William, king of the Romans (d. 1256), and the tombs of Jan and Cornelis Evertsen, two naval heroes who fell in the war against England in 1666; the latter has the monuments of the learned Hadrian Junius and of Jan Pieterszoon. The provincial court, the corn exchange, the Hof St Joris and the Hof St Sebastian (formerly buildings belonging to the guilds of archers, and now places of amusement) deserve mention. The great museum of Zealand antiquities, collected by the Zealand Society of Arts and Sciences (founded at Flushing in 1769 and transferred to Middelburg in 1801), shows that the town is the intellectual centre of the province.

The principal facts in the history of Middelburg are the sieges by the Flemings in 1288, 1296, and 1303 (the last resulting in the capture of the town by Guy of Dampierre); the recovery of the town from the Spaniards in 1574, after an investment of nearly two years; the frequent disturbances among the townsfolk in the 17th and 18th centuries; the surrender to the English in 1809; and the arrival and departure of the French in 1809 and 1814.

MIDDLEBOROUGH, a town of the United States, in Plymouth county, Massachusetts, 34 miles south of Boston. It has a handsome town-hall and a public library, manufactures woollen goods, straw goods, shovels, shoes, carriages, &c., and in 1880 had 5237 inhabitants.

MIDDLESBROUGH, situated near the mouth of the Tees, on its south bank, in the North Riding of Yorkshire, has now become the principal seat of the English iron trade. It is a municipal and parliamentary borough, locally governed by a mayor and corporation, and returns a member to parliament. The earlier history of the place is meagre. Where Middlesbrough now stands (Graves's *History of Cleveland*) there were at one time a small chapel and priory founded by Robert de Brus of Skelton Castle. These were dedicated to St Hilda, and with some lands were given by De Brus to the abbey of St Hilda at Whitby in 1130. The priory fell into ruins at the time of the Reformation, and no trace now remains beyond some stones built into the wall of a brewery. The mayor's chair also is made from a fragment. In 1801 there were upon the site of Middlesbrough only four farm-houses. In 1829 a company styling itself the Middlesbrough Owners bought 500 acres of land, and commenced building the town. In 1830 the Stockton and Darlington Railway was extended from Stockton to Middlesbrough; four years later the town was lighted with gas; and after six years more a public market was established. The census of 1831 showed the population to be 154; that of 1841 showed 5709. In 1842 the opening of the docks gave additional importance to the town. First containing an area of 9 acres, they were extended in 1872 to 12 acres, with 1700 feet of quays. Vessels of 3000 tons burden can be accommodated. From the year 1851, when J. Vaughan discovered the presence of ironstone in the Eston Hills, the town advanced with rapid strides. When the jubilee of the town was held in 1881 (a year late) the population had risen to 55,934, the area to 2731 acres, and the rateable value to £140,000, the population of the parliamentary borough (area 4715 acres) being 72,145. In the district there are upwards of

130 blast furnaces, besides large iron and steel works; and the Thomas-Gilchrist process of making steel promises for Middlesbrough importance in the future as a steel entrepôt. The make of pig-iron in 1880 was 1,991,032 tons. There are also shipbuilding, potteries, chemical works, and a salt trade. Middlesbrough is well laid out, nearly all the streets lying at right angles to one another. Many of the churches and the exchange are handsome buildings, while the station of the North Eastern Railway is probably the finest in the north of England. A splendid park of 72 acres, the gift of the late H. F. W. Bolckow, adds greatly to the amenity of the town.

Plate III. MIDDLESEX, an inland county in the south-east of England, lying between 51° 25′ and 51° 40′ N. lat., and between 0° and 0° 36′ W. long. On the south it is divided from Surrey and Kent by the Thames, on the east from Essex by the Lea, on the west from Buckinghamshire by the Colne, and on the north from Hertfordshire by a partly artificial and very irregular line. Although with the exception of Rutland it is the smallest county in England, its population is exceeded by that of Lancashire only. Its total area is 181,317 acres, of which 2592 acres are common or waste lands. The longest straight line that can be drawn in the county is one of nearly 28 miles from the north-eastern extremity near Waltham Abbey to the south-western at Staines. From north to south in the broadest part the distance is about 15 miles.

Surface and Geology.—The greater portion of the county is flat, although there are sufficient undulations to allow of a proper drainage of the land. A range of hills runs along the Hertfordshire border by Barnet, Elstree, Stanmore, and Pinner, averaging 100 feet in height; another range occupies the ground just north of London by Hornsey, Highgate, and Hampstead; Harrow occupies an isolated eminence between the two ranges.

The county lies entirely within the basin of the Thames, and the London Clay extends over a large portion of the surface. This formation stretches from the mouth of the estuary of the Thames to the neighbourhood of Marlborough. It attains its greatest breadth (little short of 30 miles) in the neighbourhood of London, and extends northward until it is lost beneath the drift of Suffolk and Norfolk. The following is a table of the various beds of rock which occur at the surface, with their greatest thickness (in feet) in the district:—

Alluvium (recent river deposits)	15
Post-Pliocene Tertiaries.	
Post-glacial beds (brick-earth, gravel, &c.)	50
Glacial drift (boulder clay, gravel, &c.)	80
Eocene Tertiaries.	
Lower Bagshot sands	100
London Clay	420
Woolwich and Reading beds	90
Cretaceous.	
Chalk with flints	800

Chalk comes to the surface in so very few places that it is scarcely worth mention. It is seen near Harefield and on the north-west side of South Mimms. The depth from the surface to the chalk varies greatly in different parts of the county. This has been proved by the borings for wells; thus at Isleworth the depth is 400 feet and at Hampstead 378, while at Ruislip it is 76 feet and at Pinner only 60. The Reading beds (plastic clays) are brought to the surface at Windsor. They follow roughly the course of the river Colne from the north of Uxbridge along the flank of the hills north-eastward, but are sometimes cut back southward along small side valleys. An outlying mass is exposed at Pinner. The Bagshot sands, consisting of gravel and sand permeable to water, once stretched over the whole extent of the London Clay, but they are now to be found only on the high grounds at Hampstead, Highgate, and Harrow. A corner of the main mass enters the south-west corner of the county near Littleton. Beds of brick-earth occur in the drift between West Drayton and Uxbridge.

Several deep borings in the London basin prove the existence beneath the chalk of beds which do not crop out in Middlesex. Three of these are in the county; and the most interesting is that at Meux's Brewery, Tottenham Court Road (about 1146 feet), which passes through the following formations:—gravel and clay, 21 feet; London Clay, 64 feet; Reading beds, 51 feet; Thanet sand, 21 feet; chalk, 655 feet; Upper Greensand, 28 feet; gault, 160 feet; Lower Greensand, 64 feet; Devonian, 80 feet.

Rivers and Canals.—The Thames is very tortuous in the 44 miles of its course from Staines to Blackwall, and makes a remarkable bend at the eastern limit of the county where it forms the so-called Isle of Dogs. The width at Staines is 200 feet, at Chiswick opposite Barnes 340 feet, at Hammersmith 525 feet, at Fulham 820 feet, at Westminster Bridge 1100 feet, but at London Bridge it is less than 800 feet; above the junction of the Lea at the Isle of Dogs the width is 1350 feet. The ordinary rise of the tide at London Bridge is 16 feet, and the tide-way ends at Teddington. The port of London begins below London Bridge, and the channel for from 2 to 3 miles is called the Pool.

The Colne from Hertfordshire enters Middlesex at the north-western corner of the county. It then runs south, joining the Thames at Staines, and in its course divides Middlesex from Buckinghamshire for 15 miles. After the river leaves Uxbridge it divides out into several small channels. The Lea from Hertfordshire enters Middlesex at the north-eastern corner of the county near Waltham Abbey. It runs south, dividing Middlesex from Essex for 15 miles, and falls into the Thames at Bow Creek. Several branches flow off from the river during its course. The Brent from Hertfordshire enters Middlesex near Finchley. It takes a circuitous direction southward through the middle of the county by Hendon, Kingsbury, Twyford, Greenford, and Hanwell to the town of Brentford, where it unites with the Thames. Where the river crosses the Edgeware Road (about 3 miles south of the town of Edgeware) it is expanded by artificial means into an extensive reservoir. The Cran (or Yedding Brook) rises in the district between Harrow and Pinner and flows under Cranford Bridge; it crosses Hounslow Heath, and bends round to Twickenham and Isleworth, where in a divided stream it falls into the Thames.

There were several other small streams in the neighbourhood of London which have left their mark in the names of places, but which are now merely sewers, such as the Wallbrook, the Westbourn, the Tyburn, the Fleet river, &c. The last-mentioned, which runs into the Thames near Blackfriars Bridge, was formerly navigable as far as Holborn Bridge; but, the Fleet Ditch, as it was then called, having become in the last century a dangerous nuisance, the lord mayor and citizens were empowered by Act of Parliament to arch it over. The work was commenced in 1734, and in 1737 Fleet market, occupying the site of the space from Holborn Bridge to Fleet Bridge, was opened to the public. The New River, an artificial water-course constructed by Sir Hugh Myddelton in the reign of James I. to supply London with water, runs through the county from north to south a little to the west of the river Lea. It derives its waters from the springs of Amwell and Chadwell, increased by a cut from the Lea, in the neighbourhood of Ware, and enters Middlesex from Hertfordshire about 2 miles north of Enfield. It passes Enfield, Tottenham, Hornsey, and Stoke Newington, and is received into the reservoir in Clerkenwell known as the New River Head.

The Grand Junction Canal leaves the Thames at Brent-

ford, proceeds in a westerly direction by way of Hanwell and Cranford to West Drayton; thence in a northerly direction it follows the valley of the Colne. It passes Uxbridge, and after leaving the county takes its further course by Rickmansworth through Hertfordshire. The Paddington Canal leaves the Grand Junction Canal at Cranford, and passes Northolt, Apperton, Twyford (where it is carried over the Brent by an aqueduct), and Kensal Green. At Paddington it joins the Regent's Canal, which passes the north of Regent's Park, and after proceeding through the eastern portions of London joins the Thames at Limehouse. The Regent's Canal is joined to the river Lea by means of Sir George Duckett's Canal, and thus there is a through communication from the north-eastern corner of the county to the south-eastern corner, thence from east to west, and northward to the north-west corner.

Climate, Soil, Agriculture, &c.—The climate of the county is equable and good, and the shelter of the northern hills makes the air mild. Highgate, Hampstead, and some other parts are supposed to be specially healthy, and are recommended for invalids by the medical profession.

The heavy poor clay in the north and north-western portion of Middlesex is chiefly covered with permanent grass. In some parts it has been made fit for arable cultivation by the addition of chalk, lime, and ashes. The rich deposits from the Thames have formed a soil which when well manured is specially suitable for market gardens. From its nearness to London the district has long been famous for high farming, and the divisions devoted to different kinds of farming are well marked. The greater part of Gore and Ossulston hundreds, portions of Spelthorne and Edmonton hundreds, and a strip down the western side of Elthorne hundred are devoted to meadow and pasture. The arable land is chiefly found on the western side, and between the Great Western Railway and the Thames. It is also to be seen in the north-western district. With the constant increase of London, houses have encroached upon the fields, and most of the market gardens which were situated in the neighbourhood of Islington and Hackney have disappeared. The strip of land by the Thames from Brentford to Chelsea was given up almost entirely to market gardens, but Fulham is fast being built over.

According to the returns for 1882, the area occupied by grain and green crops, grass, &c., was 116,470 acres. Of this amount, 16,337 acres were under corn crops (wheat, 6410; barley, 3083; oats, 3895; and beans and pease, 2636); 13,451 under green crops (including potatoes, 3019; turnips, 1539; mangolds, 1692; cabbage, &c., 1188); 3025 under clover and grasses sown in rotation; and 82,782 under permanent pasture. Orchards occupied 3419 acres; market gardens, 6900; nursery grounds, 447; and woods, 2382. In the same year the horses numbered 5939 (4188 used for agricultural purposes); cattle, 23,283 (cows, 15,390); sheep, 23,916; and pigs, 12,035.

The following were the landowners in the county (exclusive of London) at the time of the Domesday survey:—the king, the archbishop of Canterbury, the bishop and canons of London, the abbeys of Westminster and Holy Trinity at Caen, the nunnery of Barking, the Earls Roger and Morton, Geoffrey de Mannevele, Ernulf de Hesding, Walter Fitz Other, Walter de St Walery, Richard Fitz Gilbert, Robert Gernon, Robert Fafiton, Robert Fitz Roselin, Robert Blund, Roger de Rames, William Fitz Ansculf, Edmund de Salisbury, Aubrey de Vere, Ranulf Fitz Ilger, Derman, Countess Judith, and the king's almoners.

In 1873, according to the *Return of Owners of Land*, the total number of owners in the county (also exclusive of London) was 11,881, of whom 9006 owned less than an acre. The extent of lands (including common or waste lands) is given as 145,605. The gross estimated rental was £1,611,655. Sixteen owners each possessed over 1000 acres. The crown owned 2382 acres (annual value £5503); the duchy of Lancaster, 2273 acres (£4492); Ecclesiastical Commissioners, 1308 acres (£46,519); All Souls' College, Oxford, 1813 acres (£4724); Christ Church, Oxford, 1132 acres (£1635); and King's College, Cambridge, 1097 (£1084).

Many villages of Middlesex, especially those near to London, were formerly famous for their mineral springs. Some places are still supplied with water from wells; but the Barnet, the East Middlesex, the Grand Junction, the West Middlesex, and the New River Water Companies serve a large part of the county.

Manufactures and Trade.—There is little to remark with regard to the manufactures of the county outside of London. Brick-making and tile-making have always flourished, and malting, distilling, and soap-making are favourite industries. Gunpowder mills exist at Twickenham and Bedfont. The market-towns for corn are Uxbridge, Brentford, and Staines, for cattle and sheep Southall. A horse and cattle fair is held at South Mimms and Barnet.

Railways and Roads.—As London is the centre of the railway system of England, it is evident that many of the lines must run through Middlesex. For similar reasons it is well provided with roads.

Population.—The total population of Middlesex was 2,539,765 in 1871 and 2,920,485 in 1881, or excluding the seven metropolitan boroughs lying within the county 276,028 in 1871 and 394,089 in 1881. Most of the towns and villages have largely increased during the period between 1871 and 1881; the populations of Acton and Tottenham have more than doubled, and Chiswick, Ealing, Edmonton, and Willesden have almost doubled. Of the larger places the least increase has been at Brentford, which numbered 10,271 in 1871, and reached 11,808 in 1881. At the time of the Domesday survey the population of Middlesex, exclusive of London, was 2302.

Government.—Unlike other counties, Middlesex has no high sheriff appointed by the sovereign. It is subject to the City of London, and one of the sheriffs appointed by the lord mayor is sheriff for Middlesex. When Henry I. came to the throne he gave the city an extensive charter, and one of the privileges either granted or confirmed by the king was the perpetual sheriffwick of Middlesex.

The whole of the county is included in the diocese of London, and is divided between the archdeaconries of London and Middlesex. When Henry VIII. created the bishopric of Westminster he allotted the whole county (the parish of Fulham alone excepted) for its diocese. Edward VI., however, dissolved the bishopric in the fourth year of his reign.

The county is divided into six hundreds, which remain the same as they were at the time of the Domesday survey, except that the name of one has been changed:—Ossulston (Osulvestane D.), Edmonton (Delmetone D.), Gore (Gara D.), Elthorne (Heletorne or Helethorne D.), Spelthorne (Speletorne or Spelethorne D.), Isleworth (Honeslaw D., *i.e.*, Hounslow). The division into hundreds is now merely a name, and a record of a former system of local government.

There are thirty-two poor-law unions, but the unions beyond London are only eight in number, viz., Brentford, Edmonton, Fulham, Hackney, Hampstead, Hendon, Staines, Uxbridge.

The majority of hospitals are in London, but there is a training hospital at Tottenham, St John's Hospital at Twickenham, and cottage hospitals at Enfield, Ealing, Hayes, Hillingdon, Sudbury, and Teddington. The Royal India Lunatic Asylum is at Ealing, and the two county asylums at Colney Hatch and Hanwell.

The county is within the jurisdiction of the central criminal court and also of the metropolitan police (with the exception of the City).

Parliamentary Representation.—There are nine constituencies in Middlesex, returning nineteen members, viz., two for the county, four for the City of London, two for each of the boroughs of Westminster, Finsbury, Marylebone, the Tower Hamlets, Chelsea, and Hackney, with one for the university of London.

In the parliament of 1295 Middlesex was represented by two members; in 1298 London sent two members as well as the county. For the parliament of 1320 and subsequent parliaments London elected four members, but it does not appear that all were allowed to sit. From the 15th century, however, the city has always sent four members to parliament. In 1547 Westminster first sent her two members, and from that time until 1832 the only seats were those for the county and the two boroughs. In 1832 the boroughs of Finsbury, Marylebone, and Tower Hamlets were added, and in 1866 the boroughs of Chelsea and Hackney and the university of London.

History.—The district now included in Middlesex was largely occupied by forest up to a comparatively recent period, and its population must always have been very sparse. A few prehistoric remains have been discovered at various times,—bones of the elephant, hippopotamus, deer, &c., at Old Brentford, elk horns near Chelsea Hospital, fossil teeth, fish, fruit, &c., at Highgate, and quite recently, in 1879, while the foundations were being dug out for Drummond's New Bank at Charing Cross, a large number of prehistoric animal remains. Flint instruments have also been found to cover a considerable area. During the British period the district is supposed to have been inhabited by the Trinobantes, but

the late Dr Guest affirms that the valley of the Lea was the western boundary of that tribe. In answer to the question—What became of the district between the Lea and the Brent? this great authority states that the district was merely a march of the "Catuvellauni," a common through which ran a wide trackway, but in which was neither town, village, nor inhabited house. Dr Guest also declares that the boundaries of the Catuvellaunian state, a central kingdom formed or much extended by Cassivellaunus, can be traced in part along the northern limit of Middlesex by following an earthwork called Grimesditch "from Brockley Hill to the woodland of the Colne Valley and thence to the Brent, and down the Brent to the Thames."[1] Some earthworks and encampments still exist which are attributed to the Britons.

When the country was under Roman rule great improvements, due to the growing importance of Londinium, were made in this district. Several roads in connexion with the city must have been constructed, more especially the great northern and eastern roads. Dr Guest does not believe that the present Watling Street could have had any connexion with the Watling Street which came down the Edgeware Road, passed along by Park Lane, and crossed the Thames at Westminster. In the Antonine Itinerary mention is made of three stations, viz., Londinium, Sulloniacæ, and Pontes. Sulloniacæ is now Brockley Hill; Pontes is supposed by Stukeley to mean Staines, but Horsley held that it was intended for Old Windsor, and others supported the claims of Colnbrook and Longford. Roman camps have been found in many parts of the county, and Dr Stukeley supposed that the Brill, near St Pancras, was the site of the battle between Boadicea and the Roman legions which has left a slight record in the name of Battle Bridge. The Roman remains found at different times are too numerous to mention here in detail. Coins, urns, and tiles were found at Enfield, a sepulchral urn at Hampstead, and numerous gold coins and ornaments at Bentley Priory, Great Stanmore, in 1781.

Cowey Stakes, about a furlong west of Walton Bridge, is supposed to be the locality of the ford by which Julius Cæsar crossed the Thames. Cæsar makes special mention of the sharp stakes which he had to encounter, and Bede says that the remains of the stakes were to be seen in his day. Camden was the first to fix upon this as the spot where Cæsar crossed, and he is supported by Dr Guest, but the identification is not undisputed. Although a ford existed here as late as 1807, and stakes were found up to the end of the 18th century, it has been affirmed that they were placed in their position with another object than to oppose an enemy's progress. Roman remains have been found at Shepperton near Halliford, at the Middlesex end of the ford. A vase was dug up in 1817, and the remains of a Roman cemetery have also been discovered.

As to the earliest Saxon occupation we are left very much to conjecture, and the name itself is somewhat of a puzzle. It is evident that no tribe could have obtained the name of Middle Saxons until after the settlement of the districts on each side of it by the East and the West Saxons. As Middlesex was for a period dependent upon the kingdom of Essex, it is probable that the name did not come into use until London had become a Saxon city, although there is reason to believe that previously Saxon settlements had been made on several places by the river and elsewhere. Bede tells us that London was in the hands of King Sæberct in 604, and was then the chief town of Essex. Just a century afterwards—that is, in 704—the king of the East Saxons granted away land at Twickenham, showing that Middlesex was then dependent upon Essex. It is worthy of note that the two districts now forming the counties in which London and Southwark are situated were separated from the kingdoms to which they originally belonged probably on account of the importance of the city of London and the borough of Southwark, Middlesex from the kingdom of Essex and Surrey or the South Ridge (A.-S. Suð-rige) from the kingdom of Kent.

Middlesex appears never to have been independent. The administrative shire was let to the men of London and their heirs to be held in farm of the king and his heirs, and "the subject shire has to submit to the authority of the sheriffs chosen by the ruling city."[2]

Middlesex is only once mentioned in the Saxon Chronicle, under date 1011, where it is noticed as one of the districts overrun by the Danes. One manuscript (A. Winchester) mentions the Middle Saxons as receiving the true faith under their alderman Peada in 653; but this is evidently a mistake of the scribe, for the fact is taken from Bede, and he writes Middle Angles, as do the other MSS. of the Chronicle.[3]

The Saxons appear to have settled over a large portion of the district, and for the purpose of settlement they must have made considerable clearings in the vast forest of Middlesex. There seems to be good reason for believing that previous to their coming the roads passed through waste lands. By the time of Edward the Confessor a large proportion of the present towns and villages were in existence. Mr Elton, in his *Origins of English History*,[4] mentions a curious fact with relation to the tenures which prevailed in some of these places. He alludes to a ring of manors encircling ancient London where the custom of Borough English or junior right was prevalent.[5] He then goes on to point out that in this cluster of manors there are several varieties of the custom:—"Its benefit in Islington and Edmonton was confined to the youngest son; at Ealing, Acton, and Isleworth it extended to the brothers and male collateral heirs; and in a great number of instances the privilege was given to females as well as to males in every degree of relationship. These variations are of no very great importance, the custom being modified in all parts of the country by the rule that special proof must be given of any extension of that strict form of Borough English for the benefit of the younger son of which alone the courts have cognizance. But it is of the greater interest to observe that in several places near London 'it is the custom for the land to descend to the youngest, if it is under a particular value of five pounds, but if it is worth more, it is parted among all the sons' (*First Real Property Commission Evidence*, p. 254)."

The great forest of Middlesex continued long after the Norman Conquest, and even as late as the reign of Elizabeth portions of it still existed quite close to London. Fitz Stephen, the monk of Canterbury and secretary of Thomas a Becket, mentions in his interesting description of London the immense forest with its densely wooded thickets, and its coverts of game, stags, fallow deer, boars, and wild bulls. A few years after Fitz Stephen's death, in the reign of Henry III. (1218), the forest was disafforested, and some of the wealthy citizens took the opportunity of purchasing land and building upon it. Matthew Paris, in his life of the twelfth abbot of St Albans, describes the woods contiguous to the Watling Street between London and St Albans as almost impenetrable, and so much infested by outlaws and by beasts of prey that the numerous pilgrims who travelled along the Roman road to the shrine of Albanus were exposed to imminent danger.

There is little further history that can be told of Middlesex. There are many interesting incidents connected with some of the places, but corporate life has been crushed out of the county by the greatness of London. Not a single place except London has grown into importance, and nowhere outside of London is there a building of first-rate interest. The villages on the Thames early began to increase in size on account of the convenience of locomotion supplied by the river. It is only since the extension of the railway system that the villages to the north and north-west of London have grown in size, and this growth has been mainly due to the building of houses for the use of the Londoners.

3 In the above passage from the Chronicle, where the districts overrun by the Danes in 1011 are enumerated, the shires, which took their names from their chief towns, are distinctly marked off from the districts which took their names from the peoples who inhabited them. Of the latter there are, besides the Middle Saxons, the East Angles, the Kentings, and the South Saxons. Middlesex is styled an administrative shire, because it was not historically a shire, but only one for the purposes of administrative organization. Of the present forty counties twenty-eight are and twelve are not shires. Wessex was divided into six shires, and Mercia into eighteen, with the subsequent addition of Rutland, taken (it is believed) from Northamptonshire. Yorkshire was taken from Northumbria, Lancashire from Cumbria, and, last of all, Monmouthshire from Wales, by an Act of Henry VIII.'s reign.

5 Mr Corner gives the number of instances he has found at sixteen.

MIDDLETON, a market and manufacturing town of Lancashire, is situated on the Irk, near the Rochdale Canal, and on the Lancashire and Yorkshire Railway, about 5 miles north of Manchester and 4 west of Oldham. It includes the township of Tonge, an isolated portion of the parish of Prestwich. The church of St Leonards is an old structure of mixed architecture, with a low square tower. The oldest portion of the building dates from the 12th century, but the main portion from 1412, and the south aisle from 1524. It underwent extensive restoration in 1869. The Queen Elizabeth Grammar School, a building in the Tudor style, was founded in 1572. There are public baths and a free library. The prosperity of the town dates from the introduction of manufactures at the close of last century. The staple trade is the spinning and weaving of cotton, and the other industries include silk weaving, calico printing, bleaching, dyeing, ironfounding, and the manufacture of soap and chemicals. There are several collieries in the neighbourhood. The town was at an early period in possession of the Bartons, from whom it passed by marriage in the 16th century to Sir Ralph de Assheton. The population of the urban sanitary district of Middleton and Tonge in 1881 was 18,952.

MIDDLETON, Conyers (1683–1750), the earliest and most eminent example of the spirit of theological rationalism in the English Church of the 18th century, was the son of the rector of Hinderwell near Whitby, and was born at Richmond in Yorkshire, on December 27 (or, according to another account, on August 3), 1683. He graduated at Cambridge, took orders, and in 1706 obtained a fellowship, which he soon resigned upon contracting an advantageous marriage. In 1717 a dispute with Bentley, upon an extortionate demand of the latter on occasion of Middleton's being created D.D., involved him in an acrimonious controversy, which called forth several pamphlets from his pen full of powerful invective, and among them his first considerable literary performances, the *Remarks* and *Further Remarks* on Bentley's *Proposals for a New Edition of the Greek Testament* (1721). "You have laid Bentley flat upon his back," wrote Colbatch. "I scorn to read what the rascal has written," wrote Bentley,—who, however, only resorted to this affected disdain after a fruitless attempt to fix the authorship upon Colbatch, but who might justly have commented upon the impropriety of Middleton's endeavour to visit his grievances upon the text of the New Testament. Private resentment and uncurbed personality were throughout his life too frequently the motive and the note of Middleton's controversial publications. In 1723 he was involved in a lawsuit by personalities against Bentley, which had found their way into his otherwise judicious tract on library administration, written on occasion of his appointment to the honourable office of university librarian. In 1726 he gave great offence to the medical profession by a dissertation contending that the healing art among the ancients was only exercised by slaves or freedmen. Between the dates of these publications he visited Italy, and made those observations on the pagan pedigree of Italian superstitions which he subsequently embodied in his *Letter from Rome* (1729). This cogent tract, while establishing the author's main proposition with abundant learning and wit, gave at the same time the first clear indication of the anti-supernaturalistic bias of his intellect, and probably contributed to prepare the storm which broke out against him on his next publication (1731). In his remonstrance with Waterland on occasion of the latter's reply to Tindal's *Christianity as Old as the Creation*, Middleton takes a line which in his day could hardly fail to expose him to the reproach of infidelity. He gives up the literal truth of the primeval Mosaic narratives; and, in professing to indicate a short and easy method of confuting Tindal, lays principal stress on the indispensableness of Christianity as a mainstay of social order. This was to resign nearly everything that divines of the Waterland stamp thought worth defending. Middleton was warmly assailed from many quarters, and retreated with some difficulty under cover of a sheaf of apologetic pamphlets, and a more regular attendance at church. A freethinker in the strict sense of the term he certainly was; but how far freedom of thought was carried by him it is not easy to ascertain. His adversaries—some of them men who gravely maintained that Egyptian civilization originated in the age of Solomon—were unable to fix any serious imputation upon him; on the other hand it is clear that the natural attitude of his mind towards supernatural pretensions was one of suspicion, and that his temperament was by no means devout. That he was nevertheless not incapable of a disinterested hero-worship was evinced by his next important publication, the elegant but partial *Life of Cicero* (1741), a work which, if far below the standard of modern exactness, may yet compare in spirit and execution with the best productions of the Italian Renaissance. It is, indeed, as remarked by Forsyth, "rather an historical composition, in which Cicero is the principal figure, than the portrait of the man himself"; and Dr Parr has pointed out Middleton's unacknowledged obligations to the forgotten Bellendenus, which, however, with the ardour of a discoverer, he seems to have considerably overrated. The work was undertaken at the instance of Lord Hervey, in correspondence with whom also originated his disquisition on *The Roman Senate*, published in 1747. The same year and the following produced the most important of all his writings, the *Introductory Discourse* and the *Free Inquiry* concerning the miraculous powers then commonly deemed to have subsisted in the church after the apostolic age. In combating this belief Middleton indirectly established two propositions of capital importance. He showed that ecclesiastical miracles must be accepted or rejected in the mass; and he distinguished between the authority due to the early fathers' testimony to the beliefs and practices of their times and their very slender credibility as witnesses to matters of fact. Some individual grudge seems to have prompted him to expose, in 1750, Bishop Sherlock's eccentric notions of antediluvian prophecy, which had then been before the world for a quarter of a century. The same year he died of a decline at his seat at Hildesham in Cambridgeshire, leaving a widow, but no children.

Middleton's most ambitious work is obsolete from no fault of his, but his controversial writings retain a permanent place in the history of opinion. In his more restricted sphere he may not inappropriately be compared to Lessing. Like Lessing's, the character of his intellect was captious and iconoclastic, but redeemed from mere negation by a passion for abstract truth, too apt to slumber until called into activity by some merely personal stimulus. His diction is generally masculine and harmonious. Pope thought him and Hooke the only prose writers of the day who deserved to be cited as authorities on the language. Parr, while exposing his plagiarisms, heaps encomiums on his style. But his best qualities, his impatience of superstition and disdain of mere external authority, are rather moral than literary. As a scholar he is rather elegant than profound; as a controversialist he has more vigour than urbanity, and more wit than humour. He has been unjustly attacked both as author and as man by De Quincey, who strangely accuses his style of colloquialism, and taxes him with eating the church's bread while denying her doctrines. In fact Middleton's private means were ample, his ecclesiastical emoluments trifling, and his candour obstructed his path to much more considerable preferment. The best general view of his intellectual character and influence is to be found in Leslie Stephen's *English Thought in the Eighteenth Century*, chap. vi. A handsome edition of his works, containing several posthumous tracts, but not including the *Life of Cicero*, appeared in 1752.

MIDDLETON, Thomas (*c.* 1570–1627), held a leading place among the dramatists of the reign of James I. His

popularity would seem to have first come to a height about 1607. This is a fair inference from the fact that in this and the following year a whole swarm of comedies from his pen were licensed and published—*A Trick to Catch the Old One*, *The Family of Love*, *The Phœnix*, *Michaelmas Term*, *Your Five Gallants*, *A Mad World My Masters*. Only the first of these kept the stage after the author's own generation, though in point of wit and constructive skill it is not superior to *The Phœnix* (a serious comedy) or *Your Five Gallants* (a bustling and gaily humorous farcical comedy). The plot of the *Trick* bears a family likeness to that of Massinger's *New Way to Pay Old Debts*; the titles in fact might be interchanged. A ruined scapegrace outwits his creditors and a usurious uncle by coming to town with a courtesan and passing her off as a widow with a fortune, whom he treats with deferential friendship, but hardly dares to love, ruined and hopeless as he is. His uncle lends him money that he may woo in proper state; his creditors also intrigue to have the honour of supplying him with all the needs of fashion; and the lady receives many costly presents from aspirants to her hand and fortune. Though Middleton was apparently not in high popularity till 1607, he had made his debut as a satirist ten years before; and if Malone is right in his conjecture that the *Mayor of Queensborough* is identical with the *Randall Earle of Chester* mentioned by Henslowe in 1602, he had done dramatic work of a much higher kind. Like *The Changeling*, a later production, in which Middleton had the assistance of Rowley, the tragedy of the *Mayor* is named after a character in the insignificant comic underplot. Such a title scares away readers weary of half-intelligible Elizabethan fun and satire; but Simon the comic mayor is a very subordinate figure in the play, and the tragic portions alike in situation, characterization, and language rank among the very noblest productions of the Shakespearian age. There are scenes in the *Changeling* also which Mr Swinburne, with a judgment that will not be disputed, assigns to Middleton, unsurpassed for intensity of passion and appalling surprises in the whole range of Elizabethan literature. The execution of these scenes is far beyond any power that Rowley showed in single-handed work, but well within the scope of the author of the *Mayor of Queensborough* and *Women Beware Women*. This last play, in which every one of the characters important enough to be honoured with a name perishes at the end in a slaughter so rapid as to be somewhat confusing, was apparently one of Middleton's later works, and the simple and measured development of the plot in the first acts seems to show traces of the influence of Massinger. Middleton's verse, when charged with the expression of impassioned love, contains many echoes of the verse of *Romeo and Juliet*, as if his ear had been fascinated by it in his youth. His language generally proclaims him an admiring disciple of Shakespeare's; and in daring and happy concentration of imagery, and a certain imperial confidence in the use of words, he of all the dramatists of that time is the disciple that comes nearest the master. *The Witch*, by which Middleton's name has of late been linked with Shakespeare's in groundless speculation as being part author of *Macbeth*, is by no means one of Middleton's best plays. The plot is both intricate and feeble, as if the play had been written with a view to the half-comic spectacular exhibition of the witches, with their ribald revelry, their cauldrons, hideous spells, and weird incantations. Charles Lamb's comparison of Middleton's witches with Shakespeare's is one of the most exquisite morsels of criticism; but, when he says that Middleton's witches are "in a lesser degree fine creations," he ought perhaps to have added that they are merely embodiments of the vulgar superstition, put on the stage to excite laughter rather than fear among a half-believing audience, an audience ready to laugh at them in the light and in a crowded meeting, whatever each might do in the dark alone. That Middleton had any share in *Macbeth* is a conjecture resting solely on the fact that the opening words of the song of the witches about the cauldron in Shakespeare's *Macbeth* occur also in the incantations about a cauldron in the last act of Middleton's *Witch*, and that Middleton's song was inserted by Davenant in an "amended" reproduction of *Macbeth*. If either borrowed the words of this song from the other, that is no evidence of further co-operation; besides all that is common to the two was probably as much public property as a nursery rhyme. There is no evidence as to whether *The Witch* appeared before or after *Macbeth*. Middleton co-operated with Dekker in the *Roaring Girl*; with Rowley in *A Fair Quarrel*, *The Spanish Gipsy*, and *The Changeling*; and with Jonson and Fletcher in *The Widow* (one of the few of Middleton's plays reproduced after the Restoration). Towards the close of his life Middleton got into difficulties with the privy council from writing a very clever political play apropos of Prince Charles's unsuccessful wooing of the Spanish infanta in 1623. The chief personages in Spanish politics and their manœuvres were represented with most ingenious skill in the pieces and movements of *A Game at Chess*. This play was stopped by royal authority, and the prosecution of the author was allowed quietly to drop. The few unimportant facts known in Middleton's private history are collected in Mr Dyce's admirable edition of his plays. He enjoyed the office of city chronologer, and was often employed to write pageants and masques, in one case at least contracting for the whole exhibition, besides furnishing the words. He died in 1627, and was buried at Newington Butts.

MIDDLETOWN, a city and port of entry of the United States, and one of the shire towns of Middlesex county, Connecticut, lies on the right bank of the Connecticut river, about 30 miles from its mouth, directly opposite the well-known Portland quarries, and 24 miles from New Haven by rail. Built on ground rising gently from the river, with its principal streets keeping the direction of the valley, and the cross streets climbing the slope, Middletown is a place of considerable attractiveness, and the views from the higher points are particularly fine. Water Street, with the wharves and shipping, Main Street, with the commercial houses and hotels, and High Street, with its mansions and gardens and trees, are the leading lines of the city. On the high grounds behind stand the handsome buildings of the Wesleyan (Methodist Episcopal) University. The institution, mainly organized by Wilbur Fisk, D.D., was chartered in 1831. To the two buildings with which it started have been added Rich Hall, with the library of about 30,000 volumes, Judd Hall, with scientific collections of great value, the Memorial Chapel, erected in the centenary year of American Methodism, and the Observatory Hall. Since 1872 the courses of the university have been open to both sexes. In 1882 the number of professors was 20, and of students 191, including 14 females. The Berkeley Theological School (Main Street), founded by the Episcopal Church in 1854, had in 1882 7 professors and 41 students, with a library of 17,000 volumes. A hill 1¼ miles to the south-east of the city is occupied by the State General Hospital for the Insane, the principal building having a frontage of 768 feet, and the grounds extending to 230 acres; and on another hill to the south-west of the city stands the State industrial school for girls. As vessels drawing 10 feet of water can reach its wharves, Middletown carries on a considerable trade by the river. In 1882 1613 vessels, with a burden of 240,000 tons, entered the port, and 1613 vessels, with a burden of 350,000 tons,

cleared; and the Middletown district owned 83 sailing vessels and 22 steamers. Both the silver and the lead mines which were formerly worked in the vicinity have been abandoned, but cast-iron, britannia, and silver-plated goods, sewing-machines, pumps, webbing, and tape are among the local manufactures. The population of the city increased from 5182 in 1860 to 6850 in 1880. First settled in 1636, Middletown was incorporated as a town in 1654, and as a city in 1784.

MIDDLETOWN, a manufacturing village of the United States, in Wallkill township, Orange county, New York, 55 miles N.N.W. of New York, at the junction of four railroads. It is a clean well-built place, in the midst of a fine dairy-farming and stock-raising district, manufactures saws, files, felt hats, blankets, agricultural implements, printers' materials, &c., and is the seat of the State Homœopathic Insane Asylum. The population was 6049 in 1870 and 8494 in 1880.

MIDHURST, an ancient parliamentary borough and market-town of Sussex, is picturesquely situated on a gentle eminence above the south bank of the West Rother, on three railway lines, 50 miles south-west of London and 12 north from Chichester. The church of St Denis (restored in 1881–83) is chiefly Perpendicular in style, but the lower part of the embattled tower is probably Norman. At the grammar school, founded in 1672, Richard Cobden and Sir Charles Lyell were educated. A new public hall was opened in 1882. The old castle of the De Bohuns stood on a mound above the river, now overgrown with trees. In ancient times a commandery of the Knights of St John of Jerusalem had jurisdiction over the district now forming the liberty of St John. The prosperity of the town depends chiefly on agriculture. A market is held weekly, and a fair three times a year. The population of the parliamentary borough, which has an area of 26,172 acres, was 6753 in 1871, and 7221 in 1881.

Midhurst is not mentioned in Domesday, being included under Easebourne. In the reign of Henry I. it was held by the king as a minor barony. In the time of Edward I. it passed into the possession of the De Bohuns. From the time of Edward II. till 1832 it returned two members to parliament, but since then only one.

MIDIAN was one of the peoples of North Arabia whom the Hebrews recognized as distant kinsmen, representing them as sons of Abraham's wife Keturah. The word Keturah means "incense"; thus the sons of Keturah are the "incense-men," not indeed inhabitants of the far south incense-land, but presumably the tribes whose caravans brought the incense to Palestine and the Mediterranean ports. So the Midianites appear in connexion with the gold and incense trade from Yemen (Isa. lx. 6), and with the trade between Egypt and Syria (Gen. xxxvii. 28, 36). At the time of the exodus the pastures of the Midianites, or of the branch of Midian to which Moses's father-in-law (Jethro or Raguel, or Hobab) belonged, lay near Mount Horeb (Exod. iii. 1); and Num. x. 29 *sq.* implies that the tribe was at home in the desert of the wanderings. The Kenites, who, in spite of their connexion with Amalek (1 Sam. xv. 6), had friendly relations with Israel, and ultimately coalesced with the tribe of Judah, are represented in Judg. i. 16, iv. 11 as the kin of Moses's father-in-law. The Kenites, however, can have been but one fraction of Midian which took a separate course from their early relations to Israel.[1] The main body appear in Judg. vi. as a powerful Bedouin confederation, invading Canaan from the eastern desert, and ravaging the land as similar tribes have done in all ages when Palestine lacked a strong government. With their defeat by Gideon and another defeat by the Edomites in the field of Moab, probably about the same time (Gen. xxxvi. 35), the recorded history of Midian closes.

A place Midian is mentioned 1 Kings xi. 18, and in later times the name lingered in the district east of the Gulf of 'Akaba, where Eusebius knows a city Madian in the country of the Saracens and Ptolemy places Modiana. Still later Madyan was a station on the pilgrim route from Egypt to Mecca, the second beyond Aila (Elath). Here in the Middle Ages was shown the well from which Moses watered the flocks of Sho'aib (Jethro), and the place is still known as "the caves of Sho'aib." It has considerable ruins, which have been described by Rüppell (*Reisen*, 1829) and Burton (*Land of Midian*, 1879).

[1] The admixture of Midianite elements in Judah and the other border tribes of Israel is confirmed by a comparison of the names of the Midianite clans in Gen. xxv. 4 with the Hebrew genealogies (1 Chron. ii. 46, iv. 17, v. 24; Gen. xlvi. 9)

MIDNAPUR, a district in the lieutenant-governorship of Bengal, India, between 21° 37′ and 22° 57′ N. lat., and between 86° 35′ 45″ and 88° 14′ E. long., is bounded on the N. by Bánkurá and Bardwán, on the E. by Hooghly and Howrah, on the S. by the Bay of Bengal, and on the W. by Singbhúm and Mánbhúm, with an area of 5082 square miles. Its general appearance is that of a large open plain, of which the greater part is under cultivation. In the northern portion the soil is poor, and there is little wood. The country along the western boundary, known as the Jungle Mahals, is undulating and picturesque; it is almost uninhabited. The eastern and south-eastern portions are swampy and richly cultivated. The chief rivers of the district are the Hooghly and its three tributaries, the Rúpnáráyan, the Haldi, and the Rasulpur. The Midnapur high-level canal runs almost due east and west from the town of Midnapur to Ulubariá on the Hooghly 16 miles below Calcutta, and affords a continuous navigable channel 53 miles in length. There is also a tidal canal for navigation, 26 miles in length, extending from the Rúpnáráyan river. The jungles in the west of the district yield lac, *tasar* silk, wax, resin, firewood, charcoal, &c., and give shelter to large and small game.

The census of 1872 returned the population of Midnapur at 2,540,963 (1,257,194 males and 1,283,769 females), including only 122 Europeans and 157,030 Mohammedans. The aboriginal tribes belong chiefly to the jungles and hills of Chutiá Nágpur and Bánkurá; the most numerous of them are Santáls (96,921) and Bhumíjs (35,344). Of high-caste Hindus the returns show 136,500; and the number of Káyasths is given as 101,663. Among the semi-Hinduized aborigines, the most numerous are the Bágdis, a tribe of cultivators, fishermen, and day-labourers (76,825). Belonging to agricultural castes there are 1,018,686. The four municipalities are Midnapur (31,491), Chandrakona (21,311), Ghatal (15,492), and Tamlúk (5849). Rice is the staple crop. Irrigation is effected chiefly from the high-level canal. Rent rates vary from 10½d. an acre for the poorest quality of rice land to 18s. an acre for the best irrigable lands. The district suffers occasionally from drought; floods are common, and very disastrous in their results. The principal exports are rice, silk, and sugar; and the chief imports consist of cotton cloth and twist. Salt, indigo, silk, mats, and brass and copper utensils are manufactured. Apart from the rivers, communication is afforded by 482 miles of road. The total revenue in 1870–71 was £262,578, and the expenditure £53,777. The prevailing diseases are fever, diarrhœa, dysentery, and cholera. The average mean temperature is 80° Fahr., and the average annual rainfall 66 inches.

The early history of Midnapur centres round the ancient town of Tamlúk, which in the beginning of the 5th century was an important Buddhist settlement and maritime harbour. The first connexion of the English with the district dates from 1760, when Mír Kásim ceded to the East India Company Midnapur, Chittagong, and Bardwán (then estimated to furnish one-third of the entire revenue of Bengal) as the price of his elevation to the throne of Bengal on the deposition of Mír Jafar.

MIDNAPUR, chief town and headquarters station of the above district, is situated on the north bank of the Kasái river, with a population in 1872 of 31,491. The town has a large *bázár*, with commodious public offices. It is healthy, dry, and well supplied with water. An American mission maintains an excellent training school, together with a printing press, and has founded several village schools in

the district. Its efforts have been particularly successful among the Santáls, and some of the earliest and most valuable works on their language have issued from the Midnapur mission press. A brisk manufacture of brass and copper utensils takes place in the town; it is also the centre of a large indigo and silk industry.

MIDRASH. Like all nouns of a similar form *Midrash* is the equivalent of the Niph'al participle,[1] and as such yields as many modified meanings as the root *Darosh* (דָּרַשׁ), to search, &c., itself has. The practical significations, however, of *Midrash*, taken in historical order, are as follows:—(1) a book of records; (2) a recension of older, especially historical, materials; (3) search in and explanation of the Scriptures, notably the Pentateuch (in which case the plural is invariably *Midrashoth*); (4) theory as distinguished from practice; (5) a college for study and teaching; (6) an *Agadic* (that is, a free) explanation, in contradistinction to an *Halakhic* one; (7) a collection of such free explanations (in which case the plural is *Midrashim* and occasionally also *Midrashoth*). Of these seven significations (1) and (2) are to be found in the Bible,[2] (3) and (4) are mentioned for the first time in the *Mishnah*,[3] (5) is to be met with in the *Midrash*,[4] while (6) and (7) are to be found in early Rabbinic writings.[5]

The subject of this article will be—(1) the nature of *Midrash* in the sense of *Agadah*, to the exclusion of *Halakhah* (for which see MISHNAH), and (2) the development of this *Midrash Agadah* into books (*Midrashim*).

The thinking reader of the Scriptures cannot have failed to observe that by the side of their ceremonial element, be it negative or affirmative, permissive or jussive, there is also often to be met with (and sometimes so as to be inseparable from it) a spiritual element. This spiritual element rests chiefly on feeling or emotion, and produces pious works only indirectly. Now the explanation or application of this element, either by the Scriptures themselves or by the rabbis, is traditionally called *Midrash Haggadah* (recitation, preaching) or *Midrash Agadah*[6] (binding the soul to God and all that is godly).

This *Haggadah* or *Agadah* varies considerably both in nature and form. In its nature it sometimes humours, at other times threatens; it alternately promises and admonishes, persuades and rebukes, encourages and deters. In the end it always consoles, and throughout it instructs and elevates. In form it is legendary, historical, exegetic, didactic, theosophic, epigrammatic; but throughout it is ethical.

And varied as was and is the *Midrash Agadah*, so varied have been its fortunes. Whilst at times it stood very high in the estimation both of the teachers and the congregations in Israel,[7] it sank at other times very low indeed.[8] Nay, at one and the same time, whilst some rabbis exalted it to the skies,[9] other rabbis treated it with hatred,[10] or, worse still, with contempt.[11] There have actually been teachers whose treatment of it differed with the difference of the occasion.[12] The fact is the Jews liked or disliked the *Midrash Agadah* according to their political condition on the one hand and their proximity to Jewish professors of Christianity on the other. In the hour of prosperity the Jews preferred the *Halakhah*;[13] in that of adversity they ran to hear the consoling words of the *Agadah*.[14] When near Judæo-Christians, whose religious strength and argument chiefly rested on *Agadah*,[15] the Jews disliked it; when among themselves, or when dwelling among Gentiles (heathen or Christian), they showed their wonted partiality for it.

But, whatever were the likings or dislikings of the Jews for the *Midrashoth*, it is certain that these traditions were early[16] committed to writing, and formed into special volumes, known as "Books of *Agadah*."[17] Such were first some of the *Targumim* and then the *Midrashim*. Against writing down the traditional explanations of the Mosaic ceremonial there existed a distinct law,[18] which was observed down to near the end of the 6th century. At an earlier period isolated disciples only, in order to refresh their memory, wrote down short Halakhic notes, which, however, they kept in secret.[19] The *Targumim* and *Midrashim*, on the other hand, were composed very early and were numerous, while their extensive contents were circulated in public.

The *Midrash*, from whatever point of view it may be regarded, is of the highest value. It is of the highest value, of course, to the Jew as Jew first, inasmuch as he finds there recorded the noblest ideas, sayings, and teachings of his venerable sages of early times. In the next place it has value to the Christian as Christian, since only by these ideas, teachings, reasonings, and descriptions can the beautiful sayings of the Founder of Christianity, the reasonings of the apostles, and the imagery of the sublime but enigmatic Apocalypse be rightly understood. But its importance appeals also to the general scholar, because of the inexhaustible mines of information of all kinds it contains. The philologist will find here numerous hints on lexicography and grammar, chiefly, of course, of the Semitic languages, but also of other tongues, notably Greek and Latin. The historian will gather here a rich harvest on geography, chorography, topography, chronology, numismatics, &c. The philosopher will find here abundant and

[1] Comp. Nehem. viii. 8, where במקרא evidently stands for בנקרא. See also Kimhi on 2 Chron. xiii. 22, and Schiller-Szinessy, *Exposition*, &c., Cambridge, 1882, p. 11.

[18] T. B., *Gittin*, 60*b*: "In the college of R. Yishm'ael it was taught, 'These [see Exod. xxxiv. 27] thou oughtest to write down, but thou must not write down *Halakhoth*.'"

[19] T.B., *Shabbath*, 6*b*: "I found a 'secret roll,'" that is, a roll of *Halakhoth* kept secret. Comp. Rashi, *in loco*.

valuable notices on logic, psychology, metaphysics, theology, theosophy, æsthetics, rhetoric, poetry, mathematics, geometry, astronomy, zoology, botany, biology, morphology, chemistry, medicine, physics, &c. The statesman—particularly if he be inclined to follow the Psalmist's advice—"from the ancients I gather understanding" (cxix. 100)—will find here valuable information on ancient ethnography in the full sense of the term—politics, political economy, law, military science, naval affairs, &c. The true scholar will find out by the study of the *Agadah* that many a discovery thought to belong to a recent age was well known to these ancient doctors.

The sources of the *Agadah* are five:—(1) the *Targumim* and especially those on the Prophets and Hagiographa; (2) the non-canonical *Mishnah* (*Mathnitho Boraitho*; see MISHNAH), which contains many valuable pieces, the age of which is often anterior, in essence if not in form, not only to those contained in the canonical *Mishnah*, but also to the sayings of the New Testament; (3) the canonical (officially recognized) *Mishnah*, which contains several entire treatises of an *Agadic* nature, as *Aboth*,[1] *Middoth*, &c.,[2] and numerous pieces scattered here and there among the *Halakhah*; (4) both *Talmudim*[3] (the Palestinian and Babylonian), which have thousands of Agadic notices interspersed in their *Halakhoth*; and (5) the *Midrashim*, κατ' ἐξοχήν. It is of the last alone, as represented by their principal collections, that we give an historical enumeration here:—

(1) *Megillath Ta'anith* is an historical *Midrash* consisting of twelve *Peraḳim*, and is called so on the principle of *lucus a non lucendo*, seeing that in it are enumerated the days of the year on which a Jew must not fast. The Aramaic part of it alone constitutes the real *Megillah*, and belongs to the beginning of the 2d Christian century.[4] The *editio princeps* came out at Mantua, 1513, 4to; but cheap editions have been printed at Warsaw and elsewhere.

(2) *Sepher Yeẓirah* is a philosophico-cabbalistic *Midrash* divided into six *Peraḳim*, which, in their turn, are subdivided into *Mishniyyoth*. It is variously ascribed to the patriarch Abraham and to R. 'Aḳibah, the illustrious teacher, who suffered martyrdom under Hadrian. To this rabbi the book, no doubt, belongs both in substance and form.[5] It has gone through numerous editions, the *ed. princ.* being of 1562 (Mantua, 4to), and has been translated into Latin, German, and English (New York, 1877).

(3) *Othiyyoth de-Rabbi 'Aḳibah* is a *quasi*-cabbalistic *Midrash* on the alphabet, belonging, in essence if not in form, to the aforesaid teacher and martyr. *Ed. princ.*, Constantinople, 1520, 4to.

(4) *Massekheth Hekhaloth* is an astronomico-cabbalistic *Midrash* in seven *Peraḳim*. It is ascribed to R. Yishma'el the high priest. Judging from internal evidence on the one hand, and from what is known of R. Yishma'el in the *Talmudim* and *Midrashim* (*Babli Berakhoth*, 7*a* and elsewhere) on the other hand, there seems to be no valid reason for doubting that he is the author of this small but sublime book. This *Midrash* is printed in the collection *Arze Lebanon* (Venice, 1601, 4to) under the title of "*Pireḳe Hekhaloth*" and "*Massekheth Hekhaloth*," and a MS. of it is preserved in the University Library of Cambridge (Dd. 10. 11. 7. 2). The work, however, called "The Greater and the Lesser *Hekhaloth*," in thirty *Peraḳim*, printed in this century, somewhere in Poland, contains, besides the ancient literature, a good deal of matter which is of much later date.

(5) *Seder 'Olam* (the Greater and the Lesser) are two historical *Midrashim*, the former of which belongs to the 2d century, whilst the latter (which is a mere extract of the former) belongs to a late age indeed (the Gaonaic). They have been repeatedly printed, always together, the *ed. princ.* being Mantua, 1513, 4to.

(6) *Haggadah shel Pesaḥ* is a liturgical *Midrash* of the middle of the 2d century, as far as its main portions go. It exists now in three principal and several minor recensions in accordance with the various rituals (see MAḤZOR), and is recited at the domestic service of the first two Passover evenings. The editions are too numerous to be mentioned, the *ed. princ.* being Constantinople, 1505, folio.

(7) *Megillath Antiokhos* treats ostensibly, as its name indicates, of the sufferings of the Jews under Antiochus Epiphanes, and their deliverance from his tyranny, but in reality of their sufferings under Hadrian and their deliverance under Antoninus Pius. The Aramaic text, with the exception of a few interpolations, belongs to the middle of the 2d century. This little "roll" was for the first time published by Filipowsky (London, 1851, 32mo). A MS. copy of the Hebrew is preserved in the University Library of Cambridge (Dd. 8. 34).

(8) *Zohar* (*Midrash Hazzohar*, *Midrasho shel Rabbi Shim'eon b. Yoḥai*, *Midrash Yehi Or*, &c.) is a cabbalistic *Midrash* on the Pentateuch, Canticles, Ruth, and part of Lamentations. It is variously ascribed to the famous R. Shim'eon (disciple of R. 'Aḳibah, &c.) and to R. Mosheh b. Shemtob of Leon (a second-rate cabbalist of the time of Naḥmanides and Ibn Addereth). The *Zohar* belongs, strictly speaking, to neither of these, whilst, in a certain sense, it belongs to both. The fact is—the nucleus of the book is of Mishnic times, and R. Shim'eon b. Yoḥai was the author of the *Zohar* in the same sense that R. Yoḥanan was the author of the Palestinian Talmud, *i.e.*, he gave the first impulse to the composition of the book. But R. Mosheh of Leon,[6] on the other hand, was the first not only to copy and disseminate the *Zohar* in Europe, but also to disfigure it by sundry explanatory interpolations. For more details see Lumby, "Introduction to the Epistle of Jude," in the *Speaker's Commentary*, vol. iv. p. 388. The first two editions of the *Zohar*[7] on the Pentateuch came out simultaneously (Mantua, 1558–60, 4to, and Cremona, 1558, folio), and the *ed. princ.* on Canticles, Ruth, and part of Lamentations came out at Salonika (1597, 4to). The best, though by no means critical, edition on the Pentateuch is that of Brody, 1873, 8vo. Of translations, such as they are, there exist those of Knorr v. Rosenroth, *Kabbala denudata* (vol. i., Sulzbach, 1677, and vol. ii., Frankfort, 1684, 4to), and Tholuck, *Wichtige Stellen*, &c. (Berlin, 1824, 8vo), &c.[8]

(9) *Pesiḳotho*[9] (commonly, but by mistake, called *Pesiḳta*) *derab Kohano* is a homiletic *Midrash* consisting of thirty-two *Pesiḳtoth* for the principal festivals and fasts, and the historically noted sabbaths and other days. It is of the end of the 3d or the beginning of the 4th century. Having been but rarely quoted since the 12th century, so that most scholars knew of it only

[1] A valuable edition of this treatise (in Hebrew and English) has been published by Dr C. Taylor, Cambridge, 1878.

[2] To these we may add, for the sake of convenience, although they do not, strictly speaking, belong to the canonical *Mishnah*, the *Pereḳ Rabbi Meir* and the Agadic parts of the *Massekhtoth Ketannoth*.

[3] Two collections of Talmudic *Agadoth* were made early in the 16th century:—(1) *Haggadoth Hattalmud*, Constantinople, 1511, folio, of which apparently only five copies are in existence, the finest of these being preserved in the University Library of Cambridge; and (2) *'En Ya'akob* (or *'En Yisrael*), of which numerous and cheap editions exist, the *ed. princ.* being that of Salonika, 1516–22.

[4] Almost all that the latest critics have said concerning the age of the various *Targumim* and *Midrashim* will have to be unsaid. Not only are negative statements difficult of proof; in this case they are absolutely incorrect. We shall only give two examples. The statement "*Vayyiḳra Rabbah* cannot be early, as Rashi did not know of it, since he nowhere mentions it," is doubly incorrect: Rashi *does* quote it (*e.g.*, on Haggai i. 1). Again the statement "We must not omit to observe that no early Jewish commentator—Rashi, Ibn Ezra, &c.—mentions the Targum either to Proverbs or to Job and Psalms; Nathan ben Jechiel (12th century) is the first who quotes it," contains a *reductio ad absurdum* in itself. For Nathan b. Yeḥiel was, as is well known, a somewhat older contemporary of Rashi (*ob.* 1105), and lived full a hundred years before Ibn 'Ezra!

[5] See T. B., *Synhedrin*, 65*b* and 67*b*. In the former place it distinctly speaks of the *Sepher Yeẓirah* (ספר יצירה), and, although in the latter place it speaks of the *Hilckhoth Yeẓirah* (הלכות יצירה), there cannot be a doubt that *Sepher* (ספר) and *Hilekhoth* (הלכות) are there identical. Moreover, *Mishniyyoth* and *Halakhoth* are, in a certain sense, convertible terms (see MISHNAH); and our book (as remarked above) consists of *Mishniyyoth*.

[6] R. Mosheh of Leon is a fair sample of the mediocrity of his time in cabbalistic lore, and combined, as is usual, with his mediocrity an illimitable vanity; see MS. Dd. 11. 22 (Cambridge University Library), leaf 2*a*: "And I adjure every one who should deeply study this book, or who should copy it, or read it, that he do not blot out my name from my property (inheritance), for I have composed it. . . ." This statement alone would suffice to prove that R. Mosheh of Leon could never have ascribed a book composed by himself to anybody else.

[7] The *Zohar*, cleared of the main works by which it is surrounded, and of the interpolations by which it has been disfigured both by its first European copyist and by others down even to our own days, was begun in Palestine late in the 2d or early in the 3d century, and finished, at the latest, in the 6th or 7th century. It is impossible that it should have been composed after that time and before the Renaissance, as both language and contents clearly show.

[8] Whilst the principal editions of the many textual extracts made from the *Zohar* (as the *Idd'oth*, &c.) need not be specified here, those of the following supplementary and kindred works ought to be mentioned:—(1) *Tiḳḳune Hazzohar* (*ed. princ.* Mantua, 1557, 4to), and (2) *Zohar Ḥadash* (*ed. princ.* Cracow, 1603). Nor should the *Kontres missepher Hazzohar*, *Ḥibburo Tinyono* (by the otherwise very learned Yitshaḳ b. Mosheh of Satanow) be passed over. It is a mere imitation of the *Zohar*,—an imposition of a kind which is a disgrace to literature.

[9] For the three *Midrashim*—*Mekhilto*, *Siphro*, and *Siphere*—see under MISHNAH.

indirectly, it was long considered lost, till, in 1868, Salomon Buber of Lemberg, a man of learning, wealth, and love for the ancient literature of his nation, edited it from four MSS., one of which (formerly in possession of Carmoly) is now preserved in the University Library of Cambridge (Add. 1497). The printed edition appeared at Lyck, 8vo.

(10) *Pesikto Rabbathi*, consisting in the latest edition of eighty-four *Piskoth*, is a *Midrash* of the same nature, and, in its main part, almost of the same date, as (9). Both drew from the same sources. This *Midrash* has been edited five times,—the latest, best, and cheapest edition being that of Friedmann (Vienna, 1880, 8vo).

(11) *Tanna debe Eliyyahu* consists of two parts, the Greater (Rabbo) and the Lesser (Zutto),—the former in thirty-one and the latter in twenty-five *Perakim*. It is an exegetical *Midrash*, the name of which is already known to the *Bereshith Rabbah* (c. liv.) and the Babylonian Talmud (*Kethuboth*, 106*a*). It is only uncritical criticism that can declare it a Gaonaic work, although, like all other old books of the Jews, it is not without later additions. *Ed. princ.*, Venice, 1598, 4to. There are modern and cheap Polish editions.

(12) *Midrash Rabbah* (רבה) or *Rabboth* (רבות) is chiefly an exegetical and homiletical *Midrash* on the Pentateuch and the "Five Rolls" (*Hamesh Megilloth*; *i.e.*, Canticles, Ruth, Lamentations, Ecclesiastes, and Esther). It is called *Rabbah* either from the third (the first distinctive) word of its beginning (רבי הושעי' רבה...) or from its being the most voluminous[1] *Midrash*; hence also *Rabbo* (רבא). The *Midrash* on Canticles (and Ecclesiastes) is now and then also called *Midrash Hazitha* (from the first distinctive word of the beginning חזית). These ten *Midrashim* are, certainly, of various styles and ages; yet none of them is, interpolation excepted, later than the beginning of the 5th century.[2] It is remarkable that, although the *Megilloth* themselves had been early attached to the Pentateuch (since they were long before the 10th century, and still are, read through the synagogal year, even as was and still is the Pentateuch itself), the *Rabboth* had no common *editio princeps*[3]—that on the Pentateuch appearing for the first time in 1512 (Constantinople, folio), and that on the *Megilloth* in 1519 (somewhere in Italy, במדינת איטליאה, also in folio).[4] The latest and best edition is that of Vilna, 1880, folio. A translation in German is now coming out at Leipsic, by Dr A. Wünsche.

(13) *Pirke de-Rabbi Eli'ezer* (also called *Boraitho de-Rabbi Eli'ezer*) is an astronomico-theosophical *Midrash* consisting of fifty-four *Perakim*. It goes through the so-called "eighteen benedictions," the signs of the zodiac, &c., but is unfinished. It belongs, no doubt, to the 5th century. The fact that the name "Fatima" occurs in it is no proof whatever that the book is post-Mohammedan, as that name must have been already known to the idolatrous Arabs. *Ed. prin.*, Constantinople, 1514, and with a Latin translation, Leyden, 1644, both editions being in 4to. There are also now to be found cheap editions (Lemberg, Warsaw).

(14) *Tanhuma* is an exegetical and homiletical *Midrash* on the whole Pentateuch. It is quoted according to the *Parshiyyoth* of the week. Although originally of the end of the 5th or the beginning of the 6th century, it has now two principal additions, which form part of the book:—(1) several of the *Sheelloth* of Rab Ahai Gaon (of the 8th century), and (2) several pieces of the *Yesod* of R. Mosheh Haddarshan, of Narbonne (of the 11th century). On its relation to the "*Yelammedenu*" (often quoted in the 11th century, but supposed to be lost) light will soon be thrown by the before-mentioned Salomon Buber, who is now preparing a critical edition of it. The *ed. princ.* of the *Tanhuma* is Constantinople, 1522, folio; and a very valuable MS. copy of it is in the Cambridge University Library (Add. 1212).

(15) *Bahir* is a small cabbalistic *Midrash* ascribed to the pre-Mishnic teacher, R. Nehunyah b. Hakkanah,—no doubt from its beginning with the words אמר רבי נחוניה בן הקנה.... Nahmanides (*ob. c.* 1268) quotes this book often in his commentary on the Pentateuch, under the names of *Sepher Habbahir*, or of *Midrasho shel Rabbi Nehunyah b. Hakkanah*. Some have pronounced this work a late fabrication, but others, who have thoroughly studied it, justly describe it as "old in substance if not in form." *Ed. princ.*, Amsterdam, 1651, 4to. A cheap edition appeared at Lemberg (1865, 8vo), and a MS. of this work is preserved in the University Library of Cambridge (Dd. 10. 11. 4).

(16) *Yalkut* is the only existing systematic if not exhaustive collection of the *Agadoth* on the whole Bible. Its author drew not only from most of the *Midrashim* named in this article, but also from the *Boraithoth* (see MISHNAH), both *Talmudim*, and the Midrashic works now lost (as the *Abkhir*, *Hasshekhem*, or *Hashkem*, &c.).[5] This fact constitutes one of the principal points of its value. The author was R. Shim'eon, brother (and not son) of R. Helbo, and father of the distinguished grammarian, critic, and divine R. Yoseph Kara. He lived somewhere in the north of France in the 11th century. The *ed. princ.* of the *Yalkut* on Ezra, Nehemiah, and the books of Chronicles came out at Venice, 1517, folio (in the first Rabbinic Bible); that on the Prophets and Hagiographa in 1521, and that on the Pentateuch in 1526–27, both at Salonika, and in folio. An English translation of the whole work has been undertaken by a band of Rabbinic scholars in Cambridge. The first instalment, "The Yalkut on Zechariah," by E. G. King, B.D., Hebrew lecturer of Sidney Sussex College, appeared in 1882. This specimen, besides giving a correct translation, contains many valuable notes.

(17) *Lekah Tob* is a *Midrash* on the Pentateuch and the five *Megilloth*, by R. Tobiyyahu b. Eli'ezer of Greece, who lived during the crusade of 1096. This work draws, certainly, upon the old and well-known *Midrashim*, and as such it would have thoroughly deserved the censure passed upon it by the witty but somewhat irreverent Abraham Ibn 'Ezra (in his preface to his commentary on the Pentateuch). But the *Lekah Tob* has also most valuable explanations both by the collector himself and by his father (R. Eli'ezer), a fact passed over by Ibn 'Ezra in silence. The *Lekah Tob* on Leviticus, Numbers, and Deuteronomy came out for the first time at Venice, in 1546, folio, under the title of *Pesikto Zuttarto* (see leaf 93*b* in the postscript by the editor, הפסיקתא זוטרתא, which explains the somewhat vague title on the title-page פסיקתא זוטרתא או רבתא). In 1753–54 it was republished at Venice, with a Latin translation, by Blasius Ugolinus in his *Thesaurus Antiquitatum Sacrarum* (xv.–xvi.) under the name of *Pesictha*. The *Lekah Tob* on Genesis and Exodus was

[1] The *Rabbah* on Genesis has 100 *Parshiyyoth*, that on Exodus 52, that on Leviticus 37, that on Numbers 23, and that on Deuteronomy 11. These five *Midrashim* are quoted according to their chapters. The *Rabbah* on Canticles accommodates itself to the sacred text, and is quoted accordingly. Ruth has 8 *Parshiyyoth*, and is quoted according to these. Lamentations has 1 chapter consisting of 33 introductions (*Pethihotho Dehakkime*), accommodating itself, for the rest, to the sacred text. Ecclesiastes has 3 *Sedarim*, and Esther has 6 *Parshiyyoth*. At various times various modes of quoting these *Midrashim* are current,—the most common and most expedient, however, being that of quoting them according to the verses of the Bible.

[2] Here might with advantage be mentioned some pieces of literature which are kindred in nature, although some of them are of much earlier date, whilst others are much later, than the ten *Midrashim* just mentioned:—(1) *Agadath Bereshith* on Genesis, in eighty-three chapters,—edited for the first time by R. Menahem de Lonsano in his *Shete Yadoth*, Venice, 1618, 4to; (2) *Midrash Vayyisa'u* on Genesis xxxv. 5, in one chapter,—to be found in Jellinek's *Bet ha-Midrasch*, Leipsic, 1855, 8vo; (3) amplifications of chapter lxx. of our *Midrash Rabbah*, on Genesis xxviii. 22, by the incorporation of the whole Apocryphon *Tobit* in Aramaic, &c. (see *The Book of Tobit*, &c., Oxford, 1878, 8vo); (4) *Midrash Vayyosha'* on Exodus xiv. 30, xv. 1–18,—printed at Constantinople, 1519, 4to; a MS. of this *Midrash* is preserved in the University Library, Cambridge (Add. 854); (5) *Midrash 'Asereth Haddibberoth* on Exodus xx.,—printed in Jellinek's *Bet ha-Midrasch*, Leipsic, 1853, 8vo; (6) *Midrash Petirath Aharon* on Numbers xx. 23–29; (7) *Midrash Petirath Mosheh* on Deuteronomy xxxiv.; (8) *Midrash Abbo Gorion* on Esther; the last three are to be found in the before-mentioned *Bet ha-Midrasch*; (9) *Midrash Shemuel*, also called, from its beginning, *'Eth la'asoth Ladonai*, Constantinople, 1517, folio; (10) *Midrash Yonah*, Prague, 1595, 4to; (11) *Midrash Tillim* (*Tehillim*), 1512; (12) *Midrash Mishele*, 1517; the last two are printed at Constantinople, and in folio; (13) *Sepher Hayyashar* (in which a good many old traditions are preserved, although it is, of course, not the one mentioned in various books of the Bible), Venice, 1625, 4to; (14) *Dibere Hayyamim shel Mosheh*, Constantinople, 1516, 4to; a fragment of this is to be found in MS. Add. 532. 4 in the University Library of Cambridge; (15) *Yosephon* (or *Josippon*), various works of Flavius Josephus worked up rather freely, Mantua, 1480, folio,—translated into Latin (German and Spanish) several times; (16) *Zerubbabel*, Constantinople, 1519, 8vo; (17) *Elleh Ezkerah* on the "Ten Martyrs." For several other smaller *Midrashim* see Jellinek's *Bet ha-Midrasch*, i. and ii., 1853, iii., 1855, iv., 1857, all at Leipsic; v., 1873, and vi., 1877, both at Vienna; and comp. also Horowitz, *Sammlung Kleiner Midraschim*, i., ii., Frankfort, 1881–82. The *Midrashim* on Isaiah and on Job seem now irretrievably lost.

[3] As if to compensate for this drawback, the well-known Cornelio Adelkind brought out at Venice, in 1545, two editions of the *Rabboth* on the Pentateuch and *Megilloth*, the one at Bombergi's house and the other at Giustiniani's. These two editions differ in nothing but in the title-pages, &c., and the vignettes of the various books. The former edition is in possession of Dr W. Aldis Wright, and the latter in that of Dr C. Taylor. The fact of these editions having appeared simultaneously is, apparently, unknown to the bibliographers.

[4] It is noteworthy that in this edition *Ahashverosh*, *i.e.*, Esther, stands between Lamentations and Ecclesiastes, with which latter the *Midrash* on the *Megilloth* ends.

[5] We may mention here the *ed. princ.* of three cabbalistic-Midrashic collections which go under the name of *Yalkut*:—(1) *Yalkut Hadash*, Lublin, 1648, 4to; (2) *Yalkut Reubeni Hakkatan*, Prague, 1660, 4to; and (3) *Yalkut Reubeni Haggadol*. Wilhermsdorf, 1681, folio.

published, with a critical commentary, at Vilna, by Salomon Buber (1880, 8vo), where also simultaneously a third edition of this *Midrash* on the last three books of Moses, with a short commentary on it, came out by Aharon Mosheh Padova, of Carlin. The *Leḳah Tob* on the five *Megilloth* is as yet unpublished; there exist, however, several good MSS. of it, both in public and private libraries, the finest copy in every respect being that preserved in the University Library, Cambridge (Add. 378. 1).

(18) *Menorath Hammaor* is a scientific, though incomplete, collection of the principal *Agadoth* of the *Talmudim* and *Midrashim*, by R. Yizḥaḳ Abohab the elder (flourished 13th century). The editions, with and without translations, are very numerous,—the *ed. princ.* being Constantinople, 1514, folio. There are translations in Spanish, Judæo-German, and German, but not in English.

We append two specimens of *Midrashim*,—the first from *Pesiḳotho*, leaf 127*b*, and the second from *Midrash Shemoth Rabbah*, cap. ii.

First Specimen.—The Holy One (blessed be He!) said to the Prophets,[1] Go ye and comfort ye Jerusalem!

Then went Hosea to comfort her and said, The Holy One (blessed be He!) sent me to thee to comfort thee. She said, What hast thou in thine hand to comfort me? The Prophet said (xiv. 6 [5]), "I will be as the dew unto Israel!" But Jerusalem said to him, Only yesterday thou toldest me (ix. 16), "Ephraim is smitten, their root is dried up, they shall bear no fruit: yea, though they bring forth, yet will I slay even the beloved fruit of their womb!" and now thou speakest to me thus. Which shall we believe, the first or the second prophecy?

Then went Joel to comfort her and said, The Holy One (blessed be He!) sent me to thee to comfort thee. She said to him, What hast thou in thine hand to comfort me? The Prophet said (iv. 18), "And it shall come to pass in that day that the mountains shall drop down new wine, and the hills shall flow with milk, &c.!" But Jerusalem said to him, Only yesterday thou toldest me (i. 5), "Awake, ye drunkards, and weep; and howl, all ye drinkers of wine, because of the new wine; for it is cut off from your mouth!" and now thou speakest to me thus. Which shall we believe, the first or the second prophecy?

Then went Amos to comfort her and said, The Holy One (blessed be He!) sent me to thee to comfort thee. She said to him, What hast thou in thine hand to comfort me? The Prophet said (ix. 11), "In that day will I raise up the tabernacle of David that is fallen!" But Jerusalem said to him, Only yesterday thou toldest me (v. 2), "The Virgin of Israel is fallen; she shall no more rise!" and now thou speakest to me thus. Which shall we believe, the first or the second prophecy?

Then went Micah[2] to comfort her and said, The Holy One (blessed be He!) sent me to thee to comfort thee. She said to him, What hast thou in thine hand to comfort me? The Prophet said (vii. 18), "Who is a God like unto Thee, that pardoneth iniquity and passeth by the transgression of the remnant of His heritage?" But Jerusalem said to him, Only yesterday thou toldest me (i. 5), "For the transgression of Jacob is all this, and for the sins of the house of Israel, &c.!" and now thou speakest to me thus Which shall we believe, the first or the second prophecy?

Then went Nahum to comfort her and said, The Holy One (blessed be He!) sent me to thee to comfort thee. She said to him, What hast thou in thine hand to comfort me? The Prophet said (ii. 1 [i. 15]), "For the wicked shall no more pass through thee!" But Jerusalem said to him, Only yesterday thou toldest me (i. 11), "There is one come out of thee that imagineth evil against the Lord, a wicked counsellor!" and now thou speakest to me thus. Which shall we believe, the first or the second prophecy?

Then went Habakkuk to comfort her and said, The Holy One (blessed be He!) sent me to thee to comfort thee. She said to him, What hast thou in thine hand to comfort me? The Prophet said (iii. 13), "Thou wentest forth for the salvation of Thy people, even for the salvation with Thine Anointed One!" But Jerusalem said to him, Only yesterday thou toldest me (i. 2), "O Lord, how long shall I cry and Thou wilt not hear, even cry out unto Thee of violence and Thou wilt not save!" and now thou speakest to me thus. Which shall we believe, the first or the second prophecy?

Then went Zephaniah to comfort her and said, The Holy One (blessed be He!) sent me to thee to comfort thee. She said to him, What hast thou in thine hand to comfort me? The Prophet said (i. 12), "And it shall come to pass at that time that I shall search Jerusalem with lights!" But Jerusalem said to him, Only yesterday thou toldest me (i. 15), "A day of darkness and gloominess!" and now thou speakest to me thus. Which shall we believe, the first or the second prophecy?

Then went Haggai to comfort her and said, The Holy One (blessed be He!) sent me to thee to comfort thee. She said to him, What hast thou in thine hand to comfort me? The Prophet said (ii. 19), "Is the seed yet in the barn! Yea, as yet the vine and the fig tree and the pomegranate and the olive tree hath not brought forth: from this day will I bless you!" But Jerusalem said to him, Only yesterday thou toldest me (i. 6), "Ye have sown much and bring in little, &c.!" and now thou speakest to me thus. Which shall we believe, the first or the second prophecy.

Then went Zechariah to comfort her and said, The Holy One (blessed be He!) sent me to thee to comfort thee. She said to him, What hast thou in thine hand to comfort me? The Prophet said (i. 15), "And I am very sore displeased with the heathen that are at ease: for I was but a little displeased and they helped forward the affliction!" But Jerusalem said to him, Only yesterday thou toldest me (i. 2), "The Lord hath been sore displeased with your fathers!" and now thou speakest to me thus. Which shall we believe, the first or the last prophecy?

Then went Malachi to comfort her and said, The Holy One (blessed be He!) sent me to thee to comfort thee. She said to him, What hast thou in thine hand to comfort me? The Prophet said (iii. 12), "And all nations shall call you blessed: for ye shall be a delightsome land!" But Jerusalem said to him, Only yesterday thou toldest me (i. 10), "I have no delight in you!" and now thou speakest to me thus. Which shall we believe, the first or the last prophecy?

Then went all the Prophets to the Holy One (blessed be He!) saying to Him, Lord of the Universe, Jerusalem will not accept consolation at our hands. Then the Holy One (blessed be He!) said to them, "I and you will together go to comfort her; and this is why it says (Isaiah xl. 1), Comfort ye, comfort ye my people, comfort her with me.[3] Comfort her, ye celestial ones! comfort her, ye terrestrial ones! Comfort her, ye living ones! comfort her, ye dead ones! Comfort her in this world! comfort her in the world to come!

[1] Comp. *Pesiḳto Rabbathi*, ed. Friedmann, leaf 138*b*.

[2] See *Pesiḳto Rabbathi* (ed. Friedmann, leaf 138*b*), where it says (before the paragraph on *Nahum*), "'Obadyah prophesied for Edom, and Yonah for Nineveh." This, it is true, is a mere gloss; but it is the true reason why these two prophets are left out.

[3] There is a play here upon the meaning of the Hebrew עמי, which may be read either '*Ammi* ("my people") or '*Immi* ("with me").

Second Specimen.—And whom does He try? The righteous one; for it says (Ps. xi. 5), "The Lord trieth the righteous." And by what does He try him? By the feeding of sheep. David He tried by sheep and found him a good shepherd, for it says (Ps. lxxviii. 70), "And He took him from the 'restraints' of sheep." What is the meaning of '*Mimmikhleoth?*' The root is the same as that of '*vayyikkale* [*haggeshem*] (Gen. viii. 2), "And the rain was restrained." David restrained the big sheep in favour of the small ones. He brought out first the young ones, so that they should feed on the tender herbs; then he brought out the old ones that they should feed on the less tender herbs; and, finally, he brought out the strong sheep that they should feed on the coarser herbs. Upon this the Holy One (blessed be He!) said, He who understandeth to feed sheep according to their strength, let him come and feed My people! And this it is what is written (Ps. lxxviii. 71), "*From following the ewes great with young He brought him to feed Jacob His people!*" And the same was the case as regards Moses, whom the Holy One (blessed be He!) tried by sheep. Our rabbis say, When Moses our teacher (peace be upon him!) was feeding the sheep of Jethro in the wilderness, a kid ran away from him, and Moses ran after it till they came to a mountain-hollow. When it had reached the mountain-hollow there was a pool of water, and the kid stood still in order to drink. When Moses reached the kid he said to it, I did not know that thou didst run away from me because thou wast thirsty and faint. Thereupon he put it on his shoulders and walked back with it to the flock.[4] Then said the Holy One (blessed be He!), Thou art compassionate in the feeding of sheep belonging to mere flesh and blood (man); as thou livest, thou shalt feed My flock, even Israel! Behold, this it is that is written (Exod. iii. 1), "And Moses was feeding the flock, &c." (S. M. S.-S.)

MIEDZYRZECZ PODLASKI (Russian, *Mejiryechie*), a district town of Russian Poland, in the government of Siedlce, 16 miles to the east of the government capital, on the railway between Warsaw and Brest-Litovskiy. It is first mentioned in the year 1390 as a feudal dominion of King Yaghello. After frequently changing hands it became the property of the Czartoryski, and afterwards of the Potocki family, whose palace is still to be seen in the town. Its 10,000 inhabitants—half of whom are Greek nonconformists, and half Jews and Poles—carry on some trade in bristles, and pursue minor industries.

MIERIS, the name of a family of artists who practised painting at Leyden for three generations in the 17th and 18th centuries.

I. Frans van Mieris, the elder, son of Jan van Mieris, a goldsmith and diamond setter, was born, according to Houbraken, at Leyden on the 16th of April 1635, and died there on the 12th of March 1681. His father wished to train him to his own business, but Frans preferred drawing to chasing, and took service with Abraham Torenvliet, a glazier who kept a school of design. As often happens, the youth's style was influenced by his earliest surroundings. In his father's shop he became familiar with the ways and dress of people of distinction. His eye was fascinated in turn by the sheen of jewellery and stained glass; and, though he soon gave up the teaching of Torenvliet for that of Gerard Dow and Abraham van den Tempel, he acquired a manner which had more of the finish of the exquisites of the Dutch school than of the breadth of the disciples of Rembrandt. It should be borne in mind that he seldom chose panels of which the size exceeded 12 to 15 inches, and whenever his name is attached to a picture above that size we may surely assign it to his son Willem or to some other imitator. Unlike Gerard Dow when he first left Rembrandt, or Jan Steen when he started on an independent career, he never ventured to design figures as large as life. Characteristic of his art in its minute proportions is a shiny brightness and metallic polish. The subjects which he treated best are those in which he illustrated the habits or actions of the wealthier classes; but he sometimes succeeded in homely incidents and in portrait, and not unfrequently he ventured on allegory. He repeatedly painted the satin skirt which Terburg brought into fashion, and he often rivalled Terburg in the faithful rendering of rich and highly-coloured woven tissues. But he remained below Terburg and Metzu, because he had not their delicate perception of harmony or their charming mellowness of touch and tint, and he fell behind Gerard Dow, because he was hard and had not his feeling for effect by concentrated light and shade. In the form of his composition, which sometimes represents the framework of a window enlivened with

[4] Who, on reading this, does not think of such passages in the New Testament as Matt. xviii. 12, xxv. 21, and John x. 14?

greenery, and adorned with bas-reliefs within which figures are seen to the waist, his model is certainly Gerard Dow. It has been said that he possessed some of the humour of Jan Steen, who was his friend, but the only approach to humour in any of his works is the quaint attitude and look of a tinker in a picture at Dresden, who glances knowingly at a worn copper kettle which a maid asks him to mend.

It is a question whether Houbraken has truly recorded this master's birthday. One of his best-known pieces, a party of ladies and gentlemen at an oyster luncheon in the hermitage at St Petersburg, bears the date of 1650. Celebrated alike for composition and finish, it would prove that Mieris had reached his prime at the age of fifteen. Another beautiful example, the Doctor Feeling a Lady's Pulse in the gallery of Vienna, is dated 1656; and Waagen, in one of his critical essays, justly observes that it is a remarkable production for a youth of twenty-one. In 1657 Mieris was married at Leyden in the presence of Jan Potheuck, a painter, and this is the earliest written record of his existence on which we can implicitly rely. Of the numerous panels known to the writer of these lines, twenty-nine at least are dated,—the latest being an allegory, long in the Ruhl collection at Cologne, illustrating the kindred vices of drinking, smoking, and dicing, in the year 1680.

Mieris had numerous and distinguished patrons. He received valuable commissions from Archduke Leopold, the elector-palatine, and Cosmo III., grand-duke of Tuscany. His practice was large and lucrative, but never engendered in him either carelessness or neglect. If there be a difference between the painter's earlier and later work, it is that the former was clearer and more delicate in flesh, whilst the latter was often darker and more livid in the shadows. When he died his clients naturally went over to his son Willem, who in turn bequeathed his painting-room to his son Frans. But neither Willem nor Frans the younger equalled Frans the elder.

II. Willem van Mieris (1662–1747), son of Frans. His works are extremely numerous, being partly imitations of the paternal subjects, or mythological episodes, which Frans habitually avoided. In no case did he come near the excellence of his sire.

III. Frans van Mieris the younger (1689–1763) also lived on the traditions of his grandfather's painting-room.

The pictures of all the generations of the Mieris family were successfully imitated by A. D. Snaphaan, who lived at Leipsic and was patronized by the court of Anhalt-Dessau. To those who would study his deceptive form of art a visit to the collection of Wörlitz near Dessau may afford instruction.

MIGNARD, Pierre (1610–1695), called—to distinguish him from his brother Nicholas—Le Romain, was the chief French portrait-painter of the 17th century. He was born at Troyes in 1610, and came of a family of painters. In 1630 he left the studio of Simon Vouet for Italy, where he spent twenty-two years, and made a reputation which brought him a summons to Paris. Successful with his portrait of the king, and in favour with the court, Mignard pitted himself against Le Brun, declined to enter the Academy of which he was the head, and made himself the centre of opposition to its authority. The history of this struggle is most important, because it was identical, as long as it lasted, with that between the old guilds of France and the new body which Colbert, for political reasons, was determined to support. Shut out, in spite of the deserved success of his decorations of the cupola of Val de Grace (1664), from any great share in those public works the control of which was the attribute of the new Academy, Mignard was chiefly active in portraiture. Turenne, Bossuet, Maintenon (Louvre), La Vallière, Sévigné, Montespan, Descartes (Castle Howard), all the beauties and celebrities of his day, sat to him. His readiness and skill, his happy instinct for grace of arrangement, atoned for want of originality and real power. With the death of Le Brun (1690) the situation changed; Mignard deserted his allies, and succeeded to all the posts held by his opponent. These late honours he did not long enjoy; in 1695 he died whilst about to commence work on the cupola of the Invalides. His best compositions have been engraved by Audran, Edelinck, Masson, Poilly, and others.

MIGNONETTE, or Mignonnette (*i.e.*, "little darling"), the name given to a popular garden flower, the *Reseda odorata* of botanists, a "fragrant weed," as Cowper calls it, highly esteemed for its delicate but delicious perfume. The mignonette is generally regarded as being of annual duration, and is a plant of diffuse decumbent twiggy habit, scarcely reaching a foot in height, clothed with bluntish lanceolate entire or three-lobed leaves, and bearing longish spikes—technically racemes—of rather insignificant flowers at the ends of the numerous branches and branchlets. The plant thus naturally assumes the form of a low dense mass of soft green foliage studded over freely with the racemes of flowers, the latter unobtrusive and likely to be overlooked until their diffused fragrance compels attention. The native country of the original or typical mignonette has sometimes been considered doubtful, but according to the best and latest authorities it has been gathered wild on the North African coast near Algiers, in Egypt, and in Syria. As to its introduction, a MS. note in the library of Sir Joseph Banks records that it was sent to England from Paris in 1742; and ten years later it appears to have been sent from Leyden to Philip Miller at Chelsea. Though originally a slender and rather straggling plant, there are now some improved garden varieties in which the growth is more compact and vigorous, and the inflorescence bolder, though the odour is perhaps less penetrating. The small six-petalled flowers are somewhat curious in structure: the two upper petals are larger, concave, and furnished at the back with a tuft of club-shaped filaments, which gives them the appearance of being deeply incised, while the two lowest petals are much smaller and undivided; the most conspicuous part consists of the anthers, which are numerous and of a brownish red, giving the tone of colour to the inflorescence. In a new variety named Golden Queen the anthers have a decided tint of orange-yellow, which imparts a brighter golden hue to the plants when in blossom. A handsome proliferous or double-flowered variety has also been obtained, which is likely to be a very useful decorative plant, though only to be propagated by cuttings; the double white flowers grow in large massive panicles (proliferous racemes), and are equally fragrant with those of the ordinary forms.

What is called tree mignonette in gardens is due to the skill of the cultivator. Though practically a British annual, as already noted, since it flowers abundantly the first season, and is utterly destroyed by the autumnal frosts, and though recorded as being annual in its native habitat by Desfontaines in the *Flora Atlantica*, the mignonette, like many other plants treated in England as annuals, will continue to grow on if kept in a suitable temperature. Moreover, the life of certain plants of this semiannual character may be prolonged into a second season if their flowering and seeding are persistently prevented. In applying these facts to the production of tree mignonette, the gardener grows on the young plants under glass, and prevents their flowering by nipping off the blooming tips of the shoots, so that they continue their vegetative growth into the second season. The young plants are at first supported in an erect position, the laterals being removed so as to secure clean upright stems, and then at the height of one or two feet or more, as may be desired, a head of branches is encouraged to develop itself. In this way very large plants can be produced.

For ordinary purposes, however, other plans are adopted. In the open borders of the flower garden mignonette is usually sown in spring, and in great part takes care of itself; but, being a favourite either for window or balcony culture, and on account of its fragrance a welcome inmate of town conservatories, it is also very extensively

grown as a pot plant, and for market purposes with this object it is sown in pots in the autumn, and thinned out to give the plants requisite space, since it does not transplant well, and it is thereafter specially grown in pits protected from frosts, and marketed when just arriving at the blooming stage. In this way hundreds of thousands, probably, of pots of blooming mignonette are raised and disposed of year by year.

In classifying the odours given off by plants Rimmel ranks the mignonette in the class of which he makes the violet the type; and Fée adopts the same view, referring it to his class of "iosmoids" along with the violet and wallflower.

The name is sometimes, but it would appear less correctly, written mignionette. The genus *Reseda* contains some other interesting and useful species,—among them the *Reseda Luteola*, which is commonly called dyer's-weed and weld, and yields a valuable yellow dye.

MIGUEL, MARIA EVARIST (1802–1866), usually known as DON MIGUEL, whose name is chiefly associated with his pretensions to the throne of Portugal, was the third son of King John VI. of Portugal, and of Carlotta Joachima, one of the Spanish Bourbons; he was born at Lisbon on October 26, 1802. In 1807 he accompanied his parents in their flight to Brazil, where he was permitted to grow up a spoiled child and a worthless youth; in 1821, on his return to Europe, it is said that he had not yet learned to read. In 1822 his father swore fidelity to the new Portuguese constitution which had been proclaimed in his absence; and this led Carlotta Joachima, who was an absolutist of the extremest Bourbon type, and otherwise hated her husband, to resolve to seek his dethronement in favour of Miguel her favourite son. The insurrections which ensued (see PORTUGAL) resulted in her relegation to the castle of Queluz and the exile of Miguel (1824), who spent a short time in Paris and afterwards lived in Vienna, where he came under the teaching of Metternich. On the sudden death of John VI. in May 1826, Pedro of Brazil, his eldest son, renounced the crown in favour of his daughter Maria da Gloria, on the understanding that she should become the wife of Miguel. The last-named accordingly swore allegiance to Pedro, to Maria, and to the constitution which Pedro had introduced, and on this footing was appointed regent in July 1827. He arrived in Lisbon in February 1828, and, regardless of his promises, dissolved the new Cortes in March; having called together the old Cortes, with the support of the reactionary party of which his mother was the ruling spirit, he got himself proclaimed sole legitimate king of Portugal in July. The power which he now enjoyed he wielded in the most tyrannical manner for the repression of all liberalism, and his private life was characterized by the wildest excesses. The public opinion of Europe became more and more actively hostile to his reign, and after the occupation of Oporto by Don Pedro in 1832, the destruction of Miguel's fleet by Captain (afterwards Sir Charles) Napier off Cape St Vincent in 1833, and the victory of Saldanha at Santarem in 1834, Queen Christina of Spain recognized the legitimate sovereignty of Maria, and in this was followed by France and England. Don Miguel capitulated at Evora on May 29, 1834, renouncing all pretensions to the Portuguese throne, and solemnly promising never thenceforward to meddle in Peninsular affairs. He lived for some time at Rome, where he enjoyed papal recognition, but afterwards retired to Bronnbach, in Baden, where he died on November 14, 1866.

MIGULINSKAYA, a Cossack village (*stanitsa*) of Russia, in the government of the Don Cossacks, and in the district of Ust-Medvyeditsa, 79 miles to the west of that town, on the left bank of the Don. It is one of the largest and wealthiest *stanitsas* of the government, and has 20,600 inhabitants, who are engaged in agriculture and stock-breeding, and in the export of agricultural produce.

MIKHAILOVSKAYA, a Cossack village (*stanitsa*) of Russia, in the government of the Don Cossacks, and in the district of Khopersk, 14 miles to the north-west of Uryupino, on the low left bank of the Khoper, which is inundated when the river is full. It has an important fair, where Tartars from Astrakhan exchange furs and cottons for manufactured and grocery wares imported from central Russia; the inhabitants of the district also sell corn, cattle, and plain woollen stuffs. Population, 18,000.

MILAN (the Latin *Mediolanum*, Italian *Milano*, and German *Mailand*), a city of Italy, situated near the middle of the Lombard plain, on the small river Olona, in 45° 27′ 35″ N. lat. and 9° 5′ 45″ E. long. It is 390 feet above the sea-level, and lies 25 miles south of the Alps at Como, 30 miles north of the Apennines, 20 miles east of the Ticino, and 15 miles west of the Adda.

The plain around Milan is extremely fertile, owing at once to the richness of the alluvial soil deposited by the Po, Ticino, Olona, and Adda, and to the excellent system of irrigation. Seen from the top of the cathedral, the plain presents the appearance of a vast garden divided into square plots by rows of mulberry or poplar trees. To the east this plain stretches in an unbroken level, as far as the eye can follow it, towards Venice and the Adriatic; on the southern side the line of the Apennines from Bologna to Genoa closes the view; to the west rise the Maritime, Cottian, and Graian Alps, with Monte Viso as their central point; while northward are the Pennine, Helvetic, and Rhætian Alps, of which Monte Rosa, the Saasgrat, and Monte Leone are the most conspicuous features. In the plain itself lie many small villages; and here and there a larger town like Monza or Saronno, or a great building as the Certosa of Pavia, makes a white point upon the greenery.

The commune of Milan consists since 1873 of the city within the walls (area 1513 acres) and the so-called Corpi Santi[1] without the walls (area 15,415 acres). The population of the whole area increased from 134,528 in 1800 to 242,457 in 1861, 261,985 in 1871, and 321,839 in 1881,—the city within the walls contributing 110,884 in 1801, 196,109 in 1861, 199,009 in 1871, and 214,004 in 1881. The climate is very variable; there is a difference of 41° Fahr. between the extreme summer heat and winter cold. The average number of wet days is 72, and of snowy days 10 per annum.

Milan is built in a circle, the cathedral being the central point. The city is surrounded by a wall 7 miles in circumference, and immediately outside the wall a fine broad thoroughfare makes the circuit of the city. The streets inside are for the most part narrow and crooked; the main streets are the Corso Vittorio Emanuele, the Strada S. Margherita, the Via Manzoni, the Corso Porta Ticinese, and the Corso Porta Romana. There are few piazzas of any size; the largest is the Piazza del Duomo, which has recently been extended, and the houses around it modernized. To the west of the city is the open space of the Foro Bonaparte and the Piazza d'Armi, with the square keep of the Visconti castle, flanked by two granite towers, between them. The castle was partly destroyed in 1447 by the Ambrosian republic, rebuilt by Francesco Sforza, enlarged by the Spanish governors, and taken by Napoleon in 1800, when the outer fortifications were razed to the ground, and the walls left as they now are. North of the Piazza d'Armi is the modern cemetery, with a special building and apparatus for cremation, erected in 1876.

Among the buildings of Milan the most important is the cathedral, begun under Gian Galeazzo Visconti, in 1386. It is built of brick cased in marble from the quarries which Visconti gave in perpetuity to the cathedral chapter. The

[1] The name Corpi Santi (of doubtful origin) is also applied to the extra-mural portions of Cremona and Pavia.

but it is not so rich in MSS. as the celebrated Ambrosian library, for which see LIBRARIES, vol. xiv. p. 531.

Agriculture.—The district of Milan is renowned for its excellent agriculture. It may be divided into two regions, where different systems of farming are pursued and different crops produced. The first region lies on the lower slopes of the Alps, where they sink into the plain. This is called the dry Milanese, for it is watered by torrents only, which have worn themselves too deep a bed to allow of irrigation, and the peasants are obliged to collect the rain-water in large mud-lined tanks called "poppe." The soil is for the most part thin and light, and is frequently washed down the incline into the plain; in some parts it is only kept in its place by stone walls reared at great cost. The farms are smaller here than in the lower plain, and are let on a system which is a compromise between the mezzadria, which once obtained in the district, and regular leases. The tenant pays a money rent for the house; and for the land he either pays in kind or in a money equivalent, supplemented by labour given to the landlord. In cases where vines or fruit trees are grown, the landlord supplies and maintains them till they come into fruit. The landlord carries out all improvements, and the tenant holds the farm at his pleasure. The rotation of cropping is for three years. The value of these farms varies greatly, ranging from 7 to 14 lire the pertica (1000 square yards). The district produces maize and wheat in abundance, a little flax and millet, apples, and wine. The second agricultural district is that which lies in the plain; it is called the wet Milanese, from the elaborate system of irrigation which makes the meadows yield a constant succession of crops. The plain is traversed by innumerable canals at various levels, crossing one another on bridges, or by siphons, so that the peasant can flood his fields at any moment. The system is as old as the 12th century; it was improved by Leonardo da Vinci, and is now the most perfect network of irrigation in Europe. The farms vary in extent from 1500 to 4500 pertiche. They are let upon leases for nine, twelve, or fifteen years, at rents ranging from 8·50 to 12·50 lire the pertica, while those near a city may bring from 15 to 20 lire. The rotation of cropping is five-yearly. The meadows yield four crops of grass in the year; the first three—the maggengo, the agostino, and the terzuolo—are cut, the fourth is grazed off. Where the ground is perfectly flat and water can stagnate, rice is grown; this crop is continued for four years in succession, then the land is rested with cereals and grass. The other crops are maize and wheat. But the chief occupation is the supply of dairy produce. The cows are bought in the Swiss cantons of Uri, Zug, Lucerne, and Schwyz, the last furnishing the best milkers. The cheese called Parmesan comes from the Milanese; and the rich cheese, made of unskimmed milk, known as Stracchino, is made principally at the village of Gorgonzola, 12 miles east of Milan.

Industries.—The industries of this district have increased very rapidly since the union of Italy, and the city is now the chief commercial centre in North Italy. The principal industry of Milan and the Milanese is the production and manufacture of silk. For feeding the worms mulberry trees are largely cultivated on the plain; and the district counts upwards of 200 factories, where the silk thread is unwound from the cocoons, yielding 4,000,000 ℔ of raw silk in the year. Some of this is exported to France for manufacture, but the Milanese can now almost rival their neighbours in the production of silk stuffs, velvets, and brocades. Cotton is manufactured at Saronno and Legnano, fustian at Busto, linen at Cassano, combs at Burlando, and porcelain and carriages of very excellent workmanship in Milan itself.

History.—Bellovesus, king of the Celts, who crossed the Alps when Tarquinius Priscus was king in Rome, is the traditional founder of Milan. The city became the capital of the Insubrian Gauls, and was taken by the Romans in 222 B.C. As a Roman municipium it continued to increase in magnificence and importance; and under Constantine it was the seat of the imperial vicar of the West. Under Theodosius, in the 4th century, Milan, to judge from Ausonius's description (*Ordo Nob. Urbium*, v.), must have been rich in temples and public buildings. Theodosius died at Milan after doing penance, at the bidding of St Ambrose, for his slaughter of the people of Thessalonica. Ambrose is still venerated in Milan as the founder of the Milanese church and the compiler of the Ambrosian rite, which is still in use throughout the diocese. After his death the period of invasions begins; and Milan felt the power of the Huns under Attila (452), of the Heruli under Odoacer (476), and of the Goths under Theodoric (493). When Belisarius was sent by Justinian to recover Italy, Datius, the archbishop of Milan, joined him, and the Goths were expelled from the city. But Uraia, nephew of Vitigis the Gothic king, subsequently assaulted and retook the town, after a brave resistance. Uraia destroyed the whole of Milan in 539; and hence it is that this city, once so important a centre of Roman civilization, possesses so few remains of antiquity. Narses, in his campaigns against the Goths, had invited other barbarians, the Lombards, to his aid. They came in a body under Alboin, their king, in 568, and were soon masters of North Italy, and entered Milan the year following. Alboin established his capital at Pavia, and Milan remained the centre of Italian opposition to the foreign conquest.

The Lombards were Arians, and the archbishops of Milan from the days of Ambrose had been always orthodox. Though the struggle was unequal, their attitude of resolute opposition to the Lombards gained for them great weight among the people, who felt that their archbishop was a power around whom they might gather for the defence of their liberty and religion. All the innate hatred of the foreigner went to strengthen the hands of the archbishops, who slowly acquired, in addition to their spiritual authority, powers military, executive, and judicial. These powers they came to administer through their delegates, called viscounts. When the Lombard kingdom fell before the Franks under Charles the Great in 774, the archbishops of Milan were still further strengthened by the close alliance between Charles and the church, which gave a sort of confirmation to their temporal authority, and also by Charles's policy of breaking up the great Lombard fiefs and dukedoms, for which he substituted the smaller counties. Under the confused government of Charles's immediate successors the archbishop was the only real power in Milan. But there were two classes of difficulties in the situation, ecclesiastical and political; and their presence had a marked effect on the development of the people and the growth of the commune, which was the next stage in the history of Milan. On the one hand the archbishop was obliged to contend against heretics or against fanatical reformers who found a following among the people; and on the other, since the archbishop was the real power in the city, the emperor, the nobles, and the people each desired that he should be of their party; and to whichever party he did belong he was certain to find himself violently opposed by the other two. From these causes it sometimes happened that there were two archbishops, and therefore no central control, or no archbishop at all, or else an archbishop in exile. The chief result of these difficulties was that a spirit of independence and a capacity of judging and acting for themselves was developed in the people of Milan. The terror of the Hunnish invasion, in 899, further assisted the people in their progress towards freedom, for it compelled them to take arms and to fortify their city, rendering Milan more than ever independent of the feudal lords who lived in their castles in the country. The tyranny of these nobles drove the peasantry and smaller vassals to seek the protection for life and property, the equality of taxation and of justice, which could be found only inside the walled city and under the rule of the archbishop. Thus Milan grew populous, and learned to govern itself. Its inhabitants became for the first time Milanese, attached to the standard of St Ambrose,—no longer subjects of a foreign conqueror, but a distinct people, with a municipal life and prospects of their own. For the further growth of the commune, the action of the great archbishop Heribert, the establishment of the carroccio, the development of Milanese supremacy in Lombardy, the destruction of Lodi, Como, Pavia, and other neighbouring cities, the exhibition of free spirit and power in the Lombard league, and the battle of Legnano, see the article ITALY. See also LOMBARDS.

After the battle of Legnano, in 1174, although the Lombard cities failed to reap the fruit of their united action, and fell to mutual jealousy once more, Milan internally began to grow in material prosperity. After the peace of Constance (1183) the city walls were extended; the arts flourished, each in its own quarter, under a syndic who watched the interests of the trade. The manufacture of armour was the most important industry. During the struggles with the emperor Barbarossa, when freedom seemed on the point of being destroyed, many Milanese vowed themselves, their goods, and their families to the Virgin should their city come safely out of her troubles. Hence arose the powerful fraternity of the "Umiliati," who established their headquarters at the Brera, and began to develop the wool trade, and subsequently gave the first impetus to the production of silk. From this period also date the irrigation works which render the Lombard plain a fertile garden. The government of the city consisted of (A) a parlamento or consiglio grande, including all who possessed bread and wine of their own,—a council soon found to be unmanageable owing to its size, and reduced first to 2000, then to 1500, and finally to 800 members; (B) a credenza or committee of twelve members, elected in the grand council, for the despatch of urgent or secret business; (C) the consuls, the executive, elected for one year, and compelled to report to the great council at the term of their office. The way in which the burghers used their liberty and powers, secured by the peace of Constance, in attacking the feudal nobility; how they compelled the nobles to come into the city and to abandon their castles for a certain portion of the year; how the war between the two classes was continued inside the city, resulting in the establishment of the podestà; and the nature and limits of this office,—all this has been explained in the article ITALY.

This bitter and well-balanced rivalry between the nobles and the people, and the endless danger to which it exposed the city owing to the fact that the nobles were always ready to claim the protec-

tion of their feudal chief, the emperor, brought to the front two noble families as protagonists of the contending factions,—the Torriani of Valsassina, and the Visconti, who derived their name from the office they had held under the archbishops. After the battle of Cortenova, in 1237, where Frederick II. defeated the Guelf army of the Milanese and captured their carroccio, Pagano della Torre rallied and saved the remnants of the Milanese. This act recommended him to popular favour, and he was called to the government of the city,—but only for the distinct purpose of establishing the "catasta," a property tax which should fall with equal incidence on every citizen. This was a democratic measure which marked the party to which the Torriani belonged and rendered them hateful to the nobility. Pagano died in 1241. His nephew Martino followed as podestà in 1256, and in 1259 as signore of Milan,—the first time such a title was heard in Italy. The nobles, who had gathered round the Visconti, and who threatened to bring Ezzelino da Romano, the Ghibelline tyrant of Padua, into the city, were defeated by Martino, and nine hundred of their number were captured. Martino was followed by two other Torriani, Filippo his brother (1263–65) and Napoleone his cousin (1265–77), as lords of Milan. Napoleone obtained the title of imperial vicar from Rudolph of Hapsburg. But the nobles under the Visconti had been steadily gathering strength, and Napoleone was defeated at Desio in 1277. He ended his life in a wooden cage at Castel Baradello above Como.

Otho Visconti, archbishop of Milan (1262), the victor of Desio, became lord of Milan, and founded the house of Visconti, who ruled the city—except from 1302 to 1310—till 1447, giving twelve lords to Milan. Otho (1277–95), Matteo (1310–22), Galeazzo (1322–28), Azzo (1328–39), Lucchino (1339–49), and Giovanni (1349–54) followed in succession. Giovanni left the lordship to three nephews—Matteo, Galeazzo, and Bernabò. Matteo was killed (1355) by his brothers, who divided the Milanese, Bernabò reigning in Milan (1354–85) and Galeazzo in Pavia (1354–78). Galeazzo left a son, Gian Galeazzo, who became sole lord of Milan by seizing and imprisoning his uncle Bernabò. For an account of this most powerful prince see ITALY. It was under him that the cathedral of Milan and the Certosa of Pavia were begun. He was the first duke of Milan, having obtained that title from the emperor Wenceslaus. His sons Giovanni Maria, who reigned at Milan (1402–1412), and Filippo Maria, who reigned at Pavia (1402–1447), succeeded him. In 1412, on his brother's death, Filippo united the whole duchy under his sole rule, and attempted to carry out his father's policy of aggrandizement, but without success.

Filippo was the last male of the Visconti house. At his death a republic was proclaimed, which lasted only three years. In 1450 the general Francesco Sforza, who had married Filippo's only child Bianca Visconti, became duke of Milan by right of conquest if by any right. Under this duke the canal of the Martesana, which connects Milan with the Adda, and the Great Hospital were carried out. Francesco was followed by five of the Sforza family. His son Galeazzo Maria (1466–76) left a son, Gian Galeazzo, a minor, whose guardian and uncle Lodovico usurped the duchy (1479–1500). Lodovico was captured in 1500 by Louis XII. of France, and Milan remained for twelve years under the French crown. In the partial settlement which followed the battle of Ravenna, Massimiliano Sforza, a protegé of the emperor, was restored to the throne of Milan, and held it by the help of the Swiss till 1515, when Francis I. of France reconquered the Milanese by the battle of Marignano, and Massimiliano resigned the sovereignty for a revenue from France. This arrangement did not continue. Charles V. succeeded the emperor Maximilian, and at once disputed the possession of the Milanese with Francis. In 1522 the imperialists entered Milan and proclaimed Francesco Sforza (son of Lodovico). Francesco died in 1535, and with him ended the house of Sforza. From this date till the war of the Spanish succession (1714) Milan was a dependency of the Spanish crown. At the close of that war it was handed over to Austria; and under Austria it remained till the Napoleonic campaign of 1796. For the results of that campaign, and for the history of Italian progress towards independence, in which Milan played a prominent part by opening the revolution of 1848, the reader is referred to the article ITALY. The Lombard campaign of 1859, with the battles of Solferino and Magenta, finally made Milan a part of the kingdom of Italy.

Scriptores*; Sismondi, *Italian Republics*; Ferrari, *Rivoluzione d' Italia*; Litta, *Famiglie celebri, s.v.* "Torriani," "Visconti," "Sforza," and "Trivulzi;" Muratori, *Annali d'Italia*; Hallam, *History of the Middle Ages*; and *Mediolanum*, 4 vols., 1881. Bonvicino da Riva gives a contemporary account of Milan in the 12th century. (H. F. B.)

MILAZZO, a city of Italy in the province of Messina in Sicily, 20½ miles west of Messina, is built on the eastern shore of the Bay of Milazzo, partly on the isthmus of the promontory, Capo Milazzo, which divides it from the Bay of Olivieri. It consists of an old or upper town protected by strong bastioned walls, and a lower or modern town outside of the enceinte. The fine old castle is now used as a prison. Besides a certain amount of foreign commerce (37 vessels with a burden of 6707 tons entering in 1881, 93 with 13,496 in 1863), Milazzo carries on a good coasting trade (194,366 tons in 1881, 40,138 in 1861), and is one of the seats of the tunny-fishery. The communal population increased from 10,493 in 1861 to 13,565 in 1881, and that of the city was 7427 in 1871.

Milazzo is the ancient Mylæ, a seaport and fortress founded by the Zanclæans (Messanians), which gives its name to the battle of the Mylæan plain in which the Mamertines were defeated by Hiero in 270 B.C. In 1523 it was the scene of an unsuccessful conspiracy to transfer Sicily to the French. Captured by the Germans in 1718, it was besieged by the Spaniards, but relieved by a Neapolitan and English force. In July 1860 the defeat of the Neapolitans in the vicinity, and the seizure of the fortress, formed almost the crowning act of Garibaldi's victorious campaign. The Bay of Milazzo has been the scene of the defeat of the Carthaginian navy by Duilius (260 B.C.), of Pompeius by Octavian's general Agrippa (36 B.C.), and of the French and Messinian galleys by the Pisans (1268).

MILDEW (explained as "meal-dew" or, with more probability, as "honey-dew") is a popular name given to various minute fungi from their appearance, and from the sudden, dew-like manner of their occurrence. Like many other popular names of plants, it is used to denote different species which possess very small botanical affinity. The term is applied, not only to species belonging to various systematic groups, but also to such as follow different modes of life. The corn-mildew, the hop-mildew, and the vine-mildew are, for example, parasitic upon living plants, and the mildews of damp linen and of paper are saprophytes, that is, they subsist on matter which is already dead. It is generally possible to draw a distinct line between parasitic and saprophytic fungi; a species which attacks the living body of its host does not grow on dead matter, and *vice versa*. This is true so far as is known of perhaps all the higher fungi except *Saprolegnia ferax* (Gruith.), a parasite of freshwater fishes (especially of the salmon), which also grows freely on their dead bodies and on those of flies, &c. As regards mildews in general, the conditions of life and growth are mainly suitable nutrition and dampness accompanied by a high temperature. The life-history of the same species of mildew frequently covers two or more generations, and these are often passed on hosts of different kinds. In some cases again the same generation confines its attack to the same kind of host, while in others the same generation grows on various hosts. For information regarding fungi generally see FUNGUS, vol. ix. p. 827.

The following examples are of common occurrence.

The Corn-Mildew (*Puccinia graminis*, Pers., Order *Uredineæ*).—This disease of our grain crops and of many other grass plants is very widely distributed, like its hosts, over the earth, and is by far the most important to man of all mildews. Its life-history is passed in three generations —two of them on the grass plants and one on the barberry. In early spring the first generation is found on the dead leaves and leaf-sheaths of grass plants (in which the disease has hibernated), presenting to the naked eye the appearance of thin black streaks. When examined with a microscope these streaks are seen to consist of a great number of minute two-celled and thick-walled teleutospores (reproductive bodies), each situated at the end of a stalk (see A in fig. 2, vol. ix. p. 831). These have burst through the epidermis of the plant from their origin on threads among the tissues beneath. When they have been in contact with excessive moisture for a few hours, each of the spore-cells germinates by emitting a fine tube called a promycelium, on which there are borne small round thin-walled sporidia (reproductive bodies). The sporidia are easily detached and carried from place to place by the wind, and on alighting on the leaves of a barberry plant

soon germinate by pushing out a small tube which perforates the epidermis and thus gains access to the interior of the leaf, where it branches copiously, and forms a mass of thread-like tissue called mycelium. The germ-tubes of sporidia are unable to enter the leaves, &c., of grass plants. In from six to ten days this mycelium gives rise to flask-shaped bodies called spermogonia (vol. ix. p. 831, fig. 2 B, *sp*), immediately under the surface of the leaf (usually the upper one), but breaking through it at the neck of the flask, out of which there protrudes a bunch of hairs. Within the flasks are formed at the end of stalks many exceedingly small oval bodies called spermatia, which escape through the neck. The function of these bodies has not yet been definitely made out, but that they bear a very striking resemblance to the male sexual organs of other fungi there can be no doubt. In the same leaves and on the same mycelium there arise several days later numerous basin-shaped bodies containing erect stalks, bearing at the apex a number of round æcidiospores (reproductive bodies) in vertical series (vol. ix. p. 831, fig. 2 B, *a*). These constitute the second generation. On their escape they germinate by emitting a tube which, if the host on which they fall be a grass plant, enters the leaf through one of the stomata in the epidermis, and there by branching forms a new mycelium. On this there soon appears, bursting through the epidermis, a new generation consisting of round or oval uredospores produced at the end of stalks (vol. ix. p. 831, fig. 2 C). The uredospores constantly reproduce this generation, and in such abundance that the grain crops are extensively ravaged by its attack. It is in this generation that the term mildew is popularly given to the fungus. Later in autumn on the same mycelium the two-celled teleutospores appear, and these after hibernating renew in spring the life-history. This very remarkable cycle of generations was first traced by Professor de Bary.

The *Hop-Mildew* (*Sphærotheca Castagnei*, Lev., Order *Erysipheæ*) is a parasitic disease of the hop, though it is often to be found on many other plants, such as *Potentilla*, *Spiræa*, *Epilobium*, balsams, cucumbers, dandelions, plantains, &c. The thread-like mycelium appears on the young shoots and leaves of the hop in white spots, which gradually extend and finally unite. This mycelium bears many minute, round conceptacles (perithecia) which with their supporting threads are brown-coloured. Within each perithecium is found a somewhat oval body termed an ascus, containing eight ascospores (reproductive bodies).

The *Vine-Mildew* (*Erysiphe Tuckeri*, Berk., Order *Erysipheæ*) is known only in one generation—called the oidium stage. Soon after the flowering of the vine the attack takes place on the young leaves, from which the thin white mycelium spreads rapidly to the older leaves and twigs, which it does not appear to affect so injuriously. The chief damage is done to the grapes while they are in a very immature condition. The mycelium which travels over the surface sends down at intervals into the tissues short irregular protuberances called haustoria, which perform for it the functions of roots. Above these rise from the mycelium short stalks bearing each a single oval spore at the apex. The disease spreads on the same plant not only by the extension of the mycelium but by the scattering and germination of the spores. Here no perithecia are known.

The *Paper-Mildew* (*Ascotricha chartarum*, Berk., Order *Erysipheæ*) grows on damp paper, and therefore is saprophytic in its mode of life. It consists at first of a branching filamentous mycelium on which minute globular spores occur. Finally a round brown perithecium is formed among the threads which appear as radiating from it. Within the perithecium are numerous linear asci containing each a row of dark elliptic ascospores.

For the *Erysipheæ* generally see FUNGUS, vol. ix. p. 833.

MILETUS, an ancient city on the southern shore of the Latmic Gulf opposite the mouth of the Mæander. Before the Ionic migration it was inhabited by the Carians (*Iliad* ii. 876; Herod. i. 146); other authorities call the original people Leleges, who are always hard to distinguish from Carians. The Greek settlers from Pylus under Neleus massacred all the men in the city, and built for themselves a new city on the coast. It occupied a very favourable situation at the mouth of the rich valley of the Mæander, and was the natural outlet for the trade of southern Phrygia (Hipponax, *Fr.* 45); it had four harbours, one of considerable size. Its power extended inland for some distance up the valley of the Mæander, and along the coast to the south, where it founded the city of Iasus. The trade with the Black Sea, however, was the greatest source of wealth to the Ionian cities. Miletus like the rest turned its attention chiefly to the north, and after a time it succeeded in almost monopolizing the traffic. Along the Hellespont, the Propontis, and the Black Sea coasts it founded more than sixty cities—among them Abydus, Cyzicus, Sinope, Dioscurias, Panticapæum, and Olbia. All these cities were founded before the middle of the 7th century; and before 500 B.C. Miletus was decidedly the greatest Greek city. During the time when the enterprise and energy of the seafaring population, the ἀειναῦται, raised Miletus to such power and wealth, nothing is known of its internal history. The analogy of all Greek cities, and some casual statements in later writers, suggest that the usual bloody struggles took place between the oligarchy and the democracy, and that tyrants sometimes raised themselves to supreme power in the city; but no details are known. Miletus was equally distinguished at this early time as a seat of literature. The Ionian epic and lyric poetry indeed had its home farther north; philosophy and history were more akin to the practical race of Miletus, and Thales, Anaximander, Anaximenes, Hecatæus, all belonged to this city. The three Ionian cities of Caria—Miletus, Myus, and Priene—spoke a peculiar dialect of Ionic.[1]

When the Mermnad kings raised Lydia to be a great military kingdom, Miletus was their strongest adversary. War was carried on for many years, till Alyattes concluded a peace with Thrasybulus, tyrant of Miletus; the Milesians afterwards seem to have peaceably acknowledged the rule of Crœsus. On the Persian conquest Miletus passed under a new master; it headed the revolt of 500 B.C., and was taken by storm after the battle of Lade. Darius treated it with peculiar severity, massacred most of the inhabitants, transported the rest to Ampe at the mouth of the Tigris, and gave up the city to the Carians. Henceforth the history of Miletus has no special interest; it revived indeed when the Persians were expelled from the coast in 479 B.C., and was a town of commercial importance throughout the Græco-Roman period, when it shared in the general fortunes of the Ionian cities under the rule of Athenians, Persians, Macedonians, Pergamenians, and Romans in succession. Its harbours, once protected by Lade and the other Tragusæan islands, were gradually silted up by the Mæander, and Lade is now a hill some miles from the coast. Ephesus took its place as the great Ionian harbour in the Hellenistic and Roman times. It was the seat of a Christian bishopric, but its decay was sure, and its site is now a marsh.

See Schroeder, *Comment. de Reb. Miles.*; Soldan, *Rer. Miles. Comment.*; Rayet, *Milet et le Golfe Latmique*; Head, "Early Electrum Coins," in *Numism. Chron.*, vol. xvi.

MILFORD, a seaport, market-town, and contributory parliamentary borough (one of the Pembroke district) of Pembrokeshire, South Wales, is finely situated on the north side of Milford Haven, about 8 miles west-north-west of Pembroke. The land-locked estuary of Milford Haven stretches about 10 miles inland, with a

[1] The coinage of Miletus during this early period is an important subject on account of the wide commercial connexions of the city. The early electrum coinage belongs to the Phœnician or Græco-Asiatic standard, which was introduced from Phœnicia and spread over many of the Ionian and Thracian cities through the influence of Milesian trade. Very archaic coins of Miletus, Ephesus, Cyme, and Sardis are known of this standard, and at a somewhat later date of Chios, Samos, Clazomenæ, Lampsacus, Abydus, and Cyzicus. The lion is the regular Milesian type, often with a star beside or above him.

breadth of from 1 to 2 miles. In most places it has a depth of from 15 to 19 fathoms, and, as it is completely sheltered by hills, vessels can ride in it at anchor in all kinds of weather. The royal dockyard, founded at Milford in 1790, was removed in 1811, and from that time trade has been in a languishing condition. The town possesses iron-works. The shipping trade is confined chiefly to coasting vessels, but with the completion of new docks, capable of receiving vessels of the largest tonnage, it is supposed that a considerable trade may be carried on with America. The population of the urban sanitary district in 1871 was 3252, and in 1881 it was 3813.

MILFORD, a post-village of the United States, in Worcester county, Massachusetts, lies 34 miles south-west of Boston, at the junction of the Milford branch of the Boston and Albany Railroad with the Hopkinton, Milford, and Woonsocket Railroad. It is one of the principal seats of the boot manufacture in New England, and also produces large quantities of straw goods. The population was 9310 in 1880.

MILICZ, or MILITSCH, of Kremsier, Moravia, was the most influential among those preachers and writers in Moravia and Bohemia who during the 14th century paved the way for the reforming activity of Huss and through him for that of Luther. He was born about 1325, was already in holy orders in 1350, in 1360 was attached to the court of the emperor Charles IV., whom he accompanied into Germany in that year, and about the same time also held a canonry in the cathedral of Prague along with the dignity of archdeacon. About 1363 he resigned all his appointments that he might become a preacher pure and simple; he addressed scholars in Latin, and (an innovation) the laity in their native Czech, or in German, which he acquired for the purpose. The success of his labours in reclaiming the fallen made itself apparent in the reformation of a whole quarter of the city of Prague. As he dwelt more and more on ecclesiastical abuses and the corruption of the clergy, and viewed them in the light of Scripture, the conviction grew in his mind that the "abomination of desolation" was now seen in the temple of God, and that antichrist had come, and in 1367 he went to Rome (where Urban V. was expected from Avignon) to expound these views. He affixed to the gate of St Peter's a placard announcing his sermon, but before he could deliver it was thrown into prison by the Inquisition. Urban, however, on his arrival ordered his release, whereupon he returned to Prague, and from 1369 to 1372 preached daily in the Teyn Church there. In the latter year the clergy of the diocese complained of him to the papal court at Avignon, whither he was summoned in Lent 1374, and where he died before his case was decided. He was the author of a *Libellus de Antichristo*, written in prison at Rome, a series of *Postillæ* and *Lectiones Quadragesimales* in Latin, and a similar series of *Postils* in Czech.

MILITARY FRONTIER (German, *Militärgrenze*; Slavonic, *Granitza*), a narrow strip of Austrian-Hungarian territory stretching along the borders of Turkey, which had for centuries a peculiar military organization, and from 1849 to 1873 constituted a crown-land. As a separate division of the monarchy it owed its existence to the necessity of maintaining during the 15th, 16th, and 17th centuries a strong line of defence against the invasions of the Turks, and may be said to have had its origin with the establishment of the captaincy of Zengg by Matthias Corvinus and the introduction of Uskoks (fugitives from Turkey) into the Warasdin district by the emperor Ferdinand I. By the close of the 17th century there were three frontier "generalates"—Carlstadt, Warasdin, and Petrinia (the last also called the Banal). After the defeat of the Turkish power by Prince Eugene it was proposed to abolish the military constitution of the frontier, but the change was successfully resisted by the inhabitants of the district; on the other hand, a new Slavonian frontier district was established in 1702, and Maria Theresa extended the organization to the march-lands of Transylvania (the Szekler frontier in 1764, the Wallachian in 1766).[1]

As a reward for the service it rendered the Government in the suppression of the Hungarian insurrection in 1848, the Military Frontier was erected in 1849 into a crown-land, with a total area of 15,182 square miles, and a population of 1,220,503. In 1851 the Transylvanian portion (1177 square miles) was incorporated with the rest of Transylvania; and in 1871 effect was given to the imperial decree of 1869 by which the districts of the Warasdin regiments (St George and the Cross) and the towns of Zengg, Belovar, Ivanič, &c., were "provincialized" or incorporated with the Croatian-Slavonian crown-land. In 1872 the Banat regiments followed suit; and in 1873 the old military organization was abolished in all the rest of the frontier. Not till 1881, however, were the Croatian-Slavonian march-lands completely merged in the kingdoms to which they naturally belonged.

The social aspect of the military frontier régime is interesting. A communal system of land tenure natural to the old Slavonians was artificially kept in existence. The mark or plot of ground assigned to the original family of settlers remained the property of the family as such, and could not be portioned out among the several members. In this way the house-community, all under the rule of the same house-father and house-mother (who were not necessarily man and wife, nor the oldest members of the community), and all living within the same palisade, sometimes came to number two or three hundred persons. The "family" dined in a common hall, and after dinner discussed and settled matters affecting the common weal. Every man possessing real property in the country, and capable of bearing arms, was liable to military service from his twentieth year. The house-communities are now beginning to avail themselves of the permissive partition laws, and strangers are free to come and acquire property in land. Watch-towers with wooden clappers and the beacons which flashed the alarm along the whole frontier in a few hours are still features in the landscape.

MILITARY LAW consists of the statutes, rules of procedure, royal warrants, and orders and regulations which prescribe and enforce the public obligations of the officers, soldiers, and others made subject to its provisions. Its essential purpose is the maintenance of discipline; but it also includes the administrative government of the military forces of the state, more especially in the matters of enlistment, service, and billeting. The term "martial law" sometimes applied to it is, as regards modern times at least, a misnomer. For martial law as it is now understood applies not only to military persons but to the civil community, and may be described generally as the abrogation of ordinary law and the substitution for it of military force uncontrolled save by what, in the discretion of the commanding general, may be considered the necessity of the case.

The military law of England in early times existed, like the forces to which it applied, in a period of war only.

[1] By 1848 the following had come to be the division of the Military Frontier:—(1) *The Carlstadt (Carlowitz), Warasdin, and Banal Generalate*: the Licca Regiment (headquarters at Gospich), the Ottochaz Regiment (Ottochaz), the Ogulin (Ogulin), the Sluin (Carlstadt), the Cross (Belovar), the St George's (Belovar), the 1st Banal (Glina), the 2d Banal (Petrinia). (2) *The Slavonian Generalate*: the Gradiska Regiment (Neu Gradiska), the Brood Regiment (Vinkovcze), the Peterwardein (Mitrovicz), the Tchaikist Battalion (Titel). (3) *The Banat Generalate*: the German Banat Regiment (Pancsova), the Wallachian Banat (Karansebes), the Illyrian Banat (Weisskirchen). (4) *The Transylvanian Generalate*: The Szekler Regiment No. 14 (Csik Szereda), the Szekler Regiment No. 15 (Keszdi Vasarhely), the Wallachian No. 16 (Orlath), the Wallachian No. 17 (Naszod). Twelve towns, known as "military communities," had communal constitutions not unlike those of the free towns of Hungary—Carlopago, Zengg, Petrinia, Kostainicza, Belovar, Ivanič, Brood, Peterwardein, Carlowitz, Semlin, Pancsova, and Weisskirchen.

Troops were raised for a particular service, and were disbanded upon the cessation of hostilities. The crown, of its mere prerogative, made laws known as Articles of War, for the government and discipline of the troops while thus embodied and serving. Except for the punishment of desertion, which offence was made a felony by statute in the reign of Henry VI., these ordinances or Articles of War remained almost the sole authority for the enforcement of discipline until 1689, when the first Mutiny Act was passed and the military forces of the crown were brought under the direct control of parliament. Even the Parliamentary forces in the time of Charles I. and Cromwell were governed, not by an Act of the legislature, but by articles of war similar to those issued by the king and authorized by an ordinance of the Lords and Commons, exercising in that respect the sovereign prerogative. This power of law-making by prerogative was, however, held to be applicable during a state of actual war only, and attempts to exercise it in time of peace were ineffectual. Subject to this limitation it existed for considerably more than a century after the passing of the first Mutiny Act. From 1689 to 1803, although in peace time the Mutiny Act was occasionally suffered to expire, a statutory power was given to the crown to make Articles of War to operate in the colonies and elsewhere beyond the seas in the same manner as those made by prerogative operated in time of war. In 1715, in consequence of the rebellion, this power was created in respect of the forces in the kingdom. But these enactments were apart from and in no respect affected the principle acknowledged all this time that the crown of its mere prerogative could make laws for the government of the army in foreign countries in time of war. The Mutiny Act of 1803 effected a great constitutional change in this respect: the power of the crown to make any Articles of War became altogether statutory, and the prerogative merged in the Act of Parliament. So matters remained till the year 1879, when the last Mutiny Act was passed and the last Articles of War were promulgated. The Mutiny Act legislated for offences in respect of which death or penal servitude could be awarded, and the Articles of War, while repeating those provisions of the Act, constituted the direct authority for dealing with offences for which imprisonment was the maximum punishment as well as with many matters relating to trial and procedure. The Act and the Articles were found not to harmonize in all respects. Their general arrangement was faulty, and their language sometimes obscure. In 1869 a royal commission recommended that both should be recast in a simple and intelligible shape. In 1878 a committee of the House of Commons endorsed this view and made certain recommendations as to the way in which the task should be performed. In 1879 the Government submitted to parliament and passed into law a measure consolidating in one Act both the Mutiny Act and the Articles of War, and amending their provisions in certain important respects. This measure was called the "Army Discipline and Regulation Act, 1879." After one or two years' experience of its working it also was found capable of improvement, and was in its turn superseded by the Army Act, 1881, which now forms the foundation and the main portion of the military law of England. It contains a proviso saving the right of the crown to make Articles of War, but in such a manner as to render the power in effect a nullity; for it enacts that no crime made punishable by the Act shall be otherwise punishable by such Articles. As the punishment of every conceivable offence is provided for by the Act, any Articles made thereunder can be no more than an empty formality having no practical effect. Thus the history of English military law up to 1879 may be divided into three periods, each having a distinct constitutional aspect:—(1) that prior to 1689, when the army, being regarded as so many personal retainers of the sovereign rather than servants of the state, was mainly governed by the will of the sovereign; (2) that between 1689 and 1803, when the army, being recognized as a permanent force, was governed within the realm by statute and without it by the prerogative of the crown; and (3) that from 1803 to 1879, when it was governed either directly by statute or by the sovereign under an authority derived from and defined and limited by statute. Although in 1879 the power of making Articles of War became in effect altogether inoperative, the sovereign was empowered to make rules of procedure, having the force of law, which regulate the administration of the Act in many matters formerly dealt with by the Articles of War. These rules, however, must not be inconsistent with the provisions of the Army Act itself, and must be laid before parliament immediately after they are made. Thus in 1879 the government and discipline of the army became for the first time completely subject either to the direct action or the close supervision of parliament.

A further notable change took place at the same time. The Mutiny Act had been brought into force on each occasion for one year only, in compliance with the constitutional theory that the maintenance of a standing army in time of peace, unless with the consent of parliament, is against law. Each session therefore the text of the Act had to be passed through both Houses clause by clause and line by line. The Army Act, on the other hand, is a fixed permanent code. But constitutional traditions are fully respected by the insertion in it of a section providing that it shall come into force only by virtue of an annual Act of Parliament. This annual Act recites the illegality of a standing army in time of peace unless with the consent of parliament, and the necessity nevertheless of maintaining a certain number of land forces (exclusive of those serving in India) and a body of royal marine forces on shore, and of keeping them in exact discipline, and it brings into force the Army Act for one year.

Military law is thus chiefly to be found in the Army Act and the rules of procedure made thereunder, the Militia Act, 1882, the Reserve Forces Act, 1882, and the Volunteer Act, 1863, together with certain Acts relating to the yeomanry, and various royal warrants and regulations. The Army Act itself is, however, the chief authority. Although the complaint has been sometimes made, and not without a certain amount of reason, that it does not accomplish much that it might in point of brevity, simplicity, and clearness of expression, it is a very comprehensive piece of legislation, and shows some distinct improvements upon the old Mutiny Acts and Articles of War.

The persons subject to military law are the officers on the active list and the soldiers of the regular forces (including the royal marines), the permanent staff of the auxiliary (*i.e.*, the militia, volunteer, and yeomanry) forces, and the officers of the militia. The above persons are amenable to its provisions at all times except while embarked on board a commissioned ship of the royal navy, when they become subject to the Naval Discipline Act and certain orders in council made under its authority. Those who are subject to military law in certain circumstances only are—officers and men while serving in a force raised out of the United Kingdom and commanded by an officer of the regular forces; pensioners when employed in military service under the command of a regular officer; the non-commissioned officers and men of the militia, during training, when attached to the regulars or when permanently embodied; the officers of the yeomanry and the volunteers when in command of or attached to a body of men subject to military law, or when their corps is on actual military

service, or when ordered on duty with their own consent; the men of the yeomanry when they or their corps are being trained, when they are attached to or acting with the regular forces, when their corps is on actual military service, or when serving in aid of the civil power; the men of the volunteers when they are being trained with or are attached to any body of troops, or when their corps is on actual military service; the men of the army reserve and the militia reserve when called out for training or on duty in aid of the civil power; any person who in an official capacity equivalent to that of an officer accompanies a body of troops on active service beyond the seas; any person accompanying a force on active service holding a pass from the general entitling him to be treated on the footing of an officer. In this last category would of course be included newspaper correspondents, also sutlers and followers. In one or two cases persons are subjected to military law to a limited extent and in respect only of certain offences. Thus a militiaman even when not out for training or not embodied is liable to a military trial and punishment for fraudulent enlistment or making a false answer on attestation. In the same manner an army reserve man may be tried and punished by court martial for neglect to appear at the place where he is bound periodically to report himself, or for insubordination to his superiors on these occasions, or for any fraud in connexion with the receipt of his pay. A man of the army reserve or the militia reserve has the legal status of and in fact becomes a regular soldier when called out on occasions of national danger or emergency under the sovereign's proclamation.

When a person subject to military law commits an offence he is taken into military custody, which means either arrest in his own quarters or confinement. He must without unnecessary delay be brought before his commanding officer, who upon investigating the case may dismiss the charge if in his discretion he thinks it ought not to be proceeded with, or may take steps to bring the offender before a court martial. Where the offender is not an officer he may dispose of the case summarily, the limit of his power in this respect being seven days' imprisonment with hard labour, fines not exceeding 10s. for drunkenness, certain deductions from pay, confinement to barracks for twenty-eight days, this involving severe extra drills, deprivations, and other minor punishments. Where the offence is absence without leave for a period exceeding seven days, the commanding officer may award a day's imprisonment in respect of each day of such absence up to twenty-one. It is only in the case of the imprisonment exceeding seven days that the evidence before the commanding officer is taken on oath, and then only in the event of the accused so desiring it. The commanding officer is enjoined by regulation not to punish summarily the more serious kind of offences, but his legal jurisdiction in this respect is without limit as regards any soldier brought before him, and when he has dealt summarily with a case the accused is free from any other liability in respect of the offence thus disposed of. In any instance where the commanding officer has summarily awarded imprisonment, fine, or deduction from pay, the accused may claim a district court martial instead of submitting to the award.

Ordinary courts martial are of three kinds, viz.:—(1) a regimental court martial, usually convened and confirmed by the commanding officer of the regiment or detachment, presided over by an officer not under the rank of captain, composed of at least three officers of the regiment or detachment with not less than one year's service, and having a maximum power of punishment of forty-two days' imprisonment with hard labour; (2) a district court martial, usually convened by the general of the district, consisting in the United Kingdom, India, Malta, and Gibraltar of not less than five and elsewhere of not less than three officers, each with two years' service or more, and having a maximum power of punishment of two years' imprisonment with hard labour; (3) a general court martial, the only tribunal having authority to try a commissioned officer, and with a power of punishment extending to death or penal servitude, for offences for which these penalties are authorized by statute; it consists of not less than nine officers in the United Kingdom, India, Malta, and Gibraltar and of five elsewhere, each of whom must have over three years' service, five being not under the rank of captain. There is another kind of tribunal incidental to service in the field, or where, in the case of an offence against the person or property of an inhabitant, an ordinary court martial cannot be held, namely, a field general court martial. This court may consist of three officers only, and it has the power of sentencing to death. Another kind of court, called a summary court martial, may be held where an offence has been committed upon active service and an ordinary court cannot be conveniently assembled. In the event of three officers not being available it may consist of two. When thus constituted it can award only a "summary punishment" or imprisonment; where it consists of three officers, however, it can sentence to death. In the case of a field general or a summary court martial many forms and precautions prescribed in the case of ordinary courts are not necessarily observed, the whole proceeding being from the necessity of the case a somewhat rough and ready means of dealing promptly with crime.

The Army Act prescribes the maximum punishment which may be inflicted in respect of each offence. That of death is incurred by various acts of treachery or cowardice before the enemy, or by when on active service interfering with or impeding authority, leaving without orders a guard or post, or when sentry sleeping or being drunk on a post, plundering or committing an offence against the person or property of an inhabitant, intentionally causing false alarms, or deserting. Whether upon active service or not, a soldier also becomes liable to the punishment of death who mutinies or incites to or joins in or connives at a mutiny, who uses or offers violence to or defiantly disobeys the lawful command of his superior officer when in the execution of his office. Penal servitude is the maximum punishment for various acts and irregularities upon active service not distinctly of a treacherous or wilfully injurious character, for using or offering violence or insubordinate language to a superior, or disobeying a lawful command when upon active service. The same punishment is applicable when not upon active service to a second offence of desertion or fraudulent enlistment (*i.e.*, enlistment by one who already belongs to the service), certain embezzlements of public property, wilfully releasing without authority a prisoner or wilfully permitting a prisoner to escape, enlisting when previously discharged from the service with disgrace without disclosing the circumstances of such discharge, or any other offence which by the ordinary criminal law of England is punishable with penal servitude. Imprisonment with hard labour for two years is the maximum punishment for minor forms and degrees of those offences which if committed upon active service would involve death or penal servitude, such as using or offering violence or insubordinate language to a superior or disobeying a lawful command, and for the following offences:—resisting an escort, breaking out of barracks, neglect of orders, a first offence of desertion or attempted desertion or aiding or conniving at desertion, or of fraudulent enlistment, absence without leave, failure to appear at parade, going beyond prescribed bounds, absence from school, malingering or producing disease or infirmity, maiming with intent to render a soldier unfit for service, an act of a fraudulent nature, disgraceful conduct of a cruel, indecent, or unnatural kind, drunkenness, releasing a prisoner without proper authority or allowing him to escape, being concerned in the unreasonable detention of a person awaiting trial, escaping or attempting to escape from lawful custody, conniving at exorbitant exactions, making away with, losing by neglect, or wilfully injuring military clothing or equipments, ill-treating a horse used in the service, making false or fraudulent representations in public documents, making a wilfully false accusation against an officer or soldier, making a false confession of desertion or fraudulent enlistment, or a false statement in respect of the prolongation of furlough, misconduct as a witness before a court martial or contempt of such court, giving false evidence on oath, any offence specified in relation

to billeting or the impressment of carriages, making a false answer to a question put upon attestation, being concerned in unlawful enlistment, using traitorous or disloyal words regarding the sovereign, disclosing any circumstance relating to the numbers, position, movements, or other circumstances of any part of her majesty's forces so as to produce effects injurious to her majesty's service, fighting or being concerned in or conniving at a duel, attempting suicide, obstructing the civil authorities in the apprehension of any officer or soldier accused of an offence, any conduct, disorder, or neglect to the prejudice of good order and military discipline, any offence which if committed in England would be punishable by the law of England. There is another offence which can be committed by officers only, namely, "scandalous conduct unbecoming the character of an officer and a gentleman." It necessitates cashiering, a punishment which in the case of an officer may be awarded as an alternative to imprisonment in several other instances. There is also an offence peculiar to officers and non-commissioned officers, that of striking or ill-treating a soldier or unlawfully detaining his pay. A sentence of cashiering as distinguished from that of dismissal in the case of an officer involves an incapacity to serve the crown again. An officer may be also sentenced to forfeiture of seniority of rank and to reprimand or severe reprimand. A non-commissioned officer may be sentenced to be reduced to a lower grade or to the ranks, and where sentenced to penal servitude or imprisonment is deemed to be reduced to the ranks. The commander-in-chief at home or the commander-in-chief in India or in either of the presidencies may also cause a non-commissioned officer to be reduced to a lower grade or to the ranks. An acting non-commissioned officer may be ordered by his commanding officer for an offence or for inefficiency or otherwise to revert to his permanent grade,—in other words, to forfeit his acting rank.

It will have been observed that persons subject to military law are liable to be tried by court martial for offences which if committed in England would be punishable by the ordinary law, and to suffer either the punishment prescribed by the ordinary criminal law or that authorized for soldiers who commit offences to the prejudice of good order and military discipline. The effect of the latter alternative is that for many minor offences for which a civilian is liable to a short term of imprisonment, or perhaps only to a fine, a soldier may be awarded two years' imprisonment with hard labour. A court martial, however, cannot take cognizance of the crimes of treason, murder, manslaughter, treason-felony, or rape if committed in the United Kingdom. If one of these offences be committed in any place within her majesty's dominions other than the United Kingdom or Gibraltar, a court martial can deal with it only if it be committed on active service or in a place more than 100 miles from a civil court having jurisdiction to try the offence. With regard to all civil offences the military law, it is to be understood, is subordinate to the ordinary law, and a civilian aggrieved by a soldier in respect of a criminal offence against his property or person does not forfeit his right to prosecute the soldier as if he were a civilian.

The crimes for which soldiers are most usually tried are desertion, absence without leave, loss of necessaries, violence or insubordination to superiors, drunkenness, and various forms of conduct to the prejudice of discipline. The punishments are generally speaking gauged as much with regard to the character and antecedents of the prisoner as to the particular offence. For a first offence of an ordinary kind a district court martial would give as a rule fifty-six days' imprisonment with hard labour, for a second or graver crime eighty-four days. There are not many instances in which the period of imprisonment exceeds six months. Corporal punishment, which had been practically limited to offences committed upon active service, and in 1879 to crimes punishable with death, was finally abolished in 1881, and a summary punishment substituted. This summary punishment includes the liability for a term of three months to be kept in iron-fetters and handcuffs, and while so kept to be attached to a fixed object so that the offender may remain in a fixed position for a period not exceeding two hours in the day for not more than three out of any four consecutive days and for not more than twenty-one days in the aggregate. The offender may also be subjected to the like labour and restraint, and may be dealt with in the same manner as if sentenced to hard-labour imprisonment. But these summary punishments are to be inflicted so as not to cause injury to health or leave a permanent mark on the offender. The first instances in which this kind of punishment was inflicted occurred during the campaign of 1882 in Egypt. Estimated by the results, the abolition of flogging does not appear to have injuriously affected discipline, the conduct of the troops in Egypt having been exceptionally good. The practice of marking a soldier with the letters "D" (deserter) or "BC" (bad character), in order to prevent his re-enlistment, was abolished about a dozen years ago in deference to public opinion, which erroneously adopted the idea that the "marking" was effected by red-hot irons or in some other manner involving torture. Military men for the most part regret its abolition, and maintain that if the practice were still in force the army would not be tainted by the presence of many bad characters who find means of eluding the vigilance of the authorities and enlisting after previous discharge.

The course of procedure in military trials is as follows. When a soldier is remanded by his commanding officer for trial by a district or general court martial, a copy of the charge, together with the statements of the witnesses for the prosecution (called the summary of evidence), is furnished to him, and he is given proper opportunity of preparing his defence, of communicating with his witnesses or legal adviser, and of procuring the attendance of his witnesses. Further, if he desires it, a list of the officers appointed to form the court shall be given him. Any officer is disqualified to sit as a member who has convened the court, who is the prosecutor or a witness for the prosecution, who has made the preliminary inqury into the facts, who is the prisoner's commanding officer, or who has a personal interest in the case. The prisoner may also object to any officer on the ground of bias or prejudice similarly as a civilian might challenge a juror. Except as regards the delay caused by the writing out of the evidence, the procedure at a court martial is very much the same as that at an ordinary criminal trial,—the examination and cross-examination of the witnesses, addresses of the prosecutor and prisoner, and the rules governing the admission or rejection of evidence being nearly identical. At a general court martial, and sometimes at a district court, a judge advocate representing the judge advocate general officiates, his functions being very much those of a legal assessor to the court. He advises upon all points of law, and sums up the evidence just as a judge charges a jury. When the prisoner pleads guilty the court finds a verdict accordingly, reads the summary of evidence, hears any statement in mitigation of punishment, and takes evidence as to character before proceeding to pass sentence. The sentence is that of the majority of the court, except where death is awarded, when two-thirds of the members in the case of a general court martial and the whole in that of a field general court martial must concur. When an acquittal upon all the charges takes place the verdict is announced in open court, and the prisoner is released without any further proceeding. When the finding is "guilty," evidence as to character is taken, and the court deliberates in private upon the sentence, but the result is not made known until the proceedings are confirmed and promulgated. No conviction or sentence has any effect until it is thus confirmed by the proper authority. The confirming authority in the case of a regimental court is the commanding officer, in that of a district court martial the general officer commanding the district, and in that of a general court, if held in the United Kingdom her majesty, and if abroad in most cases the general officer commanding. The confirming authority may order the reassembling of the court in order that any question or irregularity may be revised and corrected, but not for the purpose of increasing a sentence. He may, however, of his own discretion, and without further reference to the court, refuse confirmation to the whole or any portion of the finding or sentence, and he may mitigate, commute, or entirely remit the punishment. In the case of a general court martial the proceedings are sent to the judge advocate general, who submits to the queen his opinion as to the legality of the trial and sentence. If they are legal in all respects he sends the proceedings to the commander-in-chief, upon whom rests the duty of advising the queen regarding the exercise of clemency. In addition to confirmation, however, every general or district court martial held out of India has another ordeal to go through. It is reviewed and examined in the office of the judge advocate general, and any illegality that may be disclosed is corrected and the prisoner is relieved of the consequences. To a certain extent a protection against illegality also exists in the case of regimental courts martial. A monthly return of those held in each regiment is laid before the general commanding the district or brigade, by whom any question that might appear to him doubtful would be referred to the adjutant general or the judge advocate general for decision. It is to be noted, however, that the judge advocate general, although fulfilling duties which are in their nature judicial, is only an adviser. He is not actually a judge in an executive sense, and has no authority directly to interfere with or correct an illegal conviction. In many cases the law thus provides no remedy for an officer or soldier who may have been wronged by the finding or sentence of a court martial,—for instance, through a verdict not justified by the evidence or through a non-observance of the rules and practice prescribed for these tribunals. A person who has suffered injustice may appeal to the Queen's Bench division of the high court of justice. But, speaking generally, that tribunal would not interfere with a court martial exercising its jurisdiction within the law as regards the prisoner, the crime, and the sentence. In most cases, therefore, the virtual protector of an accused person against illegality is the judge advocate general, who personally advises the queen and the military authorities that the law shall be complied with. As a privy councillor and member of the House of Commons that officer is responsible both to the queen and to parliament for the right and due administration of military law; and, notwithstanding his want of direct executive authority, it is not to be contemplated that any military officer would hesitate to act upon advice given by him with reference to a

legal question connected with a court martial. The department of the judge advocate general consists of the judge advocate general, who is a lawyer, a privy councillor, and a member of parliament, of a permanent deputy judge advocate general who is also a lawyer, and of three military officers as deputy judge advocates having special experience in the working of military law.

The Army Act applies to European officers and soldiers serving in India in the same manner as to the rest of the army, but natives of India are governed by their own Articles of War, and in the case of civil offences they are dealt with according to the provisions of the Indian penal code. The department of the judge advocate general in India is distinct from and independent of that of the judge advocate general of the army, and courts martial held in that country are not subject to the supervision of a professional lawyer. Certain prominent irregularities led to the appointment of a barrister as judge advocate general in India in 1869, but after a few years that appointment again became filled by a military officer. The staff of the department is, however, far more numerous in India than elsewhere. There are judge advocates general for each of the presidencies, and a deputy judge advocate at each of the more important military centres.

Statistics of Crime in the Army.—Commissioned officers are rarely subjected to trial by court martial. Where an officer commits himself in a military sense, and his misconduct is too serious to be passed over merely with a mark of official displeasure, he is usually given and seldom fails to accept the alternative of resigning his commission. In some instances the crown is advised to exercise its prerogative and remove him from the army on the ground that her majesty has no further occasion for his services. In no circumstances can an officer or soldier claim a court martial as a right. In the result, the annual number of trials of officers does not average more than four of late years. Among the non-commissioned officers and soldiers of the army, however, the trials and summary punishments by commanding officers are exceedingly numerous, as will presently be seen. In India this observation hardly holds good, for in that country desertion is physically almost impossible except at the two or three seaports where troops are stationed. Absence without leave is for a similar reason of rare occurrence, while the fact of the troops living in their own cantonments, and being free from many temptations of life existing in the large towns and garrisons at home, places them outside the influence of certain prevalent causes of crime. For this reason mainly the proportion of courts martial held in 1881 was 107 per 1000 men at home as compared with 76 abroad. Similarly the proportion of minor punishments per 1000 was 1449 at home to 1042 abroad. It is also generally found that men engaged upon active service in the field commit less crime than those serving in ordinary circumstances. But the general criminal statistics of the army for 1881 show a formidable amount of crime and punishment. Upon an average strength of 181,186 non-commissioned officers and men there were 16,523 courts martial, of which 179 were general, 8549 district, and 7795 regimental courts. There were also 224,681 minor punishments by commanding officers, including 44,108 fines for drunkenness. These figures generally show an increase of crime as compared with the two years immediately preceding, but these two exhibited a decrease upon previous years. Of the offences tried by court martial in 1881 the following were the principal:—mutiny 7, desertion 1597, offences in relation to enlistment (fraudulently enlisting while already belonging to the service or making false answers upon attestation) 1190, violence to and disobedience of superiors 1650, minor insubordination and neglect of orders 1472, quitting or sleeping on post 681, drunkenness on duty 2661, drunkenness (tried by court martial when the offence has been committed on a fifth occasion within twelve months) 2147, disgraceful conduct of various kinds 660, absence without leave not amounting to desertion 3293, making away with or losing by neglect equipment or necessaries 3768, and miscellaneous offences chiefly of an ordinary criminal character or to the prejudice of discipline 4181. Upon the 16,523 trials there were 349 findings of acquittal. Regarding the punishments awarded, it appears that no soldier was sentenced to death during the year, and the other awards were as follows:—penal servitude 104, imprisonment with or without hard labour (almost invariably the former) 12,125, discharge with ignominy without other punishment 42, stoppages of pay without other punishment 65, flogging (before the abolition of that punishment by the Act of 1881) 15, and the new summary punishment (authorized as a substitute for flogging) 3. Of the non-commissioned officers 3228 were punished by reduction to a lower grade or to the ranks, while 591 more suffered imprisonment in addition to loss of grade, the former number being in the proportion of about 12 and the latter of 2 per cent. to strength. Of the men tried 305 were pardoned.

Military Law of other Countries.—The administration of military law in other countries having large armies harmonizes in many important respects with that of England. In some indeed it is a question whether their systems are not superior and in advance. They have a considerable body of "auditors" or military lawyers who expound the law and do much to secure a uniform and exact administration of justice. Thus in Austria there are about five hundred of these auditors, one being attached to each regiment. In the same country there are also courts of appeal from the courts of first instance, these latter consisting of eight persons including the auditor. Where the prisoner is a non-commissioned officer or a private, that rank is represented on the court. Here also the confirmation of superior authority is required. In the German army there are general and regimental courts. An auditor who is a lawyer is attached to each division, and it is his duty to expound the law, collect the evidence, and read it to the court in the presence of the prisoner, who is asked if he has any thing to say. The court consists of eleven members, of whom upon the trial of a private soldier or non-commissioned officer three are of the rank of the accused. The power of commanding officers in regard to disciplinary punishments is greater than in the British army, especially in relation to officers, who may be placed in arrest for fourteen days. The non-commissioned officers and privates are liable to extra guards, drills, fatigues, and different degrees of arrest, some of a very severe character. Dismissal from the army, which is regarded as a most severe punishment, involving civil disgrace, is often awarded. In Russia there are three kinds of military courts—namely, the regimental court martial, the tribunals of military districts, and the supreme tribunal at St Petersburg. They are permanent courts, are attended by legal persons, and in certain instances have jurisdiction over the civil population as well as the army. There is a judge advocate general at St Petersburg, where the supreme tribunal consists of general officers and high war-office functionaries who have studied military law or possess a large experience of its working. In Italy there are permanent military tribunals for the trial of non-commissioned officers and soldiers, while special tribunals are appointed to try officers. The court is the absolute judge of the facts, but regarding legal errors or irregularities an appeal lies to the supreme war tribunal, which consists of four civilian judges and three general officers. The French code corresponds in many respects with those of the other great Continental armies, but it tends rather to give individual officers large powers of imprisonment graduated according to their rank. The chief distinctive feature of the French system is the institution of regiments of discipline for refractory characters. When the general officer's power of imprisonment (two months) is exhausted the offender may be sent before a court of discipline and by them drafted into a *compagnie de discipline*; and cases of habitual misconduct are thus dealt with, the man being struck off the strength of his original corps and transferred to one in Algeria. The military law of the United States is founded upon and proceeds much upon the same lines as that of England. (J. C. O'D.)

MILITARY TACTICS. See WAR.

MILITIA. The militia of the United Kingdom consists of a number of officers and men maintained for the purpose of augmenting the military strength of the country in case of imminent national danger or great emergency. In such a contingency the whole or any part of the militia is liable, by proclamation of the sovereign, to be embodied,—that is to say, placed on active military service within the confines of the United Kingdom. The occasion for issuing the proclamation must be first communicated by message to parliament if it be then in session; if it be not sitting, parliament must be called together within ten days. For the purpose of keeping the force in a condition of military efficiency, the officers and men are subjected to one preliminary training for a period not exceeding six (usually about two) months, and further to an annual training not exceeding fifty-six (usually twenty-eight) days. The force is composed of corps of artillery, engineers, and infantry. Infantry militiamen are formed into battalions constituting part of the territorial regiment of the locality of which the regular forces are the senior battalions. The officers and men when called out are liable to duty with the regulars and in all respects as regular soldiers within the United Kingdom. Of late years the men have been raised exclusively by voluntary enlistment, but where a sufficient number for any county or place is not thus raised a ballot may be resorted to in order to complete the quota fixed by the queen in council for that county or place. Each man is enlisted as a militiaman for the county, to serve in the territorial regiment or corps of the district. The period of engagement is not to exceed six years, but during the last of these years a militiaman may be re-engaged for a further period also not exceeding six years.

Men who illegally absent themselves are liable, in addition to punishment for the offence, to make up for the time of their absence by a corresponding extension of their service. The officers are appointed and promoted by the crown, but first appointments are given to persons recommended by the lord lieutenant of the county who may be approved as fulfilling the prescribed conditions in respect of age, physical fitness, and educational qualifications. Since 1877 the officers have been permanently subject to military law. The general body of the non-commissioned officers and men are so subject only when called out for training or embodiment. At other periods they have simply the legal status of civilians, except as regards a liability to trial and punishment for offences in connexion with enlistment or for military offences committed while called out. Each militia regiment has a permanent staff, consisting of an adjutant and a small body of non-commissioned officers and drummers, to conduct the recruiting drills and ordinary business of the corps; and the members of this permanent staff are always subject to military law. They mostly consist of non-commissioned officers who belong to or have served in the regular portion of the territorial regiment. Many of the militia corps have their headquarters at the brigade depôt or local establishment of the territorial regiment, and all are under the general supervision of the (regular) colonel commanding the brigade depôt. The area of service does not extend beyond the United Kingdom; but those who voluntarily offer to serve in the Channel Islands, the Isle of Man, Malta, or Gibraltar may be employed therein. The uniform of the officers and men of the militia is precisely the same as that of the regular corps with which they are associated, or rather of which they form part, except that in addition to the regimental distinguishing mark they bear the letter "M" upon their appointments, to denote that they belong to the militia portion of the corps.

As above stated, the ranks of the militia are usually filled by voluntary enlistment; but by a statute which, though temporarily suspended, can be put in force provisions are made for filling up any deficiency in the allotted quota in any county, city, or riding by ballot of the male inhabitants if within certain limits of age. The enactment provides as follows:—

The secretary of state is to declare the number of militiamen required, whereupon the lord lieutenant is to cause meetings to be held of the lieutenancy for each subdivision. To these meetings the householders of each parish are to send in lists of all male persons between the ages of eighteen and thirty dwelling in their respective houses. Before the ballot, however, the parish may supply volunteers to fill up the quota, every volunteer so provided and approved counting as if he were a balloted person. If a deficiency still exists, the persons on the lists shall be balloted for, and double the number of those required to supply the deficiency shall be drawn out. Any person whose name is so drawn may claim exemption or object; and the deputy lieutenants settle the question of his liability to serve. From the corrected list those who are of the requisite physique (the height is 5 feet 2) are enrolled in the order in which their names are numbered until the quota is completed. If the list is not sufficient to fill the quota, another ballot in the same manner is to be taken. Any balloted man becoming liable to serve may, however, provide a substitute who has the requisite physical qualifications, and is not himself liable to serve.

Within the general body of the militia is contained another having an additional and important obligation in the matter of service. It is called the "militia reserve," and is formed of men who voluntarily undertake a liability to join the regular forces and serve in any place to which they may be ordered in case of the proclamation of a state of imminent national danger or great emergency. In this respect they are in fact upon the same footing as the army reserve, and on the occasion of the mobilization of 1878 more than 20,000 of these men became part of the regular army. The present strength of the militia reserve is a little under 29,000 men, and judging by past experience it may be computed that about 25,000 could be at once added to the ranks of an army in the field in the event of national danger or emergency. It is to be observed, however, that every man thus added to the regulars would be taken away from the effective strength of the militia.

There is no statutory provision for the number of men to be maintained, that number being what from time to time may be voted by parliament. The latest information available respecting the actual condition of the militia of Great Britain relates to the year 1881, and that of Ireland to 1880, the militia of the latter country for obvious political reasons not having been called out for training in 1881 or 1882. Taking the militia of the United Kingdom in 1881, we find that the establishment provided for was 139,501, of whom 18,618 were artillery, 1317 engineers, and 119,566 infantry. Divided into ranks, this establishment was made up of 3534 sergeants and 1260 drummers of the permanent staff, and of the general body 3909 officers, 2520 sergeants, 5040 corporals, and 123,238 privates. The number actually enrolled was 127,868 of all ranks, leaving 11,633 wanting to complete. Of the number enrolled 84,864 belonged to English, 14,138 to Scotch, and 28,866 to Irish regiments, the numbers wanting to complete being for England 7420, for Scotland 162, and for Ireland 4051. As the Irish regiments were not called out, our information regarding the actual effective condition of the force as shown at the annual training does not include Ireland. With regard to the English regiments, 74,945 were present out of an enrolled strength of 84,864. Of the absentees 3144 were with and 6775 without leave. In the Scotch regiments, 12,401 appeared at the training, and of the absentees 616 were with leave and 1121 without. Of the total establishment (106,584) for Great Britain, 99,002 were enrolled, and of those enrolled 87,346 presented themselves and 3760 were absent with leave and 7896 actual defaulters. Of the English regiments five-sixths and of the Scotch regiments two-thirds were born in the county to which their regiments respectively belonged. Of 92,677 men (for Great Britain) whose occupations are disclosed, 17,665 were artisans, 22,221 mechanical labourers, 26,227 agricultural labourers, and 26,564 other trades. Speaking approximately, more than one-half of the men were between twenty and thirty years of age, about 4 per cent. between seventeen and eighteen, about 9 per cent. between eighteen and nineteen, and about 12 per cent. between nineteen and twenty, while some 20 per cent. were over thirty years of age. More than one-half those inspected in 1881 were between 5 feet 5 inches and 5 feet 7 inches in height, about 20 per cent. were under 5 feet 5 inches, while only 585 out of a total of 92,677 were 6 feet and upwards. At the date of inspection there were 296 men in military confinement and 465 in the custody of the civil power. On the last occasion (1880) on which the Irish militia were called out, upon an establishment of 32,813 and an enrolled strength of 30,515 the number present at the training was 26,399, leaving 706 absent with and 2264 without leave. Regiments numbering in the aggregate 1146 men were not trained.

As distinguished from the regular forces or standing army, the militia has been described as the constitutional military force of the country; and its history justifies the description, at least up to a recent period when it lost its distinctive character and became to a great extent merged in the regular army. It is the oldest force Britain possesses, and in fact represents the train bands of early English history. Its origin is to be found in the obligation of all freemen between certain ages to arm themselves for the preservation of the peace within their respective counties, and generally for the protection of the kingdom from invasion. This obligation, imposed in the first instance upon the individuals themselves, became shifted to the owners of land, who were compelled to keep up their proportion of horses and armour for the national defence. The forces were

placed under the lieutenant of the county, empowered in this respect by a commission from the crown. This prerogative of the sovereign, which had been in some instances a matter of controversy, was declared by statute shortly after the Restoration. By the same statute the militia of each county was placed under the lieutenant, who was vested with the appointment of officers, but with a reservation to the crown in the way of commissioning and dismissal. The cost of the annual training—for fourteen days—fell upon the local authority. Offences against discipline were dealt with by the civil magistrates, but with a power to the officers of fining and of imprisoning in default. Upon this footing the militia of England remained for nearly a century, with the general approval of the community. It was recognized as an instrument for defence and for the preservation of internal order, while it was especially popular from the circumstance that from its constitution and organization the crown could not use it as a means of violating the constitution or abridging the liberty of the subject. It was controlled and regulated in the county; it was officered by the landowners and their relatives, its ranks were filled by men not depending for their subsistence or advancement upon the favour of the crown; its numbers and maintenance were beyond the royal control; its government was by statute. While the supreme command was distinctly vested in the crown, every practical security was thus taken against its use by the crown for any object not constitutional or legitimate. It was regarded as, and was, in fact, the army of the state as distinguished from the standing army, which was very much the army of the king personally. The latter consisted of hired soldiers, and was more than once recruited by a conscription, confined, however, to persons of the vagrant class not having a lawful employment, while the former was mainly composed of those having a fixed abode and status. The militia thus enjoyed for many years as compared with the regular forces a social as well as a constitutional superiority. About the middle of the last century the militia was reconstituted, with certain modifications, not involving a sacrifice of the principle of its local government, but strengthening somewhat the supervising influence of the crown. Thus the king directly appointed the permanent staff, and was given a veto upon the appointment and promotion of the officers, who were to have a property qualification. A quota was fixed for each county, to be raised by ballot of those between the ages of eighteen and forty-five, each parish having the option of supplying volunteers at its own cost, and each man balloted being permitted in lieu of serving to pay £10 to provide a substitute. When called out for service the pay was to be the same as that of the regulars, and while embodied or assembled for annual training the officers and men were placed under the Mutiny Act and Articles of War, with, however, a proviso that in time of training no punishment was to extend to "life or limb." The crown was given the power to call out the militia in case of apprehended invasion or of rebellion, and associate it with the regular army, but only upon the condition of previously informing parliament if then sitting, and if it were not sitting of calling parliament together for the purpose. A further and important security was established to prevent an unconstitutional use of the militia by the crown: the estimate for its training was framed each year, not by an executive minister of the sovereign, but by the House of Commons itself. Upon the initiative of a committee of the House, an Act was passed providing for the pay and clothing of the militia for the year. Upon this footing substantially the militia of England remained for many years, the Irish and Scotch militias being meantime brought under the same conditions by various enactments. The force was embodied on several occasions during the last and in the early years of the present century, and it contributed largely to the army engaged in the Peninsula. From 1803 to 1813 just 100,000 men, or two-fifths of those raised for the army, came from the militia. In this way, however, it lost its distinctive character as a defensive force. During the peace which followed the final fall of Napoleon the militia was suffered to fall into decay; and up to 1852 it had only a nominal existence in the shape of an effete permanent staff with no duties to perform. In 1853 the militia was revived just in time to enable it to fulfil most valuable functions. In the war with Russia it was embodied and did garrison duty not only in the United Kingdom but in the Mediterranean garrisons, thus enabling the authorities to send most of the available regular troops to the scene of hostilities. It further contributed many officers and some 30,000 men to the line. It still gives annually about 8000 recruits to the regulars. During the Indian mutiny it filled scarcely less useful functions when again called out. It has since then been regularly assembled for annual training; and when it is brigaded with the regular forces at Aldershot and other camps of instruction its military aptitude and proficiency have generally elicited the surprised admiration of professional soldiers. In 1871 an important constitutional change was made. It was part of the new army system inaugurated in that year that the control of the militia should be removed from the lord lieutenant of the county and vested wholly in the crown. It has now virtually ceased to exist as a distinct body, and is a part of the regular forces with a limitation as to the time and area and other conditions of service. There is no longer a regiment of militia. The body that would formerly be thus described is now a collection of militiamen of a regiment largely composed of regulars. The votes for the maintenance of the militia are now part of the army estimates. The officers of the militia and the line are eligible for duty with either force, and may sit upon courts martial indiscriminately. This practical amalgamation of the old constitutional force with the standing army may appear theoretically open to the objection that it is thereby placed under the direct control of the sovereign. But the day has passed when such an objection could have any value. The fact of the whole army being placed in all respects under the direct control of a minister responsible not only to the crown but to parliament is enough to dissipate any constitutional apprehensions under this head.

The only colonial militia that forms an effective force is that of Canada, which is organized as an efficient local army. The Government of the Dominion includes a minister of militia and defence. The force is placed under the command of a general officer, assisted by an adjutant-general, belonging to the regular army and appointed by the queen. The training of the officers is a matter of special care, there being a military college at Kingston, several of the governing body and professors of which are officers of the Royal Artillery and Royal Engineers, as well as schools of gunnery and musketry. For military purposes the Dominion is mapped out in twelve districts. The militia is divided into the active and the reserve, and the male inhabitants between the ages of eighteen and sixty, with the usual exceptions, are liable to military service, the extent of which varies with the age of each man, the larger amount of duty falling upon the younger. The active militia comprises 12 regiments of cavalry, 17 field and 31 garrison batteries of artillery besides a mountain battery, 4 companies of engineers, 2 mounted rifle corps, 97 battalions of from 5 to 10 companies each and 16 independent companies of infantry. The uniform is for the most part like that of the regular army, and the organization and general efficiency of the whole body have been very favourably reported upon. Although the obligations of the Canadian militia are purely local, a large number on a late occasion offered themselves for general service; and, in the event of a war on a large scale, it is believed that the force would contribute a valuable addition to the fighting strength of the imperial army. (J. C. O'D.)

MILK is the fluid secreted by the mammary glands of the division of vertebrate animals called *Mammalia*. These glands are in a rudimentary form in the Monotremes. In *Ornithorhynchus* there is no nipple, but the mouth and tongue are closely applied over the area on which the ducts open, and the fluid is withdrawn by suction on the part of the young and compression of the gland by the mother. In *Echidna* the ducts of the gland open into a small pouch, foreshadowing the larger pouches of marsupials. In Marsupials the glands are more compact, and have a greater number of lobules. They are found behind the marsupial depressions or those of the pouch; they are not fewer than two on each side nor more than thirteen, six on each side and one midway. The ducts, long and slender during lactation, open on a nipple which is covered by a reflexion of the skin at the back of the pouch, thus forming a kind of hood or sheath. The nipple is protruded beyond the hood during lactation, and is much elongated. The number of these nipples bears a relation to the number of young at a birth; thus the kangaroo, with one at a birth, has four nipples (two, generally the anterior pair, being in use), whilst the Virginian opossum, which produces six or more at a birth, has thirteen nipples. Rodents show a corresponding provision for the nourishment of the young in the number of nipples. A seeming exception is the common guinea-pig, which frequently has eight, ten, or twelve young at intervals of two or three months, and yet the mother has only two teats to serve them, turn and turn about; the original stock of the domestic species breeds, however, only once annually, and has but one to two young, so the domestic variety is a curious anomaly due to the artificial circumstances of its life. In the porcupines there are two nipples, one midway between the fore and hind leg, and the other midway between this and the base of the fore leg. In the coypu, a creature often carrying its young on its back whilst it swims across rivers, the teats project from the flanks near the shoulders, and are of considerable length,

so that the young readily reach them. The *Insectivora* have, as a rule, more nipples than are found in any other order. Thus in the tenrec (*Centetes*) there are as many as twenty-two, and they are rarely fewer than fourteen, spread out in pairs from the pectoral to the inguinal regions. There are ten teats in the common hedgehog, six to eight in moles and shrews, two in sloths and armadillos. In *Cetacea* there are two long, narrow, flat glands lying between the dermal and abdominal muscles, with the subcutaneous blubber separating them from the skin. The peculiarity of the arrangement in these animals, where suckling is performed under water, is the large size of the central duct, which acts as a kind of reservoir, so that the young may obtain a considerable supply in a very short time. It would appear also that when suckling takes place the nose of the young is above the surface of the water. Among Ungulates, in the elephant the glands and teats are between the fore legs; in the rhinoceros they are inguinal; in the mare and ass the glands are two in number, and are found between the thighs, about 9 inches in front of the vulva; the tapir has two inguinal nipples, the peccary two ventral and two inguinal, the wild sow eight nipples, whilst in the domestic breeds there are at least ten, extending from the pectoral to the inguinal regions. Ruminants have the glands aggregated into a round mass in the inguinal region, pendulous in full function, divisible into two glands, each of which has a large reservoir. When in use the teats, one pair or two pairs being the number, in connexion with the reservoirs become so large as to receive the special name of "udder." All the deer tribe, camels, the giraffe, and all kinds of cows have four teats; most antelopes and the gazelles have two teats, whilst a few antelopes have four. As to *Carnivora*, the felines have usually six nipples; the wolf, jackal, fox, dog have usually eight; the seals and the walrus have four, the otters two, the weasels six, the bears six; and in the kinkajou (*Cercoleptes*) the number is reduced to two. Amongst *Quadrumana*, the aye-aye (*Chiromys*) has only one pair of nipples, about an inch and a half in front of the vulva; many lemurs have in addition to those a pectoral pair; in all the platyrhine and catarhine *Quadrumana* there is only one pair of glands, restricted to the pectoral region. Here the teats are between the fore legs, and the young clings to the mother's breast in human fashion, but there is no protrusion of the breast as in the human being. (For further details see Owen's *Anatomy of Vertebrates*, vol. iii. p. 769.)

In the human race the glands are two in number, forming, along with the skin and fat, two rounded eminences, one on each side, on the front of the thorax. They extend from the third to the sixth or seventh rib, and from the side of the sternum to the axilla. In the centre projects a small conical body, the *nipple*. Around the nipple is a coloured circle, or *areola*, which is darker during pregnancy, and even in women who have borne children than in the virgin state. The surface of the nipple is wrinkled, and with a magnifying glass is seen to be covered with papillæ. It is perforated by numerous openings, the mouths of the milk ducts. The tissue of the nipple contains numerous minute blood-vessels, and it has at the base muscular fibres arranged in concentric circles and in radiating bands. It has much of the character of erectile tissue, as in the *corpora cavernosa* of the penis, becoming turgid, firm, and prominent from excitement. The base of the gland lies on the pectoral muscle, a thin layer of fascia intervening. The surface is covered with fat, which gives it the smooth rounded outline. It is amply supplied with blood by the long thoracic artery, some other minute branches of the axillary artery, the internal intercostal artery, and the subjacent intercostals. The nerves come from the anterior and middle intercostal cutaneous branches, and the nipple is especially sensitive. The gland is composed of numerous lobes bound together by connective and adipose tissue, and each lobe is formed of smaller lobules. Each lobe has an excretory duct, and these ducts, from fifteen to twenty in number, converge towards the areola, beneath which they are dilated so as to form sinuses from $\frac{1}{6}$th to $\frac{1}{4}$th of an inch in calibre. From these sinuses arise the ducts which open on the surface of the nipple. The general structure will be understood by referring to the accompanying figures, along with the description.

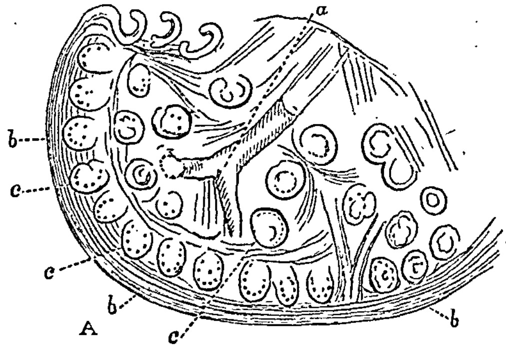

FIG. 1.—Half-diagrammatic view of a section through a lobule of the mammary gland, after Klein (*Atlas of Histology*, plate xl. fig. 1), magnified 45 diameters. *a*, a duct dividing into two branches; *b, b, b*, connective tissue surrounding and going between the ultimate pouches of the gland; *c, c, c*, the pouches or *alveoli* of the gland, the dots representing the cells lining them.

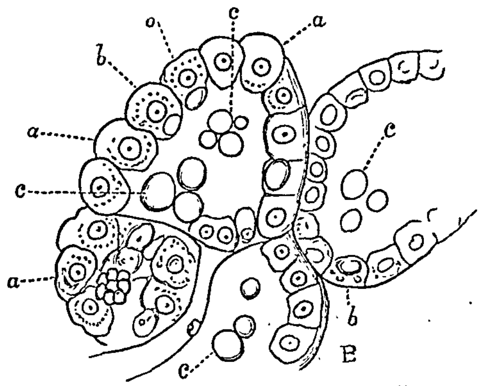

FIG. 2.—A portion of the same gland, magnified about 400 diameters, showing one complete and two incomplete alveoli. *a, a, a*, short, columnar, epithelial cells lining the alveolus, each having an oval or rounded nucleus; *b, b, b*, epithelium cells, containing, next the interior of the alveolus, a milk globule; *c, c, c, c*, milk globules which have been set free from epithelial cells.

When a duct is traced into the gland, it is found to subdivide into smaller ducts, and these into still smaller, until the smallest ductlet is reached, round the end of which are clustered several *alveoli* or pouches. Each alveolus has a wall, lined with epithelium cells. In the wall of the alveolus there are capillary blood-vessels which bring the blood near the cells. By this blood the cells are nourished. There is a minute cavity in the centre of each alveolus into which cells or their products can accumulate. There can be no doubt that the formation of the milk globule takes place in these cells. Whilst milk is not being formed the cells have a granular appearance, and the lumen or central cavity of the alveolus is small; but during secretion the cavity is enlarged and shows a few milk globules, whilst one or more milk globules can be seen in the interior of the cell. If the milk globule in the cell be very large, the nucleus of the cell is pressed outwards and the protoplasm of the cell is reduced to a thin covering, over the globule, at this stage presenting a striking resemblance to a fat cell containing an oil globule. Thus each milk globule is formed in the protoplasm of the epithelium cell, and even at an early stage each milk globule consists of a minute drop of fat or oil surrounded by a thin albuminous envelope. It has not been clearly ascertained whether epithelial cells, after having secreted milk globules, degenerate and fall off, or whether they have the power of ejecting the milk globules. The fluid constituents of milk (water holding

salts in solution) may be separated from the blood by a kind of filtration under blood pressure, as is the case in other secretory processes. The origin of the sugar of milk and of the casein is unknown. (For a description of the minute structure of the milk gland, see Klein's *Atlas of Histology*, p. 300, and references.) At the beginning of lactation the milk is rich in large irregularly-formed corpuscles (fig. 3, *a*, *a*, *a*) called *colostrum* corpuscles. These are contractile bodies, slowly changing their form and squeezing out the oily particles. At first they are the only bodies present, but they are soon replaced by the ordinary milk globules. Such globules have bright refractive edges, the surface is smooth, they vary in size from $\frac{1}{8000}$th to $\frac{1}{3000}$th of an inch in diameter, and each consists of a drop of fatty matter surrounded by a layer of albumen ("Ascherson's membrane").

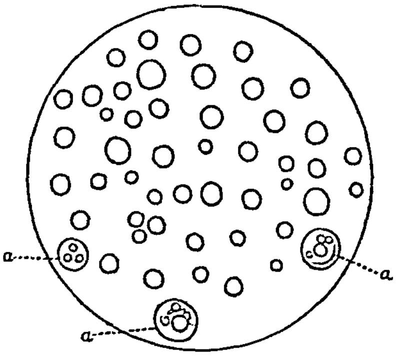

FIG. 3.—A drop of milk magnified 300 diameters. *a*, *a*, *a*, *colostrum* corpuscles.

A secretion of milk takes place in newly-born children, from the fourth to the eighth day, and also in rare cases in men (Hermann's *Physiology*, p. 158). During gestation in the human being the mammary glands increase in size; immediately after the birth of the child active secretion commences; and usually it is on the stoppage of the secretion, ten months afterwards, that the process of menstruation, which has been arrested by impregnation, again is re-established.

The secretion of milk is undoubtedly affected by the nervous system, as is shown by fear or mental distress arresting or injuring the quality of the secretion, and by the "rush" or feeling of fulness in the breast experienced by the mother when the child's mouth touches the nipple, or even when she sees her offspring. The nervous mechanism, however, is unknown, as it has been observed that secretion may continue even after section of all the nerves known to pass to the gland. The nature of the diet has a marked influence on the quality of the secretion. Thus the amount of casein and of fat is greater during an animal than during a vegetable diet. Fatty foods do not seem to increase the amount of fat or butter; an ample supply of carbo-hydrates (starches and sugars) increases the amount of sugar. These facts indicate that most if not all of the constituents of milk are formed from changes in the protoplasm of the epithelial cells. In some women the milk is deficient in fat and casein, and consequently is less nutritious. Prolonged lactation diminishes the amount of fat and sugar without materially affecting the amount of albuminous matter; but the milk is less nutritious and is unfit for the child. The occurrence of menstruation during lactation also deteriorates the milk. (J. G. M.)

Milk as Food.

The milk of various domesticated animals is more or less used by man for food. The milk of the cow, which may be taken as typical of all others, and is indeed by far the most important and valuable of all, is, when newly drawn, an opaque white fluid, with a yellowish tinge, soft, bland, and sweetish to the taste, and possessed of a faintly animal odour. This odour, according to Schreiner, is due to the presence of sulphuretted hydrogen, and disappears after a short exposure. The specific gravity of milk ordinarily ranges from 1·029 to 1·033, very seldom reaching 1·035 or falling so low as 1·027. In chemical constitution it consists of an emulsion of fatty globules (cream) in a watery alkaline solution of casein, and a variety of sugar, peculiar to milk, called lactose. The fat (which when separated we know as butter) and the lactose constitute the carbonaceous portion of the milk regarded as food. The casein, which forms the principal constituent of cheese, and a certain proportion of albumen which is present, form the nitrogenous, while the complex saline substances and water are the mineral constituents. These various substances are present in the proportions which render milk a perfect and typical food suitable to the wants of the young of the various animals for whom it is provided by nature. The milk of all animals, so far as is known, contains them, although they are present in somewhat different proportions. It is probable that the milk of ruminants possesses certain physical and physiological distinctions from that of non-ruminant animals, which will account for the virtues attributed to the milk of the ass and mare. The following table exhibits the chemical constitution of the kinds of milk most frequently used by man:—

	Cow.		Goat.	Ewe.[1]	Mare.	Ass.	Human.
	Winter Blyth.	Cameron.	Voelcker.	Voelcker.	Cameron.	Chevallier and Henry.	Gerber.
Water	86·87	87·00	84·48	83·70	90·310	91·65	88·02
Fat	3·50	4·00	6·11	4·45	1·055	0·11	2·90
Casein and albumin	4·75	4·10	3·94	5·16	1·953	1·82	1·60
Sugar	4·00	4·28	4·68	5·73	6·285	6·08	7·03
Ash	0·70	0·62	0·79	0·96	0·369	0·34	0·31

In addition to these constituents milk contains small proportions of the gases carbonic acid, sulphuretted hydrogen, nitrogen, and oxygen, and minute quantities of other principles, the constant presence and essential conditions of which have not been determined. These consist of galactin and lactochrome, substances peculiar to milk, discovered by Winter Blyth, with certain animal principles such as leucin, pepton, kreatin, tyrosin, &c. The salts in milk consist, according to the average of numerous analyses by Fleischmann, of the following constituents:—

Phosphoric acid	28·31	Potash	17·34
Chlorine	16·34	Magnesia	4·07
Lime	27·00	Ferric oxide	0·62
Soda	10·00		

Milk thus is not to be regarded as a definite chemical compound nor even as a mixture of bodies in fixed and invariable proportions. Not only does the milk of different races and breeds of cows vary within comparatively wide limits; the milk of the same animal is subject to extensive fluctuation. The principal causes of variation in the individual are age, period of lactation, nature and amount of food, state of health, and treatment, such as frequency of milking, &c. The following table indicates the range of normal variations:—

Water	90·00	to	83·65
Fat	2·80	,,	4·50
Casein and albumin	3·30	,,	5·55
Sugar	3·00	,,	5·50
Ash	0·70	,,	0·80

The average quantity of milk yielded by cows is also highly variable, both in individuals and breeds. As a rule the smaller breeds of cows yield a small amount of milk rich in cream (butter fat), while the yield of the larger breed is greater in quantity, but comparatively deficient in cream. A good milch cow should yield in a milk-giving period of from eight to nine months about

[1] Ewe's milk is exceedingly variable, especially in its percentage of fat. The above analysis is one of nine by Dr Voelcker, in which the fat was found to range from about 2 to 12¾ per cent.

500 gallons of milk, from which nearly 500 ℔ of cheese or 200 ℔ of butter would be obtainable.

Dairy Treatment.—Cows are commonly milked by hand two or three times a day. A milking machine of American origin, which was introduced about the year 1862, has been entirely abandoned. The milk should be drawn from the animals in as clean a condition as possible, but notwithstanding every precaution some amount of hair and epithelial and other animal débris invariably enters the milk-pail. It has therefore to be immediately strained through a sieve with fine wire-cloth or hair strainer. As milk is peculiarly susceptible of taint, and absorbs odours of all kinds with great avidity, it is of the utmost consequence that all vessels in which it is placed or kept should be so made as to be easily purified and that they should be kept scrupulously clean. In Switzerland milk is strained with most beneficial effect through sprigs of washed fir tops, which inserted loosely and uprightly into the hole of a funnel arrest all hair, skin, clots, and slimy matter on the acicular leaves. The milk drains through in a clean condition with a fresh slightly aromatized flavour favourable to its keeping. A fresh sprig is used on each occasion of straining milk, so that there is freedom from the risk of taint which arises through the use of imperfectly cleaned wire gauze. The milk must be removed from the cow-house as quickly as possible; and, if intended for use as new milk and for sale in the neighbourhood of the dairy, it may at once be put up for delivery. But if it has to travel a distance, or if it is to be kept for creaming or cheese-making, it should be rapidly cooled down, and kept in a cool airy milk-room if practicable, surrounded with fresh cold water.

The ordinary method of separating cream either for direct use or for butter making is by allowing it to form on the surface and skimming it off with a broad flat spoon; but ingenious adaptations of centrifugal machines—of which Laval's separator is one of the best known—have been introduced for the purpose of effecting the rapid and complete separation of the cream. The centrifugal force of such machines throws the denser portions of the fluid towards the sides of a rapidly revolving cylinder, collecting the cream on an inner layer, which is carried off by one channel while the impoverished milk escapes by another. The Laval separator gives very rich cream, as will be seen from the following analyses by Voelcker:—

	Ordinary Cream.	Cream by Separator.	Skimmed Milk by Laval Separator.	Ordinary Skimmed Milk.
Water	77·30	66·12	90·82	89·25
Butter fat	15·45	27·69	0·31	1·12
Casein	3·40	2·69	3·31	3·69
Milk sugar	3·15	3·03	4·77	5·16
Mineral matter	0·70	0·47	0·79	0·78

After being kept some time, depending principally on the temperature at which it is maintained, milk begins to turn sour owing to the formation of lactic acid, by a process of fermentation, at the expense of the lactose or milk sugar. The acid so developed causes a coagulation of the casein, and the milk separates into a solid white curd, and a thin transparent yellow milk serum or whey. These changes can to a certain extent be artificially produced, hindered, and controlled. The following are the results of analyses by Fleischmann:—

Constituents of 100 Parts of Sweet Milk.

20·00 cream	3·56 butter. 16·30 buttermilk. 0·14 loss.
79·70 skimmed milk	7·93 curd. 71·45 whey. 0·32 loss.
0·30 loss	0·30 loss.

Relative Composition of Milk and its Products.

	Water.	Fat.	Casein.	Albumin.	Milk Sugar.	Ash.
Whole milk	87·60	3·98	3·02	0·40	4·30	0·70
Cream	77·30	15·45	3·20	0·20	3·15	0·70
Skim-milk	90·34	1·00	2·87	0·45	4·63	0·71
Butter	14·89	82·02	1·97	0·28	0·28	0·56
Buttermilk	91·00	0·80	3·50	0·20	3·80	0·70
Curd	59·30	6·43	24·22	3·53	5·01	1·51
Whey	94·00	0·35	0·40	0·40	4·55	0·60

The simplest and most advantageous form in which milk can be disposed of as a commercial product is by its sale as sweet or new milk, and it is in this manner that the greater proportion of the milk produced within the reach of large centres of population is disposed of. New milk, cream, and skimmed milk are the only primary forms in which milk is sent into the market. CHEESE and BUTTER have been dealt with in separate articles (*q.v.*). Whey, the yellow liquid remaining after the separation of the curd in cheese making, is a source of milk sugar, employed to a limited extent in pharmacy; but it is principally used for feeding pigs. The buttermilk which remains after separating butter is a most wholesome and nutritious article of food.

Preservation of Milk.—The numerous methods which have been proposed for the preservation of milk in a condition fit for use over a lengthened period resolve themselves into (1) chemical treatment with alkaline salts and antiseptic bodies, (2) physical treatment, such as cooling or icing, boiling, and aeration, and (3) condensation with or without the addition of a preservative agent. All systems of preservation, however, are subject to serious disadvantages either from their serving their purpose for too limited a time, or their interfering with the natural constitution and properties of the milk. Of all preservatives cold is the most efficient and least objectionable. It has been shown by Soxhlet (*Dingler's Polytech. Journal*, ccxxiii. 329) that milk cooled by ice-water remains sweet and unaltered for fourteen days, but after that time acquires a rancid taste. After twenty-eight days it coagulates on boiling owing to the presence of acids resulting from the oxidation of the cream, and in thirty-four days it coagulates even in the ice-water. It is also found that milk which has undergone aeration with atmospheric air has its keeping properties much improved. The aeration is effected by allowing the milk to fall from some height in a state of fine division by passing it through the meshes of a sieve. By another method air cooled by passing over ice is blown through the milk.

Milk keeps sweet for a longer time when boiled, but the smell, taste, and other properties are affected, partly owing to the escape of gases mixed with it when fresh. The unpleasant flavour communicated by boiling can be avoided if the action takes place in a closed vessel and the milk is immediately cooled down in a refrigerator connected therewith. In the case of any suspicion of taint in milk either from disease in the cow, contamination from unhealthy persons, or the use of infected water in cleaning vessels, boiling is also strongly to be recommended, as it effectually destroys the germs of disease, in the carrying and spreading of which milk is a most active agent. It is with the utmost difficulty that boiled milk can be coagulated by means of rennet; but by treatment with acid it coagulates more rapidly and freely than if unboiled.

Of the various chemical compounds which have been suggested and more or less used for preserving milk, the most successful hitherto has been salicylic acid, which has the advantage of being tasteless and inodorous. By briskly stirring in rather less than 2 grains to a pint of milk, it can be kept liquid and sweet in a temperature of from 65° to 68° Fahr. for twelve hours, and at 55° Fahr. for a whole day. If 4 grains be used to a pint, coagulation in the higher temperature is delayed from two or three days, and at the lower temperature the milk may be kept good from three to five days. Boracic acid and borax are also employed by dairymen, the former being known as glacialine salt. The presence of any chemical antiseptic in milk is, however, at best a matter of doubtful advantage.

Condensation.—Milk is now treated on a large scale by a process of concentration, the product of which comes into the market in two forms—as "plain condensed milk" and as "preserved milk." The credit of originating the industry is due to Mr Gail Borden of White Plains, New York, who began his experiments about 1849. In 1851 he introduced his plain condensed milk, which is simply milk from which between three-fourths and four-fifths of the water has been removed, and in 1861 he rendered important services to the army in the field by supplying preserved milk which was in

effect milk similarly concentrated, with a proportion of sugar added, and hermetically sealed in tin cans. The manufacture was transplanted to Switzerland in 1865, after which condensing factories were established in England, Ireland, Denmark, Bavaria, Norway, and elsewhere. With the introduction of the condensing trade there has also been associated the factory system of dealing with dairy products, by which the milk of many dairies is carried to one centre and dealt with either for condensing or for cheese or butter making. The following epitome of the process of condensing milk is from a paper by Mr Willard of Cornell university, New York (*Jour. Roy. Agric. Soc.*, 2d series, vol. viii., 1872). The milk when received at the factory is first passed, he says, "through a strainer to the receiving vat; from this it is conducted off, going through another strainer into the heating cans, each holding about 20 gallons; these cans are set in hot water, and the milk is held in them till it reaches a temperature of 150° to 175° Fahr.; it then goes through another strainer into a large vat, at the bottom of which is a coil of copper pipe, through which steam is conducted, and here the milk is heated up to the boiling point. Then the best quality of white granulated sugar is added, in the proportion of 1¼ lb of sugar to the gallon of milk, when it is drawn into the vacuum-pan having a capacity of condensing 3000 quarts or more at a time. The milk remains in the vacuum-pan subjected to steam for about three hours, during which time about 75 per cent. of its bulk in water is removed, when it is drawn off into cans, holding 40 quarts each. The cans are only partially filled, and are then set in a large vat containing cold water, the water being of a height equal to that of the milk in the cans. Here it is stirred until the temperature of the condensed fluid is reduced to a little below 70°; it is then turned into large drawing-cans with faucets, in order to facilitate the filling of the small cans, ... holding 1 lb each, which are immediately soldered to exclude the air."

In the case of plain condensed milk the concentration is usually carried farther than is practised in preparing the preserved milk, it being evaporated down to between one-fourth and one-fifth of the original bulk. It is not put up in sealed tins, being intended for immediate use, and keeps sweet only for a few days, varying with the state of the weather, whereas the sugared milk in sealed cans keeps for years. The large amount, however, of cane sugar added to preserved milk seriously disturbs its balance of proportion as a perfect food, and renders it unfit to be used alone in a dilute state as a substitute for mother's milk by infants, a purpose for which it is largely employed. It should also be observed that the relative proportion of fat is small, the milk being partially skimmed before it is operated on, so that the statement that preserved milk diluted with a small proportion of water is equal to cream is not to be relied on. Preserved milk, rich in cream, has always a more or less rancid oily taste, and cannot be obtained so sweet and even in flavour as that largely deprived of fat. According to a German patent of E. Klebs in Prague, plain condensed milk may be preserved by adding to every 100 litres of the original milk a solution of 50 grains of benzoate of magnesium in one litre of water.

Adulteration.—Practically the invariable mode of sophisticating milk for sale consists in the addition of water and in the subtraction of cream,—in other words, passing off skimmed or partly skimmed as new milk. Now and again there are found certain little refinements on these simple frauds, such as adding a quantity of sugar to correct the specific gravity, flour or starch to increase opacity, and a touch of colouring matter to cover the bluish tinge which would betray skimmed milk. In the United Kingdom no official standard of what constitutes pure milk has been promulgated, but the so-called Somerset House standard has been generally recognized in law courts. According to this, new milk should contain as a minimum of solids not fat 8·6 per cent. and of fat 2·5 per cent., and of water a maximum of 88·9 per cent. The most satisfactory manner of discovering the probable genuineness of a sample of milk is by chemical analysis carried sufficiently far to determine the amount of fat and of other solids present. Numerous attempts have been made to place in the hands of dairymen, dealers, and consumers of milk a trustworthy method of estimating the condition and value of the article by simple quantitive tests for cream or fat—at once the most valuable constituent and one the presence of which in average proportion is indicative of the quality of the whole. The simplest but at the same time the least trustworthy and efficient method is by means of the so-called "creamometer," which consists merely of a graduated glass tube in which a measured amount of milk is placed and the amount of cream it throws up is read off by means of the scale. Specific gravity determinations have by themselves no significance, seeing milk deprived of its cream can by dilution with water be brought to correspond exactly with the original milk. But by a combination of two methods,—first taking the specific gravity, next observing the yield of cream by the "creamometer," and finally taking the specific gravity of the milk deprived of cream, regard being had to the temperature of the milk in these observations, an approximately accurate idea of the value of a sample may be obtained. Among so-called "lactoscopes," the operations of which are based on the fact that milk rich in cream is a much more opaque fluid than that from which cream has been taken or to which water is added, that invented by Professor Feser of Munich is one of the simplest and most useful. It consists of a glass tube open at the upper end and attenuated at its lower extremity. Into this narrower portion is fused a small cylindrical rod of opaque milk glass on which black lines are marked. These lines are invisible when the lower portion of the tube is filled with a measured quantity of milk, but on addition of water they become visible. When the black lines become by the gradual admixture of water perfectly distinct, the richness of the milk in cream globules is indicated by the height to which the mixture of milk and water has risen in the wide portion of the tube, which has engraved on it a scale showing on one side the amount of water added and on the other the proportion of cream equivalent to the transparency resulting from such addition.

Statistics.—In the year 1878 it was calculated by Mr J. C. Morton that the total yield of milk from the 2,250,000 cows and heifers in milk or in calf in England and Scotland amounted to about 1,000,000,000 gallons yearly. He assumed that about one-sixth of that quantity (167,000,000 gallons) went to feed calves, and that the daily consumption of the population was 1,000,000 gallons, being rather more than a quarter of a pint per head, which accounts for 365,000,000, still leaving 468,000,000 gallons to be used for butter and cheese making. Two-thirds of this quantity, or 312,000,000 gallons, Mr Morton assumes was used for cheese-making, yielding 2,800,000 cwts. of cheese (rather less than 1 lb per gallon of milk), and the remainder, 156,000,000 gallons, of milk devoted to butter-making would yield 530,000 lb of butter, or 1 lb of butter for every 21 pints of milk. In these figures no account is taken of Ireland, whence at that period there were sent to England alone yearly 3,500,000 lb of salted butter. In June 1882 the number of cows and heifers in milk and in calf in Great Britain did not vary greatly from the number on which Mr Morton's estimate for 1878 was based, being 2,267,175, whilst in Ireland the number was 1,398,965, making the total for the United Kingdom 3,682,317. If we take approximately Mr Morton's data as the basis of calculation, the 3,682,317 milk cows and heifers in the United Kingdom would yield, at 440 gallons per head, 1,620,219,480 gallons of milk. Further, assuming that one-sixth of this is consumed by calves, one-third consumed by population, one-third used for cheese-making, and one-sixth used for butter-making, we have as the yield of cheese 4,846,000 cwts. and as the yield of butter 920,000 cwts. As Ireland is much more a butter-producing than a cheese-yielding country, the quantity of cheese made is probably overestimated in these figures, and the amount of butter made is correspondingly understated. To bring out the consumption of dairy products for the year the following imports must be added:—

	Cwts.	Value.
Cheese	1,692,495	£4,742,368
Butter (including butterine)	2,167,428	11,339,226

Thus we find the total supply of cheese to the United Kingdom in 1882 was 6,538,495 cwts., and of butter the supply was 3,087,428 cwts. Estimating the home produce of both articles at the same value as the imports, the cheese supply cost £18,320,000, and the butter £16,150,000. Adding to these the probable cost of the milk consumed as such (say 550,000,000 gallons at 1s. per gallon =£27,500,000), we have for the year 1882 in round numbers £62,000,000 expended on dairy produce within the United Kingdom.

The total number of milch cows at present (1883) in the United States is stated at 15,000,000, which, taking the 440 gallons basis, yield annually 6,600,000,000 gallons, or nearly 30,000,000 tons of milk. In America the factory system of treating milk has attained much greater dimensions than in Europe, and that perfection of treatment, combined with the cheapness of raising and feeding stock, enables the American companies to enter the European markets with large quantities of cheese and other dairy products of uniformly good quality which find a ready and remunerative sale.

Koumiss.—Under this name is properly understood a fermented drink prepared from mare's milk by the Tartar tribes of the Russian empire and by all the nomad races of the northern parts of Asia. It is made by diluting mare's milk with about one-sixth part of its quantity of water, and adding as a ferment about one-eighth part of very sour milk or of old koumiss. This mixture is placed in a wooden vessel which is covered over with a thick cloth, and so left for about twenty-four hours in a moderately warm situation. During that time a thick coagulum rises to the surface, which is thoroughly reincorporated by churning. After standing for another day, the whole mass is again thoroughly churned and mixed up, and in this state it forms new koumiss, having an agreeable subacid taste. The liquor is mostly stored and preserved by the Tartars in skin bottles, in which the fermentation continues developing its alcoholic qualities, and mellowing and improving its taste. Genuine Tartar koumiss has the following composition:—alcohol 3·21, lactic

acid 0·19, sugar 2·10, albuminoids 1·86, fat 1·78, salts 0·509, carbonic acid 0·177, and water 93·46. A distilled spirit is prepared from koumiss, which is drunk among the Tartars under the name of araca or arsa. Koumiss has of late years come into prominent notice as a remedial agent in cases of pulmonary consumption, and generally as a nutritious form of food easily assimilated by delicate stomachs. It is probable that all its virtues reside in the original milk from which it is prepared, in which case the koumiss can only be regarded as valuable in so far that it is a convenient form under which the essential properties of the milk can be preserved for use. Under the name of koumiss a preparation of cow's milk is now very generally sold. It is made by adding to each quart of new milk about a tablespoonful of common sugar and brewer's yeast, allowing the fermentation to proceed a sufficient length, then bottling and corking as in the case of aerated waters. Such a preparation contains about the same proportion of alcohol as genuine koumiss, but a non-alcoholic variety can also be obtained, made by a process of natural fermentation, which continuing after bottling develops a large amount of carbonic acid and renders the liquor highly effervescent. (J. PA.)

MILL, JAMES (1773–1836), historian and political and mental philosopher, was born 6th April 1773, in the little village called Northwater Bridge (Bridge of North Esk), in the parish of Logie-Pert, in the county of Forfar. His father, James Mill, was a shoemaker; his mother, Isabel Fenton, belonged to a race of respectable farmers. The father was industrious, good-natured, and pious, but not known as specially intelligent. The mother was of a proud disposition, and resolved to educate James, her eldest son, for a superior destiny. He began his education at the parish school, and went on to the Montrose Academy, where he remained till the unusual age of seventeen and a half, when he went to the college of Edinburgh (1790). According to the usage of the time and neighbourhood, he ought to have been sent about thirteen or fourteen to Marischal College, Aberdeen. His remaining so long at the Montrose Academy, and his going to Edinburgh for his university course, must be connected with his being taken up by Sir John and Lady Jane Stuart of Fettercairn, who engaged him to be tutor to their only daughter, known for having inspired the affection of Sir Walter Scott, and for being the mother of Principal James David Forbes. Sir John and Lady Jane Stuart contracted a warm attachment for Mill, which lasted throughout their lives. At Edinburgh University Mill was distinguished as a Greek scholar. But he received his greatest impulse from Dugald Stewart, for whom he always expressed unbounded admiration. In October 1798 he was licensed as a preacher, but seems to have preached very seldom. His years from 1790 to 1802, besides being occupied with incessant studies extending into history and moral and political philosophy, were devoted to various tutorships.

Failing to find a career to his mind in Scotland, in 1802 he went to London in company with Sir John Stuart, then member of parliament for Kincardineshire. He soon obtained literary occupation, to which he applied himself with untiring energy. His first important venture was to start a periodical on a new plan, entitled *The Literary Journal*, which began to appear in January 1803, and continued under his editorship till the end of 1806. It was the most comprehensive in its aims of any periodical hitherto in existence, being a summary view of all the leading departments of human knowledge. Thomas Thomson, the chemist, took charge of science; and many other men of ability co-operated. Mill himself wrote largely in biography, history, political philosophy, political economy, and also in theology, on which his views at the time were broad without being sceptical. The publisher of the journal was Baldwin, who was also the proprietor of the *St James's Chronicle*, a Conservative paper appearing three times a week. For two or three years, from 1805 onwards, Mill was editor, but at last gave it up, partly on conscientious grounds, although in conducting it he never lent himself to the expression of any illiberal views, but often made it the vehicle of the opposite.

In 1804 he wrote a pamphlet on the *Corn Trade*, advocating the impolicy of a bounty on the exportation of grain. This was the beginning of his career as a political economist. In 1805 he published a translation of Villers's work on the *Reformation*, an unsparing exposure of the vices of the papal system. He added notes and quotations by way of confirmation of the author's views. On this subject also he continued to hold strong opinions all through life, and often recurred to it in his articles in the reviews. In 1805 he married Harriet Burrow, whose mother, a widow, kept an establishment for lunatics in Hoxton. He then took a house in Rodney Street, Pentonville, where his eldest son, John Stuart, was born in 1806. It was about the end of 1806 that he entered upon the composition of the *History of India*, which he expected to finish in three or four years. He was actually engaged upon it for twelve, giving, however, a considerable portion of his time to other writing for the support of his family. The strain upon his energies for those years was enormous.

He became acquainted with Jeremy Bentham in 1808, and was for many years Bentham's chief companion and ally. In 1810 Bentham, to have Mill nearer him, gave him Milton's house, which adjoined his own, and was his property. After a few months' trial Mill had to give up this house on account of his wife's health, and went to live in Newington Green; but in 1814 Bentham leased the house No. 1 Queen's Square, now 40 Queen Anne's Gate, close to his own garden, and gave it to Mill at a reduced rent; here he remained till 1831. The intimacy with Bentham was rendered still closer. For four years, from 1814 to 1817, Bentham was at Ford Abbey, near Chard, in Somersetshire, and there Mill and his family were domesticated with him nine or ten months each year,—in which retirement it is probable that Mill was able to accelerate the completion of his history.

In the twelve years between 1806 and 1818 he wrote a great many articles for various periodicals. Among these were the *Anti-Jacobin Review*, the *British Review*, and the *Eclectic Review*; but there is no means of tracing his contributions. In 1808 he began to write for the *Edinburgh Review*, and contributed steadily till 1813, most of his articles being known. In the *Annual Review* for 1808 two articles of his are traced—a "Review of Fox's History," and an article on "Bentham's Law Reforms," probably his first published notice of Bentham. The first known article in the *Edinburgh* was on "Money and Exchange" (October 1808). In 1809 (January and July) he wrote at great length on Spanish America and General Miranda, with whom he was on terms of intimate friendship. In the July number he also wrote on China. In 1810 (April) he made a severe attack on the East India Company. He also wrote on the liberty of the press and on the Church of England in connexion with the Lancasterian schools. He was an active member of the committee for promoting education on Lancaster's plan. In 1811 a periodical named the *Philanthropist* was started by William Allen, and published in quarterly numbers till 1817. Mill co-operated with Allen both in the writing and in the management. He contributed largely to every number,—his principal topics being education, freedom of the press, and prison discipline (under which he expounded Bentham's "Panopticon"). He made powerful onslaughts on the church in connexion with the Bell and Lancaster controversy. In 1814 Macvey Napier engaged him to contribute to the supplement to the fifth edition of the *Encyclopædia Britannica*. Many of the articles became notable. The list included "Government," "Jurisprudence," "Liberty of the Press," "Prisons and Prison Discipline," "Colony,"

"Law of Nations," "Education," "Beggar," "Benefit Societies," "Banks for Savings." In "Jurisprudence" and "Prisons" he was largely indebted to Bentham; in most of the others he was either altogether or in great part original. The article on "Government" will occupy a permanent position in English history.

In 1818 was published the *History of India*, which had a great and speedy success. It was the means of changing the author's future position. The year following he was appointed an official in the India House, in the important department of the examiner of Indian correspondence. He gradually rose in rank till he was appointed, in 1830, head of the office. He introduced his eldest son into the same department in 1823.

In 1824 Bentham projected the *Westminster Review*, and Mill was a principal writer for three years. Some of his most vigorous writings are included among those contributions. The first was an elaborate criticism of the *Edinburgh Review* as a whole; it was followed by an onslaught on the *Quarterly*. Other articles dealt with English history and with ecclesiastical establishments, which he severely impugned. To a periodical of short duration, *The Parliamentary History and Review*, he contributed an elaborate political retrospect of the parliament of 1820–26. In 1829 appeared the *Analysis of the Human Mind*. From 1831 to 1833 he was largely occupied in the defence of the East India Company during the controversy attending the renewal of its charter, he being in virtue of his office the spokesman of the court of directors. In 1834 Sir William Molesworth projected the *London Review*, and Mill contributed to it during the last two years of his life. His most notable article was one entitled "The Church and its Reform," which was much too sceptical for the time, and injured the *Review*. His last published book was the *Fragment on Mackintosh*, which appeared in 1835. He died on the 23d June 1836.

A considerable space would be required to do justice to Mill's character—intellectual and moral—as shown both in his writings and in his intensely active and influential career. He was an excellent scholar, in the sense of knowing the Greek and Roman classics. His other accomplishments included general history, the philosophy of politics in the most comprehensive acceptation, logic, ethics, and mental philosophy. The type of his intellect was logical in the highest degree; he was, above all things, clear and precise, an enemy of every form of looseness of reasoning, and a crusher of prevailing fallacies. This is the most notable feature in his writings throughout. His was also an original mind. Except in a few subjects, which had been so well elaborated by Bentham that he was content to be little more than an expounder of Bentham's views, he gave a fresh turn to whatever topic he took up. At a time when social subjects were subjected almost exclusively to an empirical handling, he insisted on bringing first principles to bear at every point; in this lay both his strength and his weakness.

His greatest literary monument is the *History of India*. The materials for narrating the acquisition by England of its Indian empire were put into shape for the first time; a vast body of political theory was brought to bear on the delineation of the Hindu civilization; and the conduct of the actors in the successive stages of the conquest and administration of India was subjected to a severe criticism. The work itself, and the author's official connexion with India for the last seventeen years of his life, effected a complete change in the whole system of governing that country.

Mill played a great part as a politician and political philosopher in English affairs as well. He was, more than any other man, the founder of what was called philosophical radicalism. His writings on government and his personal influence among the Liberal politicians of his time determined the change of view from the French Revolution theories of the rights of man and the absolute equality of men to the claiming of securities for good government through a great extension of the electoral suffrage. Under this banner it was that the Reform Bill was fought and won.

His work on *Political Economy* was intended as a text-book of the subject, and shows all the author's precision and lucidity. It followed up the views of Ricardo, with whom Mill was in habitual intimacy. It urged strongly the modern application of the principle of population, and started the doctrine of taxing land for the unearned increment of value.

By his *Analysis of the Mind* and his *Fragment on Mackintosh* Mill acquired a position in the history of psychology and ethics. Attached to the *a posteriori* school, he vindicated its claims with conspicuous ability. He took up the problems of mind very much after the fashion of the Scotch school, as then represented by Reid, Stewart, and Brown, but made a new start, due in part to Hartley, and still more to his own independent thinking. He carried out the principle of association into the analysis of the complex emotional states, as the affections, the æsthetic emotions, and the moral sentiment, all which he endeavoured to resolve into pleasurable and painful sensations. But the salient merit of the *Analysis* is the constant endeavour after precise definition of terms and clear statement of doctrines. The *Fragment on Mackintosh* is a severe exposure of the flimsiness and misrepresentations of Mackintosh's famous dissertation on ethical philosophy. It discusses, in a very thorough way, the foundations of ethics from the author's point of view of utility.

Mill's influence on the young men of his time by his conversation has been especially celebrated. Among those that came under this influence were some of the greatest names in the generation that succeeded him. He had himself a very high ideal of public virtue, which he carried out, at the risk of sacrificing all his chances of worldly advancement, and he impressed this ideal on those that surrounded him,—most of all on his own son, who has since eclipsed his father in fame, if not in genius.

See J. S. Mill's *Autobiography*, Bain's *Life of James Mill*, G. S. Bower's *Hartley and James Mill*. (A. B.*)

MILL, John (*c.* 1645–1707), editor of an historically important critical edition of the New Testament, was born about 1645 at Shap in Westmoreland, entered Queen's College, Oxford, as a servitor in 1661, and took his master's degree in 1669. Soon afterwards he was chosen fellow and tutor of his college; in 1676 he became chaplain to the bishop of Oxford, and in 1681 he obtained the rectory of Blechingdon, Oxfordshire, and was made chaplain to Charles II. From 1685 till his death he held the appointment of principal of St Edmund's Hall; and in 1704 he was nominated by Queen Anne to a prebendal stall in Canterbury. He died on June 23, 1707, just a fortnight after the publication of his Greek Testament.

Mill's *Novum Testamentum Græcum, cum lectionibus variantibus MSS. Exemplarium, Versionum, Editionum SS. Patrum et Scriptorum Ecclesiasticorum, et in easdem notis* (Oxford, fol. 1707), was undertaken by the advice and encouragement of Fell, his predecessor in the field of New Testament criticism; it represents the labour of thirty years, and is admitted to mark a great advance on all that had previously been achieved. The text indeed is that of R. Stephanus (1550), but the notes, besides embodying all previously existing collections of various readings, add a vast number derived from his own examination of many new MSS. and Oriental versions (the latter unfortunately he used only in the Latin translations). He was the first to notice, though only incidentally, the value of the concurrence of the Latin evidence with the Codex Alexandrinus, the only representative of an ancient non-Western Greek text then sufficiently known; this hint was not lost on Bentley (see Westcott and Hort, *Introduction to New Testament*). Mill's various readings, numbering about thirty thousand, were attacked by Whitby in his *Examen* as destroying the validity of the text; Antony Collins also argued in the same sense though with a different object. The latter called forth a reply from Bentley (*Phileleutherus Lipsiensis*). In 1710 Kuster reprinted Mill's Testament at Amsterdam with the readings of twelve additional MSS.

MILL, John Stuart (1806–1873), son of James Mill (*q.v.*), was born in London on the 20th May 1806. His education was from first to last undertaken by his father, and is likely long to remain a standing subject for wonder and discussion. Much of the wonder is no doubt due to his father's monstrous inversion of custom, the boy being set almost as soon as he could speak to work at our time-honoured subjects of secondary and higher education. He was taught the Greek alphabet at the age of three, and one of his earliest recollections, as he has recorded in his autobiography, was learning lists of common Greek words with their English meanings, written for him by his father on cards. By his eighth year he had gone through in the original a great many Greek books. "Of grammar," he says, "until some years later, I learnt no more than the inflexions of the nouns and verbs, but after a course of vocables proceeded at once to translation; and I faintly

remember going through *Æsop's Fables*, the first Greek book which I read. The *Anabasis*, which I remember better, was the second. I learnt no Latin until my eighth year. At that time I had read under my father's tuition a number of Greek prose authors, among whom I remember the whole of Herodotus and of Xenophon's *Cyropædia* and *Memorials of Socrates*, some of the lives of the philosophers by Diogenes Laertius, part of Lucian, and Isocrates *Ad Demonicum* and *Ad Nicoclem*. I also read, in 1813, the first six dialogues (in the common arrangement) of Plato, from the *Euthyphron* to the *Theætetus* inclusive." Besides all these Greek books, he had read a great deal of history in English—Robertson's histories, Hume, Gibbon, Watson's *Philip II. and III.*, Hooke's *Roman History*, Rollin's *Ancient History*, Langhorne's *Plutarch*, Burnet's *History of My Own Times*, thirty volumes of the *Annual Register*, Millar's *Historical View of the English Government*, Mosheim's *Ecclesiastical History*, M'Crie's *Knox*, and two histories of the Quakers.

That Mill "knew Greek" and "read Plato" before he was eight years old is often repeated, sometimes as an instance of amazing precocity, sometimes as an awful example of injudicious parental forcing. The astonishment that a child should have done so much at such an age is probably as little grounded in reason as was Mill's own opinion that any child might have done the same. It is forgotten that many thousands of persons have known Greek before the age of eight without a knowledge of the technicalities of Greek grammar. In presence of the fact that Mill was never distinguished for great memory of detail or richness of historical or literary allusion, it is a fair conclusion that the matter of his reading at this age was of as little service to him in after life as if he had read the trashiest of boy's own books. This is not to say that for educational purposes his early years were wasted as in his own and his father's opinion they generally are. But undoubtedly the main factor in Mill's education was not the literature put into his hands, but his constant intercourse with the active richly stored mind and strenuous character of his father. If any should be tempted to imitate the method, they should bear in mind that this was the cardinal element of it. The tutor was of more importance than the books. The reading of Plato's dialogues would have been only an exercise in rough translation if the boy had not had a Socrates with him in living communion. The child was a constant inmate of his father's study, and trotted by his side in his walks, giving from jottings on slips of paper as good an account as he could of what he had read. He thus learnt at an unusually early age by example, precept, and practice the habit of strenuous application to difficult work. The fact that Mill was taught thus early to take his chief pleasure in overcoming intellectual difficulties, and to realize the meaning of general terms, accounts for the singular and altogether unparalleled ease which he acquired in the treatment of political and social generalizations, not in barren abstract vagueness, but in close relation with facts. This on the intellectual side; and on the moral side the child was almost from the dawn of consciousness instructed to regard himself as consecrated to a life of labour for the public good; his ambition was kindled to follow in the footsteps of the great men of all ages, and at the same time the utmost care was taken to purify that ambition from unworthy motives.

A contemporary record of Mill's studies from eight to thirteen is published in Dr Bain's sketch of his life. It shows that the *Autobiography* rather understates than overstates the amount of work done. At the age of eight he began Latin, Euclid, and algebra, and was appointed schoolmaster to the younger children of the family—a post, he hints, more serviceable to his intellect than to his manners. His main reading was still history, but he went through all the Latin and Greek authors commonly read in the schools and universities, besides several that are not commonly read by undergraduates. He was not taught to compose either in Latin or in Greek, and he was never an exact scholar in the academic sense; it was for the subject-matter that he was required to read, and by the age of ten he could read Plato and Demosthenes with ease. His father's *History of India* was published in 1818; immediately thereafter, about the age of twelve, John, under his energetic direction, began a thorough study of the scholastic logic, at the same time reading Aristotle's logical treatises in the original. In the following year he was introduced to political economy. And there, when the pupil was nearly fourteen, this remarkable education terminated. From that time he worked less immediately under his father's eye. It was an inevitable incident of such an education that Mill should acquire many of his father's speculative opinions, and his father's way of defending them. But his mind did not receive the impress passively and mechanically. "One of the grand objects of education," according to the elder Mill, "should be to generate a constant and anxious concern about evidence"; and he laboured with all the energy of his strong will against allowing his son to become a parrot of his own opinions and arguments. The duty of collecting and weighing evidence for himself was at every turn impressed upon the boy; he was taught to accept no opinion upon authority; he was soundly rated if he could not give a reason for his beliefs. John Stuart Mill was deliberately educated as an apostle, but it was as an apostle of reasoned truth in human affairs, not as an apostle of any system of dogmatic tenets. It was purposely to prevent any falling off from this high moral standard till it should become part of his being that his father kept the boy so closely with himself. Much pity has been expressed over the dreary cheerless existence that the child must have led, cut off from all boyish amusements and companionship, working day after day on his father's treadmill; but a childhood and boyhood spent in the daily enlargement of knowledge, with the continual satisfaction of difficulties conquered, buoyed up by day-dreams of emulating the greatest of human benefactors, need not have been an unhappy childhood,—and Mill expressly says that his was not unhappy. It seems unhappy only when we compare it with the desires of childhood left more to itself, and when we decline to imagine its peculiar enjoyments and aspirations. Mill complains that his father often required more than could reasonably be expected of him, but his tasks were not so severe as to prevent him from growing up a healthy, hardy, and high-spirited boy, though he was not constitutionally robust, and his tastes and pursuits were so different from those of other boys of the same age.

Most of Mill's fifteenth year was spent in France in the family of Sir Samuel Bentham. Away from his father, he maintained his laborious habits; the discipline held. Copious extracts from a diary kept by him at this time are given by Dr Bain, and show how methodically and incessantly he read and wrote, studied botany, tackled advanced mathematical problems, made notes on the scenery and the people and customs of the country. On his return in 1821 he continued his old studies with the addition of some new ones. One of the new studies was Roman law, which he read with John Austin, his father having half decided on the bar as the best profession open to him. Another was psychology. In 1823, when he had just completed his seventeenth year, the notion of the bar as a livelihood was abandoned, and he entered as a clerk in the examiner's office of the India House, "with the under-

standing that he should be employed from the beginning in preparing drafts of despatches, and be thus trained up as a successor to those who then filled the highest departments of the office."

Mill's work at the India House, which was henceforth his livelihood, did not come before the public, and those who have scouted his political writings as the work of an abstract philosopher, entirely unacquainted with affairs, have ignored the nature of his duties. From the first he was more than a clerk, and after a short apprenticeship he was promoted, in 1828, to the responsible position of assistant-examiner. The duty of the so-called examiners was to examine the letters of the agents of the Company in India, and to draft instructions in reply. The character of the Company's government was almost entirely dependent upon their abilities as statesmen. For twenty years, from 1836 to 1856, Mill had charge of the Company's relations with the native states. In the hundreds of despatches that he wrote in this capacity, much, no doubt, was done in accordance with established routine, but few statesmen of his generation had a wider experience of the responsible application of principles of government to actual emergencies. That he said so little about this work in the *Autobiography* was probably because his main concern there was to expound the influences that affected his moral and mental development. A man of different temperament might have found abundance of dramatic interest in watching the personal and political changes in so many distinct states. But Mill makes no reminiscences of this kind, nor does he give any clue to the results of his own initiative.

To return to his extra-official activity, which received an immense impulse about the time of his entering the India House from what must strike a man of the world as a strange source. The reading of Dumont's exposition of Bentham's doctrines in the *Traité de Législation* was an epoch in Mill's life. It awoke in him an ambition as enthusiastic and impassioned as a young man's first love. The language that he uses about it in his autobiography reveals a warmth of inner life that few people would suspect from the record of his dry studies. When he laid down the last volume, he says, he had become a different being. It gave unity to the detached and fragmentary component parts of his knowledge and beliefs. "I now had opinions—a creed, a doctrine, a philosophy—in one among the best senses of the word, a religion, the inculcation and diffusion of which could be made the principal outward purpose of a life. And I had a grand conception laid before me of changes to be effected in the condition of mankind through that doctrine." He had been carefully bred to contemplate work for human welfare as the ruling motive of his life; that motive had now received definite direction.

Many a youth has entered the world with ambition equally high, but few have felt as Mill felt the first shock of despair, and fewer still have rallied from that despair with such indomitable resolution. The main secret of the great "crisis" of his youthful life is probably to be found in the lofty ardour of the aspirations then conceived and shaped. For four years he worked with faith and hope in his mission, and these were years of incessant propagandist activity. The enthusiast of seventeen, burning to reorganize human affairs so as to secure the greatest happiness of the greatest number, set siege to the public mind through several approaches. He constituted a few of his youthful friends, imbued with the principles of his new creed, into a society which he called the "Utilitarian" Society, taking the word, as he tells us, from one of Galt's novels. Two newspapers were open to him—the *Traveller*, edited by a friend of Bentham's, and the *Chronicle*, edited by his father's friend Black. One of his first efforts was a solid argument for freedom of discussion, in a series of letters to the *Chronicle* apropos of the prosecution of Richard Carlile. But he watched all public incidents with a vigilant eye, and seized every passing opportunity of exposing departures from sound principle in parliament and courts of justice. Another outlet was opened up for him in 1824 by the starting of the *Westminster Review*, and still another in the following year in the *Parliamentary History and Review*. This year also he found a congenial occupation in editing Bentham's *Rationale of Judicial Evidence*. Into this he threw himself with zeal. And all the time, his mind full of public questions, he discussed and argued eagerly with the many men of promise and distinction who came to his father's house. He engaged in set discussions at a reading society formed at Grote's house in 1825, and in set debates at a Speculative Society formed in the same year.

"A very disquisitive youth," was Peacock's description of young Mill at this period, and this was probably how the enthusiast struck most of his outside acquaintances. But the glow of a great ambition as well as the energy of a piercing intellect might have been felt in his writings. His mission was none the less arduous that he proposed to convert the world by reason. Only the fulness of unbroken hope could have supported his powers, if he had had a frame of iron, under the strain of such incessant labour. All of a sudden, a misgiving which he compares to the Methodist's "first conviction of sin" made a rift in the wholeness of his faith in his mission. "It was in the autumn of 1826. I was in a dull state of nerves, such as everybody is occasionally liable to; unsusceptible to enjoyment or pleasurable excitement; one of those moods when what is pleasure at other times becomes insipid or indifferent. . . . . In this frame of mind it occurred to me to put the question directly to myself, 'Suppose that all your objects in life were realized, that all the changes in institutions and opinions which you are now looking forward to could be completely effected at this very instant, would this be a great joy and happiness to you?' And an irrepressible self-consciousness distinctly answered, 'No!' At this my heart sank within me; the whole foundation on which my life was constructed fell down. All my happiness was to have been found in the continual pursuit of this end. The end had ceased to charm, and how could there ever again be any interest in the means? I seemed to have nothing left to live for."

The passage in his autobiography in which Mill gives an account of this prostrating disenchantment and his gradual release from its benumbing spell is one of the most interesting chapters in personal history. The first break in the gloom came, he tells us, from his reading in Marmontel's *Mémoires* "the passage which relates his father's death, the distressed position of the family, and the sudden inspiration by which he, then a mere boy, felt and made them feel that he would be everything to them—would supply the place of all that they had lost." Mill was moved to tears by the narrative, and his burden grew lighter at the thought that all feeling was not dead within him, that he was not a mere intellectual machine. This incident, and the delight that he now began to take in Wordsworth's "Poems founded on the Affections," gives a clue to one of the secrets of Mill's despondency. It was an unsatisfied longing for personal affection, for love and friendship, of which his life hitherto had been barren. His father seems to have been reserved, undemonstrative even to the pitch of chilling sternness in his intercourse with his family; and among young Mill's comrades contempt of feeling was almost a watchword, because it is so often associated with mischievous prejudice and wrong conduct. Himself absorbed in abstract questions and pro-

jects of general philanthropy, he had been careless of winning or keeping personal attachment. But it was not till despair first seized him, as he looked back at the poverty of the results of his work as an apostle, that Mill began to feel the void in his affections and the need of human sympathy. We must remember how little when his ambition was formed he knew of the living world around him. He knew in terms that political and social change must be slow; he could whisper patience to himself, and say to himself that his life must be happy because the attainment of his great object must occupy the whole of it; but without experience he could not have been prepared for the actual slowness of the reformer's work, or armed against its terribly oppressive influence. Inevitably he underrated the stolidity and strength of the forces arrayed against him. Four years seems a long time at that age. In 1826 Mill could look back to four years of eager toil. What were the results? He had become convinced that his comrades in the Utilitarian Society, who never numbered more than ten, had not the stuff in them for a world-shaking propaganda; the society itself was dissolved; the *Parliamentary Review* was a failure; the *Westminster* did not pay its expenses; Bentham's *Judicial Evidence* produced little effect on the reviewers. His own reception at the Speculative Debating Society, where he first measured his strength in public conflict, was calculated to produce self-distrust. He found himself looked upon with curiosity as a precocious phenomenon, a "made man," an intellectual machine set to grind certain tunes. The most clear and cogent reasoning failed to sway his audience. Great things had been expected of this society as a means of bringing together for close discussion the leading young men then in public life or looking forward to it. Its first session proved a fiasco. The leaders that had been expected stayed away. With these repulses to his hopes along the whole line of his activity, Mill must also have suffered from the nervous exhaustion that only the hope and heat of the fight had kept him from feeling before. No wonder that he was disheartened, began to feel defects in his father's training, to question and analyse his own faith, to yearn for the solace of personal affection, and to reconstitute his scheme of life.

That in spite of this rude shock the foundations laid by his early training remained stable appears from the facts that all through the period of his gloom he continued working as before, and that he considered himself bound, once convinced that his old plan of life was insufficient, to build up a thoroughly reasoned new plan wherewith to give new heart and hope to his work. The new system was much less different from the old than might be supposed from what he says of the struggle that it cost him to reach it. Regard for the public good was still his religion, the ruling motive that gave unity to his conduct. But he now recognized that this was too vague and insubstantial an object to be sufficient of itself for the satisfaction of a man's affections. It is a proof of the dominating force of his father's character that it cost the younger Mill such an effort to shake off his stern creed about poetry and personal emotion. Like Plato, the elder Mill would have put poets under ban as ministers of prejudice and enemies of truth. And he often insisted on the wisdom of restricting as much as possible the private affections, while expanding as much as possible the public affections. Landor's maxim of "few acquaintances, fewer friends, no familiarities" had his cordial approval. These doctrines the younger Mill at first took up with boyish enthusiasm and pedantry, but it was against this part of his father's creed that he now felt himself forced in reason to revolt. He stood too much in awe of his father to make him the confidant of his difficulties. He wrestled with them in the gloomy solitude of his own mind. He was victorious; he reached firm ground at last; but the struggle left him in several respects changed. He carried out of the struggle as the fruits of victory a more catholic view of the elements of human happiness, a delight in the poetry of nature and the affections as well as the poetry of heroic unselfish character and action, a disposition to study more sympathetically the point of view of opponents, a more courteous style of polemic, a hatred of sectarianism, an ambition no less noble and disinterested but moderated to practical possibilities.

In the course of the next few years Mill wrote comparatively little, but he "carried on," as he says, "a quantity of thinking respecting a host of subjects." It was a period of search, deliberation, germination, and striking root. Coincident if not causally connected with the relief from his spiritual crisis came his first consciousness of power as "an original and independent thinker." In the dialectic conversations with a small band of students at Grote's house, he regained the self-confidence that had been shaken in the larger and rougher arena of the Speculative Debating Society. The beginning of his works on logic and political economy may be traced back to those discussions, and he learnt from them, he tells us, the habit of "never accepting half solutions of difficulties as complete; never abandoning a puzzle, but again and again returning to it until it was cleared up; never allowing obscure corners of a subject to remain unexplored, because they did not appear important; never thinking that he perfectly understood any part of a subject until he understood the whole." He learnt also an important moral lesson from the Speculative Society, besides learning the strong points of other political and social creeds and the weak points of Benthamism from defending it point by point against all comers. With all his despondency, he did not abandon the meetings of the society after the fiasco of the first session. He stood by it firmly, and in a short time had the triumph of seeing its debates famous enough to attract men with whom it was profitable for him to interchange opinions, among others Maurice and Sterling. He ceased to attend the society in 1829, but he carried away from it the strengthening memory of failure overcome by persevering effort, and the important doctrinal conviction that a true system of political philosophy was "something much more complex and many-sided than he had previously had any idea of, and that its office was to supply, not a set of model institutions, but principles from which the institutions suitable to any given circumstances might be deduced."

The first sketch of Mill's political philosophy appeared in a series of contributions to the *Examiner* in the autumn of 1830 on "Prospects in France." He was in Paris soon after the July Revolution, made the acquaintance of the leading spirits among the younger men; and in his discussion of what they were doing and what they should do in making a new constitution we find the germs of many thoughts afterwards more fully developed in his *Representative Government.*

The division of a man's life into periods must always be a rough partition, but we may conveniently and with tolerable accuracy take these letters as marking the close of his period of meditative search, of radication, and his return to hopeful aspiring activity. It was characteristic of the nature of the man that he should be stirred to such delight by the Revolution in France, and should labour so earnestly to make his countrymen understand with what gravity and sobriety it had been effected. Their own Reform Bill came soon after, and it is again characteristic of Mill—at once of his enthusiasm and of his steady determination to do for humanity the work that nobody else

seemed able or willing to do—that we find him in the heat of the struggle in 1831 writing to the *Examiner* a series of letters on "The Spirit of the Age" which drew from Carlyle the exclamation, "Here is a new mystic!" We can easily see now what it was in these remarkable essays that fascinated Carlyle; it was the pervading opinion that in every natural state of society power must be in the hands of the wisest. This was the condition of stability; when power and wisdom ceased to coincide, there was a disturbance of the equilibrium till this coincidence was again effected. But whether Carlyle was right in the epithet "mystic" may be judged from the fact that Mill's inductive logic was the direct result of his aspirations after political stability as determined by the dominion of the wisest. "Why is it," he asked, "that the multitude accept implicitly the decisions of the wisest, of the specially skilled, in physical science?" Because in physical science there is all but complete agreement in opinion. "And why this agreement?" Because all accept the same methods of investigation, the same tests of truth. Is it possible then to obtain unanimity as to the methods of arriving at conclusions in social and political matters, so as to secure similar agreement of opinion among the specially skilled, and similar general respect for their authority? The same thought appears in a review of Herschel's *Natural Philosophy*, written about the same time. Mill remarks that the uncertainty hanging over the very elements of moral and social philosophy proves that the means of arriving at the truth in those sciences are not yet properly understood. "And whither," he adds, "can mankind so advantageously turn, in order to learn the proper means, and to form their minds to the proper habits, as to that branch of knowledge in which by universal acknowledgment the greatest number of truths have been ascertained, and the greatest possible degree of certainty arrived at?"

By 1831 Mill's enthusiasm for humanity had been thoroughly reawakened, and had taken the definite shape of an aspiration to supply an unimpeachable method of search for conclusions in moral and social science. From the platform on which Carlyle and Mill met in 1831 they travelled different roads,—the one to preach the duty of obedience to the wisest, the other to search for a means by which wisdom might be acquired such as would command respect and win the assent of free conviction. No mystic ever worked with warmer zeal than Mill. But his zeal encountered a check which baffled him for several years, and which left its mark in various inconsistencies and incoherences in his completed system. He had been bred by his father in a great veneration for the syllogistic logic as an antidote against confused thinking. He attributed to his early discipline in this logic an impatience of vague language which in all likelihood was really fostered in him by his study of the Platonic dialogues and of Bentham, for he always had in himself more of Plato's fertile ingenuity in canvassing the meaning of vague terms than the schoolman's rigid consistency in the use of them. Be this as it may, enthusiastic as he was for a new logic that might give certainty to moral and social conclusions, Mill was no less resolute that the new logic should stand in no antagonism to the old. In his *Westminster* review of Whately's *Logic* in 1828 (invaluable to all students of the genesis of Mill's logic) he appears, curiously enough, as an ardent and brilliant champion of the syllogistic logic against highfliers such as the Scotch philosophers who talk of "superseding" it by "a supposed system of inductive logic." His inductive logic must "supplement and not supersede." It must be concatenated with the syllogistic logic, the two to be incorporated in one system. But for several years he searched in vain for the means of concatenation.

Meantime, while recurring again and again, as was his custom, to this cardinal difficulty, Mill worked indefatigably in other directions where he saw his way clear, expatiating over a wide range of political, social, economical, and philosophical questions. The working of the new order in France, and the personalities of the leading men, had a profound interest for him; he wrote on the subject in the *Examiner*. He had ceased to write for the *Westminster* in 1828; but during the years 1832 and 1833 he contributed many essays to *Tait's Magazine*, the *Jurist*, and the *Monthly Repository*. In 1835 the *London Review* was started, with Mill as editor; it was amalgamated with the *Westminster* in 1836, and Mill continued editor till 1840. Much of what he wrote then was subsequently incorporated in his systematic works; some of his essays were reprinted in his first two volumes of *Dissertations and Discussions* (1859). The essays on Bentham and Coleridge constituted the first manifesto of the new spirit which Mill sought to breathe into English Radicalism. But the reprinted papers give no just idea of the immense range of Mill's energy at this time. His position in the India Office, where alone he did work enough for most men, cut him off from entering parliament; but he laboured hard though ineffectually to influence the legislature from without by combating the disposition to rest and be thankful. In his *Autobiography* he admits that the attempt to form a Radical party in parliament at that time was chimerical.

It was in 1837, on reading Whewell's *Inductive Sciences* and re-reading Herschel, that Mill at last saw his way clear both to formulating the methods of scientific investigation and joining on the new logic as a supplement to the old. Epoch-making as his logic undoubtedly was, from the multitude of new views opened up, from the addition of a new wing to the rambling old building, and from the inspiring force with which every dusty chamber was searched into and illuminated, Mill did not escape all the innumerable pitfalls of language that beset the pioneer in such a subject. It is evident from a study of his purposes and the books from which he started that his worst perplexities were due to his determination to exhibit scientific method as the complement of scholastic logic. In his defence of the syllogism he confounds the syllogistic forms with deductive reasoning. Every deductive reasoning may be thrown into the form of a syllogism, but not every syllogism is deductive. The reasoning in several of the syllogistic forms is not deductive at all in the sense of involving a movement from general to particular. Although he knew Aristotle in the original, Mill did not recognize the fact that the syllogistic machinery was primarily constructed for the reasoning together of terms. As regards the word induction, Mill uses it in different connexions to cover three or four distinguishable meanings—induction viewed as the establishment of predications about a general term, induction viewed as inference from the known to the unknown, induction viewed as verification by experiment, and induction viewed as the proof of propositions of causation. The form of his system was really governed by the scholastic notion of induction as a means of establishing general propositions; the inductive part of his system is introduced after the deductive under this character; while the greater portion of the substance of what he treats of under the name of induction, and especially the so-called experimental methods, have nothing whatever to do with the establishment of general propositions, in the technical sense of general propositions.

But the permanent value and influence of Mill's inductive logic is not to be measured by technical inaccuracies and inconsistencies, to which an academic mind may easily attach undue importance. In the technical history of the science, Mill's *Logic* may be viewed as an attempt to fuse

the practical tests of truth set forth in Herschel's *Discourse on Natural Philosophy* with the theoretic views of induction propounded in Whately's *Logic*. But in the history of thought the great importance of the work is due not so much to its endeavour to formulate the methods of science and lay bare the first principles on which they rest as to its systematic application of scientific method to what he called the moral sciences. Mill has often been criticized as if he had pretended to teach men how to conduct their investigations and how to make discoveries in the physical sciences. His work was rather to educe from the practice of men of science the principles on which they proceed in testing and proving their speculations concerning cause and effect in the physical world, and see whether the same principles could not be applied in testing and proving speculations concerning cause and effect in the moral world. What is the effect upon human character and human happiness of given social and physical conditions—climate, institutions, customs, laws? How can conclusions upon such points be proved? These were the questions in which Mill was interested, and the striking novelty of his work was its endeavour to show that propositions of cause and effect in human affairs must be proved, if they admit of proof at all, absolute or approximate, on the same principles with propositions of cause and effect in the material world.

The *Logic* was published in 1843. In 1844 appeared his *Essays on Some Unsettled Questions in Political Economy*. These essays were worked out and written many years before, and show Mill in his first stage as a political economist. Four out of the five essays are elaborate and powerful solutions of perplexing technical problems—the distribution of the gains of international commerce, the influence of consumption on production, the definition of productive and unproductive labour, the precise relations between profits and wages. Though Mill appears here purely as the disciple of Ricardo, striving after more precise statement, and reaching forward to further consequences, we can well understand in reading these essays, searching, luminous, large and bold in outline, firmly wrought in detail, how about the time when he first sketched them he began to be conscious of power as an original and independent thinker.

That originality and independence became more conspicuous when he reached his second stage as a political economist, struggling forward towards the standpoint from which his systematic work was written. It would seem that in his fits of despondency one of the thoughts that sat upon him like a nightmare and marred his dreams of human improvement was the apparently inexorable character of economic laws, condemning thousands of labourers to a cramped and miserable existence, and thousands more to semi-starvation. From this oppressive feeling he found relief in the thought set forth in the opening of the second book of his *Political Economy*—that, while the conditions of production have the necessity of physical laws, the distribution of what is produced among the various classes of producers is a matter of human arrangement, dependent upon alterable customs and institutions. There can be little doubt that this thought, whether or not in the clear shape that it afterwards assumed, was the germ of all that is most distinctive in his system of political economy. It was as far as possible from the rigidity of his method of exposition to fall into the confusion of supposing that it was for political economy to discuss the equity of different modes of distribution, or the value of other objects of human endeavour conflicting with the production of wealth; but he put economic inquiries clearly in their proper place as leading to conclusions that were not always final and binding on the practical statesman, but had to be taken with other considerations as governing rational human action. Besides thus putting political economy in its just correlation with other parts of social science and conduct, Mill widened the scope of economic inquiries by discussing the economic consequences of various ideal social arrangements, and more especially different modes of distributing produce between landlord, capitalist, and labourer. Mill certainly redeemed political economy from the reproach of being a dry science. Nobody with any interest in human improvement can read his work with indifference. And he did this without in any way disturbing the original conception of political economy as the science of cause and effect in the production of wealth. One of his most eminent successors, the late Professor Cairnes, thus admirably summed up his work as a political economist:—"As he himself used to put it, Ricardo supplied the backbone of the science; but it is not less certain that the limbs, the joints, the muscular developments—all that renders political economy a complete and organized body of knowledge—have been the work of Mill."

While his great systematic works were in progress, Mill wrote very little on events or books of the day. He turned aside for a few months from his *Political Economy* during the winter of the Irish famine (1846–47) to advocate the creation of peasant-proprietorships as a remedy for distress and disorder in Ireland. He found time also to write elaborate articles on French history and Greek history in the *Edinburgh Review* apropos of Michelet, Guizot, and Grote, besides some less elaborate essays.

The *Political Economy* was published in 1848. Mill could now feel that the main work he had proposed for himself was accomplished; but, though he wrote comparatively little for some years afterwards, he remained as much as ever on the alert for opportunities of useful influence, and pressed on with hardly diminished enthusiasm in his search for useful truth. Among other things, he made a more thorough study of socialist writers, with the result that, though he was not converted to any of their schemes as being immediately practicable, he began to look upon some more equal distribution of the produce of labour as a practicability of the remote future, and to dwell upon the prospect of such changes in human character as might render a stable society possible without the institution of private property. This he has called his third stage as a political economist, and he says that he was helped towards it by the lady, Mrs Taylor, who became his wife in 1851, and with whom he had lived in intimate friendship for more than twenty years before. It is generally supposed that he writes with a lover's extravagance about this lady's powers when he compares her with Shelley and Carlyle. But a little reflexion will show that he wrote with his usual accuracy and sobriety when he described her influence on him. He expressly says that he owed none of his technical doctrine to her, that she influenced only his ideals of life for the individual and for society; and his language about her is really only a measure of the importance that he attached to such ideals above any systems of reasoned truth. There is very little propositional difference between Mill and his father; but it is obvious from what he says that his inner life became very different after he threw off his father's authority. This new inner life was strengthened and enlarged by Mrs Taylor. We must remember also that Mill in his early years had been so strictly secluded from commonplace sentiment that what the general world would consider commonplace must have come to him with all the freshness of a special revelation.

During the seven years of his married life Mill published less than in any other period of his career, but four of his

generally regarded as the main causes of his defeat in the general election of 1868. But, as he suggests himself, his studied advocacy of unfamiliar projects of reform had made him unpopular with "moderate Liberals." When he was first elected on a sudden impulse of enthusiasm, extremely little was known about him by the bulk of the electorate; and his writing about checks against democracy had prepared many for a more conservative attitude on questions of practical politics. He retired with a sense of relief to his cottage and his literary life at Avignon. His parliamentary duties and the quantity of correspondence brought upon him by increased publicity had absorbed nearly the whole of his time. The scanty leisure of his first recess had been devoted to writing his St Andrews rectorial address on higher education and to answering attacks on his criticism of Hamilton; of the second, to annotating, in conjunction with Mr Bain and Mr Findlater, his father's *Analysis of the Mind*. But now he could look forward to a literary life pure and simple, and his letters show how much he enjoyed the change. His little cottage was filled with books and newspapers; the beautiful country round it furnished him with a variety of walks; he read, wrote, discussed, walked, botanized. His step-daughter, Miss Taylor, his constant companion after his wife's death, "architect and master-mason all in one," carried out various improvements in their quiet home for the philosopher's comfort. "Helen," he wrote to Mr Thornton, "has carried out her long-cherished scheme (about which she tells me she consulted you) of a 'vibratory' for me, and has made a pleasant covered walk, some 30 feet long, where I can vibrate in cold or rainy weather. The terrace, you must know, as it goes round two sides of the house, has got itself dubbed the 'semi-circumgyratory.' In addition to this Helen has built me a herbarium, a little room fitted up with closets for my plants, shelves for my botanical books, and a great table whereon to manipulate them all. Thus, you see, with my herbarium, my vibratory, and my semi-circumgyratory, I am in clover; and you may imagine with what scorn I think of the House of Commons, which, comfortable club as it is said to be, could offer me none of these comforts, or, more perfectly speaking, these necessaries of life." Mill was an enthusiastic botanist all his life long, and a frequent contributor of notes and short papers to the *Phytologist*. One of the things that he looked forward to during his last journey to Avignon was seeing the spring flowers and completing a flora of the locality. His delight in scenery frequently appears in letters written to his friends during his summer and autumn tours.

No recluse ever had a more soothing retreat than Mill's Avignon cottage, but to the last he did not relax his laborious habits nor his ardent outlook on human affairs. The essays in the fourth volume of his *Dissertations*—on endowments, on land, on labour, on metaphysical and psychological questions—were written for the *Fortnightly Review* at intervals after his short parliamentary career. One of his first tasks was to send his treatise on the *Subjection of Women* through the press. The essay on *Theism* was written soon after. The last public work in which he engaged was the starting of the Land Tenure Reform Association. The interception by the state of the unearned increment, and the promotion of co-operative agriculture, were the most striking features in his programme. He wrote in the *Examiner* and made a public speech in favour of the association a few months before his death. The secret of the ardour with which he took up this question probably was his conviction that a great struggle was impending in Europe between labour and capital. He regarded his project as a timely compromise.

Mill died at Avignon on the 8th of May 1873.

Within the limits of this article it is impossible to attempt a criticism of Mill's conclusions in so many fields of research; one must be content with trying to indicate the purpose and the spirit of his work. Perhaps we still stand too near to judge without bias; some years hence men will be better able to say whether he made sciolism less reckless or brought mankind appreciably nearer that dominion of the wisest which was the remote goal of his endeavour. It will be long before humanity finds a nobler example of the searcher after the best means of social improvement. He sought after clear ideas with the ardour of a mystic, the patience and laborious industry of a man of science; he encountered opponents with a generosity and a courtesy worthy of any *preux chevalier* of mediæval romance, while he was not inferior to that ideal in the vigour of his blows against injustice. As regards his influence, it has been well said that "no calculus can integrate the innumerable pulses of knowledge and of thought that he has made to vibrate in the minds of his generation." He quickened thought upon every problem that he touched. Any estimate of Mill's service to political or philosophical thought at this moment is liable to be injuriously affected by the temporary discredit into which some of his doctrines have fallen. He was not infallible; he made no claim to dogmatic authority. But in criticism of detail, according to our present light, we may easily blind ourselves to the greatness of the work that Mill accomplished in the development of opinion. (W. M.)

MILLAU, or MILHAU, capital of an arrondissement in the department of Aveyron, France, is situated on the left bank of the Tarn, half a mile below the point at which that river is joined by the Dourbie, and 48 miles to the south-east of Rodez, on the Rodez and Montpellier line. Itself 1210 feet above the level of the sea, it is overlooked by hills covered with vineyards and fruit trees or by bare and scarped rocks. The streets of Millau are narrow, and some of the houses of great antiquity, but the town is surrounded by spacious boulevards. On two sides the Place d'Armes is adorned by stone columns supporting galleries of wood; the only buildings of special interest are the Romanesque church of Notre Dame, and the belfry of the old hôtel de ville. The principal industry is the manufacture of gloves, but various branches of the leather manufacture are also carried on. The chief articles of commerce are wool (both raw and prepared), Roquefort cheese, wine, almonds, and live stock. The population in 1881 was 16,628.

The viscounts of Millau are mentioned as early as the 10th century; in the 16th it became one of the leading strongholds of the Reformed party in the south of France. Its industry suffered severely by the revocation of the edict of Nantes.

MILLENNIUM. In the history of Christianity three main forces are found to have acted as auxiliaries of the gospel. They have elicited the ardent enthusiasm of many whom the bare preaching of the gospel would never have made decided converts. These are (1) a belief in the speedy return of Christ and in His glorious reign on earth; (2) mystical contemplation, which regards heavenly blessings as a possible possession in the present life; and (3) faith in a divine predestination of some to salvation and others to perdition. Each of these forces has at particular times proved too strong for church authority and burst the embankments with which the church had at once narrowed and protected Christian life and thought. They have produced ecclesiastical, social, and political convulsions, where the elemental force of religious conviction has destroyed all organization, whether of church or of state. They have released from its fetters the free spirit of Christianity, though often enough they have associated with it a fanaticism more damaging to the gospel than the temporizing policy of the hierarchy.

First in point of time came the faith in the nearness of Christ's second advent and the establishing of His reign of glory on the earth. Indeed it appears so early that it might be questioned whether it ought not to be regarded as an essential part of the Christian religion. That question, however, will scarcely be answered in the affirmative. The ideas of the Sermon on the Mount, or the pregnant thoughts of the Pauline theology, are independent of the expectation that the kingdom of glory will shortly

be established. On the other hand, it must be admitted that this expectation was a prominent feature in the earliest proclamation of the gospel, and materially contributed to its success. If the primitive churches had been under the necessity of framing a "Confession of Faith," it would certainly have embraced those pictures by means of which the near future was distinctly realized. But then these pictures and dreams and hopes were just the things that made systematized doctrine impossible; it is possible to formulate the mythological ideas, but not the shifting imagery of the imagination.

In the anticipations of the future prevalent amongst the early Christians (*c.* 50–150) it is necessary to distinguish a fixed and a fluctuating element. The former includes (1) the notion that a last terrible battle with the enemies of God was impending; (2) the faith in the speedy return of Christ; (3) the conviction that Christ will judge all men, and (4) will set up a kingdom of glory on earth. To the latter belong views of the Antichrist, of the heathen world-power, of the place, extent, and duration of the earthly kingdom of Christ, &c. These remained in a state of solution; they were modified from day to day, partly because of the changing circumstances of the present by which forecasts of the future were regulated, partly because the indications—real or supposed—of the ancient prophets always admitted of new combinations and constructions. But even here certain positions were agreed on in large sections of Christendom. Amongst these was the expectation that the future kingdom of Christ on earth should have a fixed duration,—according to the most prevalent opinion, a duration of one thousand years. From this fact the whole ancient Christian eschatology was known in later times as "chiliasm,"—a name which is not strictly accurate, since the doctrine of the millennium was only one feature in its scheme of the future.

1. This idea that the Messianic kingdom of the future on earth should have a definite duration has—like the whole eschatology of the primitive church—its roots in the Jewish apocalyptic literature, where it appears at a comparatively late period. At first it was assumed that the Messianic kingdom in Palestine would last for ever (so the prophets; *cf.* Jerem. xxiv. 6; Ezek. xxxvii. 25; Joel iv. 20; Daniel vi. 27; Sibyll. iii. 49 *sq.*, 766; Psalt. Salom. xvii. 4; Enoch lxii. 14), and this seems always to have been the most widely accepted view (John xii. 34). But from a comparison of prophetic passages of the Old Testament learned apocalyptic writers came to the conclusion that a distinction must be drawn between the earthly appearance of the Messiah and the appearance of God Himself amongst His people and in the Gentile world for the final judgment. As a necessary consequence, a limited period had to be assigned to the Messianic kingdom. It is not altogether improbable that the mysterious references to the sufferings of the Messiah had also an influence on some minds. This, however, is doubtful. It is certain at all events that the whole conception marks the beginning of the dissolution of realistic and sensuous views of the future. The age was too advanced to regard the earthly Messianic kingdom as the end. There was an effort to find a place among the hopes of the future for those more spiritual and universal anticipations, according to which eternal and heavenly blessedness will be the portion of the faithful, this earth and heaven will pass away, and God will be all in all. As to the period to be assigned to this earthly kingdom, no agreement was ever reached in Judaism, any more than in the detailed descriptions of its joys and pleasures. According to the Apocalypse of Baruch (xl. 3) this kingdom will last "donec finiatur mundus corruptionis." In the Book of Enoch (xci. 12) "a week" is specified, in the Apocalypse of Ezra (vii. 28 *sq.*) four hundred years. This figure, corresponding to the four hundred years of Egyptian bondage, occurs also in the Talmud (Sanhedrin 99*a*). But this is the only passage; the Talmud has no fixed doctrine on the point. The view most frequently expressed there (see Von Otto in *Hilgenfeld's Zeitschrift*, 1877, p. 527 *sq.*) is that the Messianic kingdom will last for one thousand (some said two thousand) years. "In six days God created the world, on the seventh He rested. But a day of God is equal to a thousand years (Ps. xc. 4). Hence the world will last for six thousand years of toil and labour; then will come one thousand years of Sabbath rest for the people of God in the kingdom of the Messiah." This idea must have already been very common in the first century before Christ. The combination of Gen. i., Dan. ix., and Ps. xc. 4 was peculiarly fascinating.

2. Jesus Himself speaks of only one return of the Son of Man—His return to judgment. In speaking of it, and of the glorious kingdom He is to introduce, He makes use of apocalyptic images (Matt. viii. 11, xxvi. 29; Luke xxii. 16; Matt. xix. 28); but nowhere in the discourses of Jesus is there a hint of a limited duration of the Messianic kingdom. The apostolic epistles are equally free from any trace of chiliasm (neither 1 Cor. xv. 23 *sq.* nor 1 Thess. iv. 16 *sq.* points in this direction). In the Apocalypse of John, however, it occurs in the following shape (chap. xx.). After Christ has appeared from heaven in the guise of a warrior, and vanquished the antichristian world-power, the wisdom of the world, and the devil, those who have remained steadfast in the time of the last catastrophe, and have given up their lives for their faith, shall be raised up, and shall reign with Christ on this earth as a royal priesthood for one thousand years. At the end of this time Satan is to be let loose again for a short season; he will prepare a new onslaught, but God will miraculously destroy him and his hosts. Then will follow the general resurrection of the dead, the last judgment, and the creation of new heavens and a new earth. That *all* believers will have a share in the first resurrection and in the Messianic kingdom is an idea of which John knows nothing. The earthly kingdom of Christ is reserved for those who have endured the most terrible tribulation, who have withstood the supreme effort of the world-power,—that is, for those who are actually members of the church of the last days. The Jewish expectation is thus considerably curtailed in the hands of John, as it is also shorn of its sensual attractions. "Blessed and holy is he that hath part in the first resurrection; on such the second death hath no power; but they shall be priests of God and of Christ, and shall reign with Him a thousand years." More than this John does not say. But other ancient Christian authors were not so cautious. Accepting the Jewish apocalypses as sacred books of venerable antiquity, they read them eagerly, and transferred their contents bodily to Christianity. Nay more, the Gentile Christians took possession of them, and just in proportion as they were neglected by the Jews—who, after the war of Bar-Cochba, became indifferent to the Messianic hope and hardened themselves once more in devotion to the law—they were naturalized in the Christian communities. The result was that these books became "Christian" documents; it is entirely to Christian, not to Jewish, tradition that we owe their preservation. The Jewish expectations are adopted, for example, by Papias, by the writer of the epistle of Barnabas, and by Justin. Papias actually confounds expressions of Jesus with verses from the Apocalypse of Baruch, referring to the amazing fertility of the days of the Messianic kingdom (Papias in Iren. v. 33). Barnabas (*Ep.*, 15) gives us the Jewish theory (from Gen. i. and Ps. xc. 4) that the present condition of the world is to last six thousand years

The German and Swiss Reformers also believed that the end of the world was near, but they had different aims in view from those of the Anabaptists. It was not from poverty and apocalypticism that they hoped for a reformation of the church. In contrast to the fanatics, after a brief hesitation they threw millennarianism overboard, and along with it all other "opiniones Judaicæ." They took up the same ground in this respect which the Roman Catholic Church had occupied since the time of Augustine. How millennarianism nevertheless found its way, with the help of apocalyptic mysticism and Anabaptist influences, into the churches of the Reformation, chiefly among the Reformed sects, but afterwards also in the Lutheran Church, how it became incorporated with Pietism, how in recent times an exceedingly mild type of "academic" chiliasm has been developed from a belief in the verbal inspiration of the Bible, how finally new sects are still springing up here and there with apocalyptic and chiliastic expectations,—these are matters which cannot be fully entered upon here. But one remark ought to be made in conclusion. A genuine and living revival of chiliastic hopes is always a sign that the church at large has become secularized to such a degree that tender consciences can no longer feel sure of their faith within her. In this sense all chiliastic phenomena in the history of the church demand respectful attention. But when attempts are made to find room for millennarianism in a dogmatic system, it must always assume a form in which it would be utterly unrecognizable to the millennarians of the ancient church, who, just because they were millennarians, despised dogmatic, in the sense of philosophical theology. The claims of chiliasm are sufficiently met by the acknowledgment that in former times it was associated—to all appearance inseparably associated—with the gospel itself. Those who try to remodel it, so as to conserve its "elements of truth," put contempt on it while they destroy it; for it was in its day the most uncompromising enemy of all remodelling, and it can only exist along with the unsophisticated faith of the early Christians.

Cf. Schürer, *Lehrbuch der Neutestamentlichen Zeitgeschichte*, 1874, §§ 28, 29; Corrodi, *Kritische Geschichte des Chiliasmus*, 1781. A thorough history of chiliasm has not yet appeared. (A. HA.)

MILLER, HUGH (1802–1856), eminent in science and literature, and one of the most remarkable among self-taught men of genius, was born at Cromarty, on the north-east coast of Scotland, on the 10th of October 1802. His father, a sagacious and strong-willed seaman, who earned a livelihood by sailing his own sloop, perished at sea when Hugh was five years old. His mother looked much, in the upbringing of her son, to her two brothers, James and Alexander Wright, the one a saddler, the other a carpenter. Scrupulous integrity, sincere religion, unflagging industry, and resolute contentment were the lessons which these men, not so much by precept as by example, impressed upon the boy. But young Miller had inherited from his father a strong individuality and obstinate force of will, and began at a very early age to take a line of his own. The enchantment of open air and freedom—the irresistible charm of mother nature on the hill and by the sea—made him at thirteen an incorrigible truant; and his schoolmaster thought it likely that he would prove a dunce. Nevertheless the truant schoolboy was already giving indications of the destination of the man. At an age too early to date he had found in his pen a divining rod that led him to waters of inexhaustible delight. His mother summed up, in the singular dialect of the district, the impression derived from her son's boyhood and youth in the words, "he was aye vritin." But the writing from the first, and increasingly as time went on, could be discriminated from the ordinary productions of boyhood. A continuity of idea, an indefinable grace and freshness, marked his performances. They were never bombastic or verbose. At no period of his life did he suffer from a flux of words. But, boy and man, he had a felicitous knack of fitting words into their right places and avoiding jerkiness and inequality. In verse he lacked the passionate intensity required for true rhythmic movement, but he had a fine sense of cadence and modulation in prose.

It is a curious fact that what determined Hugh Miller to apprentice himself to a stone-mason was his delight in literary composition. Unemployed during the winter frosts, the mason, he perceived, could enjoy for some months every year the ecstacy of writing. One result of his decision was that he never learned any language but English. Another was that fifteen years of the quarry and the hewing-shed, with stern experiences of over-work and privation, sowed in his frame the seeds of incurable disease. Meanwhile the advantages of his decision were indisputable. Under the discipline of labour the refractory schoolboy became a thoughtful, sober-minded man. Miller always looked back to his years of hand-labour with a satisfaction that has something in it of solemnity and pathos. "Noble, upright, self-relying toil," he exclaims; "who that knows thy solid worth and value would be ashamed of thy hard hands, and thy soiled vestments, and thy obscure tasks,—thy humble cottage, and hard couch, and homely fare!"

It cannot be added that his fifteen years of close and constant intercourse with fellow-workmen inspired him with much respect for their class. He was most unfortunate in his comrades during the two seasons, 1824 and 1825, when he worked at Niddrie in the neighbourhood of Edinburgh. Swinish in their enjoyments, meanly selfish in their class ambitions, and fatuously subject to talking charlatans, that Niddrie squad of reprobates which he describes in *My Schools and Schoolmasters* stamped on the mind of Hugh Miller an indelible conviction of the incapacity and degradation of the hand-workers.

Returning to Cromarty, he worked in happy patience as a stone-cutter year after year, sedulously prosecuting at the same time the grand object of his ambition, to write good English. He found time to invigorate and enrich his mind by careful reading, and was habitually and keenly observant both of man and of nature. His reading was not extensive but well chosen, and embraced Locke and Hume; Goldsmith and Addison were, more than any others, his masters in style. It was to get time to write that he had become a stone-mason; another of the surprises of his career is that it was in advertising himself as a mason that he came before the world as a literary man. A stone-mason, figuring as a poetical contributor to the *Inverness Courier*, might, he thought, be asked by some of the readers to engrave inscriptions on tombs. He therefore forwarded some of his verses to the editor. These seem to have been consigned to the waste-paper basket, which had been the fate of an "Ode on Greece" offered to the *Scotsman* when he was at Edinburgh. Piqued by his second failure, he now resolved, at all hazards, to see himself in print. In 1829 appeared the small volume containing *Poems Written in the Leisure Hours of a Journeyman Mason*. It procured its author the valuable friendship of Mr Robert Carruthers, and was favourably noticed by the press. Miller looked at his poems in print, and concluded, at once and irreversibly, that he would not succeed as a poet. It was a characteristic and very manly decision, proving that there was no fretting vanity in his disposition. Doubtless also it was right. His field was prose. But, though his poems yielded nothing in the way of fortune, they were a beginning of fame. The simple natives of Cromarty began to think him a wonder. Some very elo-

MILLET (French, *millet*; Italian, *miglietto*, diminutive of *miglio*=Latin *mille*, a thousand, in allusion to its fertility) is a name applied with little definiteness to a considerable number of often very variable species of cereals belonging to distinct genera and even subfamilies of *Gramineæ*. The true millet, however, is generally admitted to be *Panicum* (*Setaria*) *miliaceum*, L. (German *Hirse*, with which *P. miliare*, Lam., is reckoned by some botanists). It is indigenous to the East Indies and North Australia, but is mentioned by Hippocrates and Theophrastus as already cultivated in South Europe in their time. Some suppose it to be one of the earliest grains used in bread-making, and ascribe the origin of its name to *panis*, bread, rather than to the paniculate inflorescence. It is annual, requires rich but friable soil, grows to about 3 or 4 feet high, and is characterized by its bristly, much branched nodding panicles. One variety has black grains. It is largely cultivated in India, southern Europe, and northern Africa, and ripens as far north as southern Germany, in fact, wherever the climate admits of the production of wine. The grain, which is very nutritious, is used in the form of groats, and makes excellent bread when mixed with wheaten flour. It is also largely used for feeding poultry and cage-birds, for which purpose mainly it is imported. *P. italicum*, L. (*Setaria italica*, Beauv.), is of similar origin and distribution, and is one of the most wholesome and palatable Indian cereals. It is annual, grows 4 to 5 feet high, and requires dry light soil. German Millet (*P. germanicum*, German *Kolbenhirse*, *Mohar*) is probably merely a less valuable and dwarf variety of *P. italicum*, having an erect, compact, and shorter spike. The grains of both are very small, only one half as long as those of common millet, but are exceedingly prolific. Many stalks arise from a single root, and a single spike often yields 2 oz. of grain, the total yield being five times that of wheat. They are imported for poultry feeding like the former species, but are extensively used in soups, &c., on the Continent. Numerous other species belonging to this vast genus—the largest among grasses, of which the following are among the most important—are also cultivated in tropical or sub-tropical countries for their grain or as fodder grasses, or both, each variety of soil, from swamp to desert, having its characteristic forms. They are very readily acclimatized wherever the temperature is sufficient, *e.g.*, in Australia, and seem destined to rise in agricultural importance.

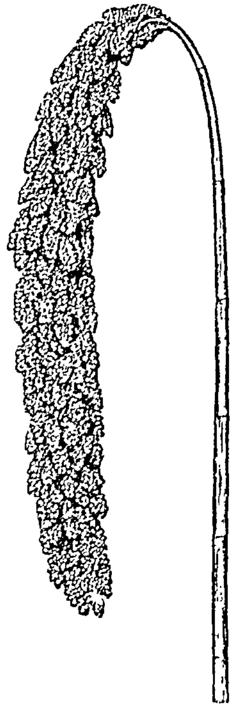

FIG. 1.—*Panicum italicum.*

Polish Millet is *P. digitaria*; *P. frumentaceum*, Roxb., Shamalo, a Deccan grass, is probably a native of tropical Africa; while the perennial *P. sarmentosum*, Roxb., also largely cultivated in tropical countries, is from Sumatra. *P. decompositum* is the Australian millet, its grains being made into cakes by the aborigines. *P. maximum*, Jacq., is the Guinea Grass; it is perennial, grows 8 feet high, and yields abundance of highly nutritious grain. *P. spectabile*, Nees., is the Coapim of Angola, but has been acclimatized in Brazil and other tropical countries. Other gigantic species 6 or 7 feet high form the field crops on the banks of the Amazons. Of species belonging to allied genera, *Pennisetum thyphoideum*, Rich. (*Penicellaria spicata*, Willd.), Bajree, sometimes also called Egyptian Millet, a Guinea corn, is largely cultivated in tropical Asia, Nubia, and Egypt. *P. distichum* grows south of the Sahara. Species of *Paspalum*, *Eleusine*, and *Milium* are also cultivated as millets.

But the most important dry grain of the tropical countries of Africa and Asia, particularly of India, is *Sorghum vulgare*, Pers. (*Holcus Sorghum*, L., *Andropogon Sorghum*, Roxb.), Durra, Great Millet, Indian Millet, Turkish Millet, or Guinea Corn (the French *sorgho*, German *Mohrenhirse* or *Kaffernkorn*, Tamil *Cholum*, Bengalese *Jowari*). It ranges probably as extensively as wheat, being also largely cultivated in southern Europe, the United States, and the West Indies. In Asia Minor, Arabia, Italy, and Spain it may be said to replace oats and barley. It is annual, and may reach 12 feet in height; it is extremely prolific, even rivalling maize, of which it is a near congener. Its flour is very white, but does not easily make good bread; it is largely used in cakes and puddings and for feeding cattle and poultry. The panicles are used for brooms, and the roots for velvet-brushes. *S. bicolor*, *S. nigrum*, *S. rubrum*, *S. Kaffrorum* (Kaffre Corn), *S. saccharatum*, and other species or varieties are also of economic importance, the last-named (the "Chinese sugar-cane") being much cultivated in the United States as a source of molasses, the juice, which contains much glucose but comparatively little cane sugar, being simply expressed and concentrated by evaporation. *S. vulgare* is the grain referred to by Pliny as millet.

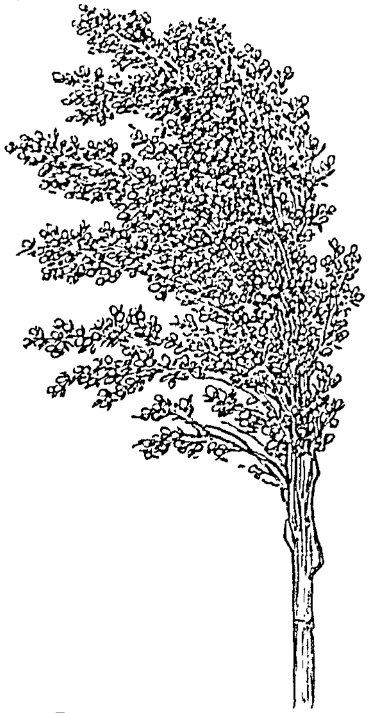

FIG. 2.—*Sorghum vulgare.*

For systematic and economic purposes, see GRASSES; Luerssen, *Med.-Pharm. Botanik*, Leipsic, 1880; Drury, *Useful Plants of India*, London, 1873; F. v. Müller, *Select Plants for Naturalization in Victoria*, Melbourne, 1876. For archæology, see Helm's *Kulturpflanzen*, &c., Berlin, 1877. On *Sorghum cerunum* ("rice corn," &c., of western Kansas) see Drummond's "Report" in *Parl. Papers*, No. 2570 (1880).

MILLET, JEAN FRANÇOIS (1814–1875), was a painter of French peasant life, and it may be questioned whether France has produced in our day any greater or more original artist. He himself came of a peasant family, and was born on the 4th of October 1814 in the hamlet of Gruchy, near Gréville (La Manche), in the wild and picturesque district called La Hague. His boyhood was passed working in his father's fields, but the sight of the engravings in an old illustrated Bible set him drawing, and thenceforth, whilst the others slept, the daily hour of rest was spent by Millet in trying to render the familiar scenes around him. From the village priest the lad learnt to read the Bible and Virgil in Latin, and acquired an interest in one or two other works of a high class which accompanied him through life; he did not, however, attract attention so much by his acquirements as by the stamp of his mind. The whole family seems, indeed, to have worn a character of austerity and dignity, and when Millet's father finally decided to test the vocation of his son as an artist, it was with a gravity and authority which recalls the patriarchal households of Calvinist France. Two drawings were prepared and placed before a painter at Cherbourg named Mouchel, who at once recognized the boy's gifts, and accepted him as a pupil; but shortly after (1835) Millet's father died, and the eldest son, with heroic devotion, took his place at home, nor did he return to his work until the

pressing calls from without were solemnly enforced by the wishes of his own family. He accordingly went back to Cherbourg, but after a short time spent there with another master (Langlois) started with many misgivings for Paris. The council-general of the department had granted him a sum of 600 francs, and the town council promised an annual pension of 400, but in spite of friendly help and introductions Millet went through great difficulties. The system of the École des Beaux Arts was hateful to him, and it was not until after much hesitation that he decided to enter an official studio—that of Delaroche. The master was certainly puzzled by his pupil; he saw his ability, and, when Millet in his poverty could not longer pay the monthly fees, arranged for his free admission to the studio, but he tried in vain to make him take the approved direction, and lessons ended with "Eh, bien, allez à votre guise, vous êtes si nouveau pour moi que je ne veux rien vous dire." At last, when the competition for the Grand Prix came on, Delaroche gave Millet to understand that he intended to secure the nomination of *another*, and thereupon Millet withdrew himself, and with his friend Marolle started in a little studio in the Rue de l'Est. He had renounced the beaten track, but he continued to study hard whilst he sought to procure bread by painting portraits at 10 or 15 francs a piece and producing small "pastiches" of Watteau and Boucher. These works are classed as those of his "flowery manner," and Millet has been reproached—he whose whole life was an act of conviction—with having sacrificed his convictions to curry favour with the public. It is true that he himself has recorded his aversion to both these masters. "In the Louvre," he said, "I received vivid impressions from Mantegna, complete from Michelangelo; after Michelangelo and Poussin I have remained faithful to the early masters." Boucher was for him an object of "repulsion," and in Watteau "I saw," he said, "a little theatrical world which oppressed me." Thus it was then that Millet naturally felt and saw, but the strongest genius knows moments of self-doubt. Later in life Millet was heard to say that were it not for the small group who believed in him he should have lost faith in himself. In earlier years, before he was certain of his own leading, he was naturally influenced by the advice of others whose arguments were enforced by the pressure of dire poverty. Even so from time to time the native vein showed strong. In 1840, as soon as he had despatched a portrait to the Salon, Millet went back to Gréville, where he painted Sailors Mending a Sail and a few other pictures—reminiscences of Cherbourg life. His first success was obtained in 1844 when his Milkwoman and Lesson in Riding (pastel) attracted notice at the Salon, and friendly artists presented themselves at his lodgings only to learn that his wife had just died, and that he himself had disappeared. Millet was at Cherbourg; there he remarried, but having amassed a few hundred francs he went back to Paris and presented his St Jerome at the Salon of 1845. This picture was rejected and exists no longer, for Millet, short of canvas, painted over it Œdipus Unbound, a work which during the following year was the object of violent criticism. He was, however, no longer alone; Diaz, Eugène Tourneux, Rousseau, and other men of note supported him by their confidence and friendship, and he had by his side the brave Catharine Lemaire, his second wife, a woman who bore poverty with dignity and gave courage to her husband through the cruel trials in which he penetrated by a terrible personal experience the bitter secrets of the very poor. To this date belong Millet's Golden Age, Bird Nesters, Young Girl and Lamb, and Bathers; but to the Bathers (Louvre) succeeded The Mother Asking Alms, The Workman's Monday, and The Winnower. This last work, exhibited in 1848, obtained conspicuous success, but did not sell till Ledru Rollin, informed of the painter's dire distress, gave him 500 francs for it, and accompanied the purchase with a commission, the money for which enabled Millet to leave Paris for Barbizon, a village on the skirts of the forest of Fontainebleau. There he settled in a three-roomed cottage for the rest of his life—twenty-seven years, in which he wrought out the perfect story of that peasant life of which he alone has given a "complete impression." Jules Breton has coloured the days of toil with sentiment; others, like Courbet, whose eccentric Funeral at Ornans attracted more notice at the Salon of 1850 than Millet's Sowers and Binders, have treated similar subjects as a vehicle for protest against social misery; Millet alone, a peasant and a miserable one himself, saw true, neither softening nor exaggerating what he saw. In a curious letter written to M. Sensier at this date (1850) Millet expressed his resolve to break once and for all with mythological and undraped subjects, and the names of the principal works painted subsequently will show how stedfastly this resolution was kept. In 1852 he produced Girls Sewing, Man Spreading Manure; 1853, The Reapers; 1854, Church at Gréville (Luxembourg); 1855—the year of the International Exhibition, at which he received a medal of second class—Peasant Grafting a Tree; 1857, The Gleaners; 1859, The Angelus (Louvre, engraved Waltner), The Woodcutter and Death; 1860, Sheep Shearing; 1861, Woman Shearing Sheep, Woman Feeding Child; 1862, Potato Planters, Winter and the Crows; 1863, Man with Hoe, Woman Carding; 1864, Shepherds and Flock, Peasants Bringing Home a Calf Born in the Fields; 1869, Knitting Lesson; 1870, Buttermaking; 1871, November—recollection of Gruchy. Any one of these works will show how great an influence Millet's previous practice in the nude had upon his style. The dresses worn by his figures are not clothes, but drapery through which the forms and movements of the body are strongly felt, and their contour shows a grand breadth of line which strikes the eye at once. Something of the imposing unity of his work was also, no doubt, due to an extraordinary power of memory, which enabled Millet to paint (like Horace Vernet) without a model; he could recall with precision the smallest details of attitudes or gestures which he proposed to represent. Thus he could count on presenting free from after thoughts the vivid impressions which he had first received, and Millet's nature was such that the impressions which he received were always of a serious and often of a noble order, to which the character of his execution responded so perfectly that even a Washerwoman at her Tub will show the grand action of a Medea. The drawing of this subject is reproduced in *Souvenirs de Barbizon*, a pamphlet in which M. Piédagnel has recorded a visit paid to Millet in 1864. His circumstances were then less evil, after struggles as severe as those endured in Paris. A contract by which he bound himself in 1860 to give up all his work for three years had placed him in possession of 1000 francs a month. His fame extended, and at the exhibition of 1867 he received a medal of the first class, and the ribbon of the Legion of Honour, but he was at the same moment deeply shaken by the death of his faithful friend Rousseau. Though he rallied for a time he never completely recovered his health, and on the 20th January 1875 he died. He was buried by his friend's side in the churchyard of Chailly.

See A. Sensier, *Vie et Œuvre de J. F. Millet*, 1874; Piédagnel, *Souvenirs de Barbizon*, &c. (E. F. S. P.)

MILLVILLE, a city of the United States, in Cumberland county, New Jersey, at the head of navigation of Maurice river, 40 miles by rail from Philadelphia by the Cape May, Millville, and Vineland section of the West Jersey Railroad.

It is one of the chief seats of glass-making in the State, and also manufactures cotton, iron pipes for water and gas, turbines, &c. The population was 7660 in 1880.

MILMAN, Henry Hart (1791–1868), dean of St Paul's, was born February 10, 1791, and was the third son of Sir Francis Milman, physician to George III. He was educated at Eton and at Brasenose College, Oxford; his university career was brilliant, and among other distinctions he gained the Newdigate prize with a poem on the Apollo Belvedere. In 1816 he was ordained, and was soon afterwards presented to the living of St Mary's, Reading. He had already made his appearance as a dramatic writer, his tragedy of *Fazio*, founded on a narrative in the *Annual Register* for 1795, having been brought on the stage without his knowledge under the title of *The Italian Wife*. It was subsequently produced at Covent Garden, and obtained great success from the acting of Miss O'Neill as Bianca. The merit of the play consists chiefly in the powerful situation; the diction is florid and ornate. The same criticism, by the author's own confession, applies to his epic, *Samor, the Lord of the Bright City* (Gloucester), a poem written in early youth. The subject is taken from British legend, and Milman has failed to invest it with serious interest. He was more successful in his next attempts, where the subjects were well adapted to an imagination easily kindled by the historical or the moral picturesque. The death struggle of an expiring nation in the *Fall of Jerusalem* (1820), the conflict of new truth and old order, of religious enthusiasm and earthly affection, in the *Martyr of Antioch* (1822), are depicted with great eloquence and real insight into human nature. Milman's characters, however, are personified tendencies rather than personages, and in poetical style he was unable to free himself from the influence of Byron. *Belshazzar* (1822) is in general a pale copy of Byron's *Sardanapalus*, but contains some fine lyrics. Milman's lyrics, indeed, especially his hymns, have frequently a fine ring and sweep, though the thought is generally commonplace. His tragedy of *Anne Boleyn* (1826) is a poor performance. With the exception of admirable versions of the Sanskrit episode of Nala and Damayanti, and of the *Agamemnon* and *Bacchæ*, this was Milman's last poetical work. He was elected professor of poetry at Oxford, and in 1827 delivered the Bampton lectures, selecting as his subject the conduct and character of the apostles as an evidence of Christianity. In 1830 his *History of the Jews* appeared in the Family Library. The contracted limits of this series forbade any adequate treatment of the subject; the work is nevertheless memorable as the first by an English clergyman which treated the Jews as an Oriental tribe, recognized sheikhs and emirs in the Old Testament, sifted and classified documentary evidence, and evaded or minimized the miraculous. Milman was violently attacked, especially by Dr Faussett and Bishop Mant, and the odium thus occasioned stopped the publication of the Family Library, and long impeded the preferment of the writer. In 1835, however, Sir Robert Peel made him rector of St Margaret's and canon of Westminster, and in 1849 he became dean of St Paul's. The unpopularity attaching to him had by this time nearly died away; and now, generally revered and beloved, intimate with men of all pursuits, politics, and persuasions, counted among the chief ornaments of the most polished society of the metropolis, he occupied a singularly dignified and enviable position, which he constantly employed for the promotion of culture and enlightenment, and in particular for the relaxation of subscription to ecclesiastical formularies. His *History of Christianity under the Empire* had appeared in 1840, but had been as completely ignored as if, said Lord Melbourne, the clergy had taken a universal oath never to mention it to any one. Widely different was the reception of the continuation, his great *History of Latin Christianity* to the death of Pope Nicholas V., which appeared in 1855. He also edited Gibbon and Horace, and at his death in 1868 left behind him almost finished a delightful history of his own cathedral, which was completed and published by his son.

Milman possessed a large share of the imagination which enters into and calls up the past, and of that which interprets actions and apprehends opinions by the power of sympathy. In creative imagination he was deficient, a defect which alone prevented him from attaining the first rank as an historian. His pages are crowded with splendid names rather than with living personages; the springs of action are disclosed with remarkable penetration, but the actor himself is rather heard than seen. There are, however, exceptions, such as his portrait of Sir Christopher Wren; and he possessed a peculiar power of investing mere intellectual tendencies with personality and life. His parallel of Latin and Teutonic Christianity, for example, is a piece of finished historical character painting. His power of sympathy rendered him in effect, as his natural equity and benignity made him in intention, a model of historical candour, only chargeable, perhaps, with too much gentleness. It will be long ere his great work is superseded; but he will perhaps be remembered even longer as an embodiment of all the qualities which the higher ecclesiastical preferment can be supposed capable of encouraging or rewarding among the clergy of a great historical church. (R. G.)

MILO, one of the most famous athletes of Greece, whose name became proverbial for personal strength. He lived about the end of the 6th century B.C., was six times crowned at the Olympic games and six times at the Pythian for wrestling, and was famous throughout the civilized world for his feats of strength, such as carrying an ox on his shoulders through the stadium at Olympia. In his native city of Crotona he was much honoured, and he commanded the army which defeated the people of Sybaris in 511 B.C. When Democedes, the physician of Darius, deserted the Persian service, he sent a boastful message to the king of Persia informing him of his marriage to the daughter of Milo. The traditional account of his death is often used to point a moral: he found a tree which some woodcutters had partially split with a wedge, and attempted to rend it asunder; but the wedge fell out, and the tree closed on his hand, imprisoning him till wolves came and devoured him.

MILO was the surname of T. Annius Papianus, one of the best-known of the partisan leaders and ruffians in the stormy times that preceded the dissolution of the Roman republic. His father was C. Papius Celsus, but he was adopted by his mother's father T. Annius Luscus. He joined the Pompeian party, and led the band of mercenaries and gladiators which was required to defend the cause and its chief supporters in the public streets. P. Clodius, the leader of the ruffians who professed the democratic cause, was his personal enemy, and their brawls in the streets and their mutual accusations in the law courts lasted for several years, beginning when Milo was tribune of the commons in 57 B.C. In 53 their quarrels came to a height when Milo was candidate for the consulship and Clodius for the prætorship; and when the two leaders met by accident on the Appian Way at Bovillæ, Clodius was murdered (January 20, 52 B.C.). This act of violence strengthened the hands of Pompey, who was nominated sole consul, and proposed several stringent laws to restore order in the city. Milo was impeached; his guilt was clear, and his enemies took every means of intimidating his supporters and his judges. Cicero was afraid to deliver the speech he had prepared *Pro Milone*, and the extant oration is an expanded form of the unspoken defence. Milo went into exile at Massilia, and his property was sold by auction. He joined the insurrection of M. Cælius in 48 B.C., and was soon slain near Thurii in Lucania. His wife Fausta was daughter of the dictator Sulla.

MILTIADES. See Greece, vol. xi. p. 99.

MILTON, JOHN (1608–1674), was born in Bread Street, Cheapside, London, on the 9th of December 1608. His father, known as Mr John Milton of Bread Street, scrivener, was himself an interesting man. He was a native of Oxfordshire, having been born there in or about 1563, the son of a Richard Milton, yeoman of Stanton-St-John's, of whom there are traces as one of the sturdiest adherents to the old Roman Catholic religion that had been left in his district. The son, however, had turned Protestant, and, having been cast off on that account, had come to London, apparently about the year 1586, to push his fortune. Having received a good education, and having good abilities, especially in music, he may have lived for some time by musical teaching and practice. Not till 1595, at all events, when he was long past the usual age of apprenticeship, do we hear of his preparation for the profession of a scrivener; and not till February 1599–1600, when he was about thirty-seven years of age, did he enter the profession as a qualified member of the Scriveners' Company. It was then that he set up his "house and shop" in Bread Street, and began, like other scriveners, his lawyerly business of drawing up wills, marriage-settlements, and the like, with such related business as that of receiving money from clients for investment and lending it out to the best advantage. It was at the same time that he married. Till recently there has been the most extraordinary uncertainty as to the maiden name of his wife, the mother of the poet. It has been now ascertained, however, that she was a Sarah Jeffrey, one of the two orphan daughters of a Paul Jeffrey, of St Swithin's, London, "citizen and merchant-taylor," originally from Essex, who had died before 1583. At the date of her marriage she was about twenty-eight years of age. Her widowed mother, Mrs Ellen Jeffrey, came to reside in the house in Bread Street, and died there in February 1610–11. Before this death of the maternal grandmother, three children had been born to the scrivener and his wife, of whom only two survived,—the future poet, and an elder sister, called Anne. Of three more children, born subsequently, only one survived,—Christopher, the youngest of the family, born December 3, 1615.

The first sixteen years of Milton's life, coinciding exactly with the last sixteen of the reign of James I., associate themselves with the house in Bread Street, and with the surroundings of that house in Old London. His father, while prospering in business, continued to be known as a man of "ingeniose" tastes, and even acquired some distinction in the London musical world of that time by his occasional contributions to important musical publications. Music was thus a part of the poet's domestic education from his infancy. Whatever else could be added was added without stint. Again and again Milton speaks with gratitude and affection of the ungrudging pains bestowed by his father on his early education. "Both at the grammar school and also under other masters at home," is the statement in one passage, "he caused me to be instructed daily." This brings us to about the year 1619, when Milton was ten years of age. At that time his domestic tutor was Thomas Young, a Scotsman from Perthshire, and graduate of the university of St Andrews, afterwards a man of no small distinction among the English Puritan clergy, but then only curate or assistant to some parish clergyman in or near London, and eking out his livelihood by private teaching. Young's tutorship lasted till 1622, when he was drawn abroad by an offer of the pastorship or chaplaincy to the congregation of English merchants in Hamburg. Already, however, for a year or two, his tutorship had been only supplementary to the education which the boy was receiving by daily attendance at St Paul's public school, close to Bread Street. The headmaster of the school was Mr Alexander Gill, an elderly Oxford divine, of high reputation for scholarship and teaching ability. Under him, as usher or second master, was his son, Alexander Gill the younger, also an Oxford graduate of scholarly reputation, but of blustering character. Milton's acquaintanceship with this younger Gill, begun at St Paul's school, led to subsequent friendship and correspondence. Far more affectionate and intimate was the friendship formed by Milton at St Paul's with a certain young Charles Diodati, his schoolfellow there, the son of a naturalized Italian physician, Dr Theodore Diodati, who had settled in London in good medical practice, and was much respected, both on his own account, and as being the brother of the famous Protestant divine, Jean or Giovanni Diodati of Geneva. Young Diodati, who was destined for his father's profession, left the school for Oxford University early in 1623; but Milton remained till the end of 1624. A family incident of that year was the marriage of his elder sister, Anne, with Edward Phillips, a clerk in the Government office called the Crown Office in Chancery. Milton had then all but completed his sixteenth year, and was as scholarly, as accomplished, and as handsome a youth as St Paul's school had sent forth. We learn from himself that his exercises "in English or other tongue, prosing or versing, but chiefly this latter," had begun to attract attention even in his boyhood. This implies that he must have had a stock of attempts in English and Latin by him of earlier date than 1624. Of these the only specimens that now remain are his *Paraphrase on Psalm CXIV.* and his *Paraphrase on Psalm CXXXVI.*

On February 12, 1624–25, Milton, at the age of sixteen years and two months, was entered as a student of Christ's College, Cambridge, in the grade of a "Lesser Pensioner." His matriculation entry in the books of the university is two months later, April 9, 1625. Between these two dates James I. had died, and had been succeeded by Charles I.

Cambridge University was then in the full flush of its prosperity on that old system of university education which combined Latin and Greek studies with plentiful drill and disputation in the scholastic logic and philosophy, but with little of physical science, and next to no mathematics. There were sixteen colleges in all, dividing among them a total of about 2900 members of the university. Christ's College, to which Milton belonged, ranked about third in the university in respect of numbers, counting about 265 members on its books. The master was Dr Thomas Bainbrigge; and among the thirteen fellows were Mr Joseph Meade, still remembered as a commentator on the Apocalypse, and Mr William Chappell, afterwards an Irish bishop. It was under Chappell's tutorship that Milton was placed when he first entered the college. At least three students who entered Christ's after Milton, but during his residence, deserve mention. One was Edward King, a youth of Irish birth and high Irish connexions, who entered in 1626, at the age of fourteen; another was John Cleveland, afterwards known as royalist and satirist, who entered in 1627; and the third was Henry More, subsequently famous as the Cambridge Platonist, who entered in 1631, just before Milton left. Milton's own brother, Christopher, joined him in the college in February 1630–31, at the age of fifteen.

Milton's academic course lasted seven years and five months, or from February 1624–25 to July 1632, bringing him from his seventeenth year to his twenty-fourth. The first four years were his time of undergraduateship. It was in the second of these, the year 1626, that there occurred that quarrel between him and his tutor, Mr Chappell, which Dr Johnson, making the most of a lax tradition from Aubrey, magnified into the supposition that Milton may have been one of the last students in either of the English universities that suffered the indignity of

went through, he tells us, a systematic course of reading in the Greek and Latin classics, varied by mathematics, music, and the kind of physical science we should now call cosmography.

It is an interesting fact that Milton's very first public appearance in the world of English authorship was in so honourable a place as the second folio edition of *Shakespeare* in 1632. His enthusiastic eulogy on Shakespeare, written in 1630, was one of three anonymous pieces prefixed to that second folio, along with reprints of the commendatory verses that had appeared in the first folio, one of them Ben Jonson's immortal tribute to Shakespeare's memory. Among the poems actually written by Milton at Horton the first, in all probability, after the Latin hexameters *Ad Patrem*, were the exquisite companion pieces *L'Allegro* and *Il Penseroso.* There followed, in or about 1633, the fragment called *Arcades.* It was part of a pastoral masque got up by the young people of the noble family of Egerton in honour of their venerable relative the countess-dowager of Derby, and performed before that lady at her mansion of Harefield, near Uxbridge, about 10 miles from Horton. That Milton contributed the words for the entertainment was, almost certainly, owing to his friendship with Henry Lawes, one of the chief court musicians of that time, whose known connexion with the Egerton family points him out as the probable manager of the Harefield masque. Next in order among the compositions at Horton may be mentioned the three short pieces, *At a Solemn Music*, *On Time*, and *Upon the Circumcision*; after which comes *Comus*, the largest and most important of all Milton's minor poems. The name by which that beautiful drama is now universally known was not given to it by Milton himself. He entitled it, more simply and vaguely, "A Masque presented at Ludlow Castle, 1634, before the Earl of Bridgewater, Lord President of Wales." The existence of this poem is certainly due to Milton's intimacy with Lawes. The earl of Bridgewater, the head of the Egerton family, had been appointed to the high office of the presidency or viceroyalty of Wales, the official seat of which was Ludlow in Shropshire; it had been determined that among the festivities on his assumption of the office there should be a great masque in the hall of Ludlow Castle, with Lawes for the stage manager and one of the actors; Milton had been applied to by Lawes for the poetry; and, actually, on Michaelmas night, September 29, 1634, the drama furnished by Milton was performed in Ludlow Castle before a great assemblage of the nobility and gentry of the Welsh principality, Lawes taking the part of "the attendant spirit," while the parts of "first brother," "second brother," and "the lady" were taken by the earl's three youngest children, Viscount Brackley, Mr Thomas Egerton, and Lady Alice Egerton.—From September 1634 to the beginning of 1637 is a comparative blank in our records. Straggling incidents in this blank are a Latin letter of date December 4, 1634, to Alexander Gill the younger, a *Greek Translation of Psalm CXIV.*, a visit to Oxford in 1635 for the purpose of incorporation in the degree of M.A. in that university, and the beginning in May 1636 of a troublesome lawsuit against his now aged and infirm father.—The lawsuit, which was instituted by a certain Sir Thomas Cotton, baronet, nephew and executor of a deceased John Cotton, Esq., accused the elder Milton and his partner Bower, or both, of having, in their capacity as scriveners, misappropriated divers large sums of money that had been entrusted to them by the deceased Cotton to be let out at interest. The lawsuit was still in progress when, on the 3d of April 1637, Milton's mother died, at the age of about sixty-five. A flat blue stone, with a brief inscription, visible on the chancel-pavement of Horton church, still marks the place of her burial. Milton's testimony to her character is that she was a "a most excellent mother and particularly known for her charities through the neighbourhood." The year 1637 was otherwise eventful in his biography. It was in that year that his *Comus*, after lying in manuscript for more than two years, was published by itself, in the form of a small quarto of thirty-five pages. The author's name was withheld, and the entire responsibility of the publication was assumed by Henry Lawes. Milton seems to have been in London when the little volume appeared. He was a good deal in London, at all events, during the summer and autumn months immediately following his mother's death. The plague, which had been on one of its periodical visits of ravage through England since early in the preceding year, was then especially severe in the Horton neighbourhood, while London was comparatively free. It was probably in London that Milton heard of the death of young Edward King of Christ's College, whom he had left as one of the most popular of the fellows of the college, and one of the clerical hopes of the university. King had sailed from Chester for a vacation visit to his relatives in Ireland, when, on the 10th of August, the ship, in perfectly calm water, struck on a rock and went down, he and nearly all the other passengers going down with her. There is no mention of the sad accident in two otherwise very interesting Latin *Familiar Epistles* of Milton, of September 1637, both addressed to his medical friend Charles Diodati, and both dated from London; but how deeply the death of King had affected him appears from his occupation shortly afterwards. In November 1637, and probably at Horton, whence the plague had by that time vanished, he wrote his matchless pastoral monody of *Lycidas.* It was his contribution to a collection of obituary verses, Greek, Latin, and English, which King's numerous friends, at Cambridge and elsewhere, were getting up in lamentation for his sad fate. The collection did not appear till early in 1638, when it was published in two parts, with black-bordered title-pages, from the Cambridge University press, one consisting of twenty-three Latin and Greek pieces, the other of thirteen English pieces, the last of which was Milton's monody, signed only with his initials "J. M." It was therefore early in 1638, when Milton was in his thirtieth year, that copies of his *Lycidas* may have been in circulation among those who had already become acquainted with his *Comus.*

Milton was then on the wing for a foreign tour. He had long set his heart on a visit to Italy, and circumstances now favoured his wish. The vexatious Cotton lawsuit, after hanging on for nearly two years, was at an end, as far as the elder Milton was concerned, with the most absolute and honourable vindication of his character for probity, though with some continuation of the case against his partner, Bower. Moreover, Milton's younger brother, Christopher, though but twenty-two years of age, and just about to be called to the bar of the Inner Temple, had married a wife; and the young couple had gone to reside at Horton to keep the old man company. There being nothing then to detain Milton, all was arranged for his journey. Before the end of April 1638 he was on his way across the Channel, taking one English man-servant with him. At the time of his departure the last great news in England was that of the National Scottish Covenant, or solemn oath and band of all ranks and classes of the Scottish people to stand by each other to the death in resisting the ecclesiastical innovations which Laud and Charles had been forcing upon Scotland. To Charles the news of this "damnable Covenant," as he called it, was enraging beyond measure; but to the mass of the English Puritans it was far from unwelcome, promising, as it seemed to do, for England herself, the subversion at last of that system of "Thorough," or despotic

government by the king and his ministers without parliaments, under which the country had been groaning since the contemptuous dissolution of Charles's third parliament ten years before.

Through Paris, where Milton made but a short stay, receiving polite attention from the English ambassador, Lord Scudamore, and having the honour of an introduction to the famous Hugo Grotius, then ambassador for Sweden at the French court, he moved on rapidly to Italy, by way of Nice. After visiting Genoa, Leghorn, and Pisa, he arrived at Florence, August 1638. Enchanted by the city and its society, he remained there two months, frequenting the chief academies or literary clubs, and even taking part in their proceedings. Among the Florentines with whom he became intimate were Jacopo Gaddi, young Carlo Dati, Pietro Frescobaldi, Agostino Coltellini, the grammarian Benedetto Buommattei, Valerio Chimentelli, and Antonio Francini. It was in the neighbourhood of Florence also that he "found and visited" the great Galileo, then old and blind, and still nominally a prisoner to the Inquisition for his astronomical heresy. From Florence, by Siena, Milton went to Rome. He reached the Eternal City some time in October, and spent about another two months there, not only going about among the ruins and antiquities and visiting the galleries, but mixing also, as he had done in Florence, with the learned society of the academies. Among those with whom he formed acquaintance in Rome were the German scholar, Lucas Holstenius, librarian of the Vatican, and three native Italian scholars, named Cherubini, Salzilli, and Selvaggi. There is record of his having dined once, in company with several other Englishmen, at the hospitable table of the English Jesuit College. The most picturesque incident, however, of his stay in Rome was his presence at a great musical entertainment in the palace of Cardinal Francesco Barberini. Here he had not only the honour of a specially kind reception by the cardinal himself, but also, it would appear, the supreme pleasure of listening to the marvellous Leonora Baroni, the most renowned singer of her age. Late in November he left Rome for Naples. Here also he was fortunate. The great man of the place was the now very aged Giovanni Battista Manso, marquis of Villa, the friend and biographer of the great Tasso, and subsequently the friend and patron of the sweet Marini. By a happy accident Milton obtained an introduction to Manso, and nothing could exceed the courtesy of the attentions paid by the aged marquis to the young English stranger. He had hardly been in Naples a month, however, when there came news from England which not only stopped an intention he had formed of extending his tour to Sicily and thence into Greece, but urged his immediate return home. "The sad news of civil war in England," he says, "called me back; for I considered it base that, while my fellow-countrymen were fighting at home for liberty, I should be travelling abroad for intellectual culture." In December 1638, therefore, he set his face northwards again. His return journey, however, probably because he learnt that the news he had first received was exaggerated or premature, was broken into stages. He spent a second two months in Rome, ascertained to have been January and February 1638–39; during which two months, as he tells us, he was in some danger from the papal police, because the English Jesuits in Rome had taken offence at his habit of free speech, wherever he went, on the subject of religion. Though he did not alter his demeanour in the least in this particular, nothing happened; and from Rome he got safely to Florence, welcomed back heartily by his Florentine friends, and renewing his meetings with them privately and in their academies. His second visit to Florence, including an excursion to Lucca, extended over two months; and not till April 1639 did he take his leave, and proceed, by Bologna and Ferrara, to Venice. About a month was given to Venice; and thence, having shipped for England the books he had collected in Italy, he went on, by Verona and Milan, over the Alps, to Geneva. In this Protestant city he spent a week or two in June, forming interesting acquaintanceships there too, and having daily conversations with the great Protestant theologian Dr Jean Diodati, the uncle of his friend Charles Diodati. From Geneva he returned to Paris, and so to England. He was home again in August 1639, having been absent in all fifteen or sixteen months.

Milton's Continental tour, and especially the Italian portion of it, remained one of the chief pleasures of his memory through all his subsequent life. Nor was it quite without fruits of a literary kind. Besides two of his Latin *Epistolæ Familiares*, one to the Florentine grammarian Buommattei, and the other to Lucas Holstenius, there have to be assigned to Milton's sixteen months on the Continent his three Latin epigrams *Ad Leonoram Romæ Canentem*, his Latin scazons *Ad Salsillum Poetam Romanum Ægrotantem*, his fine and valuable poem in Latin hexameters entitled *Mansus*, and his *Five Italian Sonnets, with a Canzone*, celebrating the charms of some Italian lady he had met in his travels.

One sad and marring memory did mingle itself with all that was otherwise so delightful in his Italian reminiscences. His bosom friend and companion from boyhood, the half-Italian Charles Diodati, who had been to him as Jonathan to David, and into whose ear he had hoped to pour the whole narrative of what he had seen and done abroad, had died during his absence. He had died, in Blackfriars, London, in August 1638, not four months after Milton had gone away on his tour. The intelligence had not reached Milton till some months afterwards, probably not till his second stay in Florence; and, though he must have learnt some of the particulars from the youth's uncle in Geneva, he did not know them fully till his return to England. How profoundly they affected him appears from his *Epitaphium Damonis*, then written in memory of his dead friend. The importance of this poem in Milton's biography cannot be overrated. It is perhaps the noblest of all his Latin poems; and, though in the form of a pastoral, and even of a pastoral of the most artificial sort, it is unmistakably an outburst of the most passionate personal grief. In this respect *Lycidas*, artistically perfect though that poem is, cannot be compared with it; and it is only the fact that *Lycidas* is in English, while the *Epitaphium Damonis* is in Latin, that has led to the notion that Edward King of Christ's College was peculiarly and pre-eminently the friend of Milton in his youth and early manhood.

That Milton, now in his thirty-first year, had been girding himself for some greater achievement in poetry than any he had yet attempted, *Comus* not excepted, we should have known otherwise. What we should not have known, but for an incidental passage in the *Epitaphium Damonis*, is that, at the time of his return from Italy, he had chosen a subject for such a high literary effort of a new Miltonic sort. The passage is one in which, after referring to the hopes of Diodati's medical career as so suddenly cut short by his death, Milton speaks of himself as the survivor and of his own projects in *his* profession of literature. In translation, it may run thus:—

"I have a theme of the Trojans cruising our southern headlands
Shaping to song, and the realm of Imogen, daughter of Pandras,
Brennus and Arviragh, dukes, and Bren's bold brother, Belinus;
Then the Armorican settlers under the laws of the Britons,
Ay, and the womb of Igraine fatally pregnant with Arthur,
Uther's son, whom he got disguised in Gorlois' likeness,
All by Merlin's craft. O then, if life shall be spared me,
Thou shalt be hung, my pipe, far off on some dying old pine-tree,

Much-forgotten of me; or else your Latian music
Changed for the British war-screech! What then? For one to do all things,
One to hope all things, fits not! Prize sufficiently ample
Mine, and distinction great (unheard-of ever thereafter
Though I should be and inglorious all through the world of the stranger),
If but the yellow-haired Ouse shall read me, the drinker of Alan,
Humber, which whirls as it flows, and Trent's whole valley of orchards,
Thames, my own Thames, above all, and Tamar's western waters,
Tawny with ores, and where the white waves swinge the far Orkneys."

Interpreted prosaically, this means that Milton was meditating an epic of which King Arthur was to be the central figure, but which should include somehow the whole cycle of British and Arthurian legend, and that not only was this epic to be in English, but he had resolved that all his poetry for the future should be in the same tongue.

Not long after Milton's return the house at Horton ceased to be the family home. Christopher Milton and his wife went to reside at Reading, taking the old gentleman with them, while Milton himself preferred London. He had first taken lodgings in St Bride's Churchyard, at the foot of Fleet Street; but, after a while, probably early in 1640, he removed to a "pretty garden house" of his own, at the end of an entry, in the part of Aldersgate Street which lies immediately on the city side of what is now Maidenhead Court. His sister, whose first husband had died in 1631, had married a Mr Thomas Agar, his successor in the Crown Office; and it was arranged that her two sons by her first husband should be educated by their uncle. John Phillips, the younger of them, only nine years old, had boarded with him in the St Bride's Churchyard lodgings; and, after the removal to Aldersgate Street, the other brother, Edward Phillips, only a year older, became his boarder also. Gradually a few other boys, the sons of well-to-do personal friends, joined the two Phillipses, whether as boarders or for daily lessons, so that the house in Aldersgate Street became a small private school. The drudgery of teaching seems always to have been liked by Milton. What meanwhile of the great Arthurian epic? That project, we find, had been given up, and Milton's mind was roving among many other subjects, and balancing their capabilities. How he wavered between Biblical subjects and heroic subjects from British history, and how many of each kind suggested themselves to him, one learns from a list in his own handwriting among the Milton MSS. at Cambridge. It contains jottings of no fewer than fifty-three subjects from the Old Testament, eight from the Gospels, thirty-three from British and English history before the Conquest, and five from Scottish history. It is curious that all or most of them are headed or described as subjects for "tragedies," as if the epic form had now been abandoned for the dramatic. It is more interesting still to observe which of the subjects fascinated Milton most. Though several of them are sketched pretty fully, not one is sketched at such length and so particularly as *Paradise Lost*. It is the first subject on the list, and there are four separate drafts of a possible tragedy under that title, two of them merely enumerating the *dramatis personæ*, but the last two indicating the plot and the division into acts. Thus, in 1640, twenty-seven years before *Paradise Lost* was given to the world, he had put down the name on paper, and had committed himself to the theme.

To these poetic dreamings and schemings there was to be a long interruption. The Scottish National Covenant had led to extraordinary results. Not only were Charles and Laud checkmated in their design of converting the mild Episcopal system which King James had established in Scotland into a high Laudian prelacy; but, in a General Assembly held at Glasgow in the end of 1638, Episcopacy had been utterly abolished in Scotland, and the old Presbyterian system of Knox and Melville revived. To avenge this, and restore the Scottish bishops, Charles had marched to the Border with an English army; but, met there by the Covenanting army under General Alexander Leslie, he had not deemed it prudent to risk a battle, and had yielded to a negotiation conceding to the Scots all their demands. This "First Bishops' War," as it came to be called, was begun and concluded while Milton was abroad. About the time of his return, however, Charles had again broken with the Scots. Milton had been watching the course of affairs since then with close and eager interest. He had seen and partaken in the sympathetic stir in favour of the Scots which ran through the popular and Puritan mind of England. He had welcomed the practical proof of this sympathy given in that English parliament of April 1640, called "The Short Parliament," which Charles, in his straits for supplies against the Scots, had reluctantly summoned at last, but was obliged to dismiss as unmanageable. Charles had, nevertheless, with money raised somehow, entered on the "Second Bishops' War." This time the result was momentous indeed. The Scots, not waiting to be attacked in their own country, took the aggressive, and invaded England. In August 1640, after one small engagement with a portion of Charles's army, they were in possession of Newcastle and of all the northern English counties. The English then had their opportunity. A treaty with the Scots was begun, which the English Puritans, who regarded their presence in England as the very blessing they had been praying for, were in no haste to finish; and, on the 3d of November 1640, there met that parliament which was to be famous in English history, and in the history of the world, as "The Long Parliament."

Of the first proceedings of this parliament, including the trial and execution of Strafford, the impeachment and imprisonment of Laud and others, and the break-down of the system of Thorough by miscellaneous reforms and by guarantees for parliamentary liberty, Milton was only a spectator. It was when the church question emerged distinctly as the question paramount, and there had arisen divisions on that question among those who had been practically unanimous in matters of civil reform, that he plunged in as an active adviser. There were three parties on the church question. There was a high-church party, contending for Episcopacy by divine right, and for the maintenance of English Episcopacy very much as it was; there was a middle party, defending Episcopacy on grounds of usage and expediency, but desiring to see the powers of bishops greatly curtailed, and a limited Episcopacy, with councils of presbyters round each bishop, substituted for the existing high Episcopacy; and there was the root-and-branch party, as it called itself, desiring the entire abolition of Episcopacy and the reconstruction of the English Church on something like the Scottish Presbyterian model. Since the opening of the parliament there had been a storm of pamphlets crossing one another in the air from these three parties. The chief manifesto of the high-church party was a pamphlet by Joseph Hall, bishop of Exeter, entitled *Humble Remonstrance to the High Court of Parliament*. In answer to Hall, and in representation of the views of the root-and-branch party, there had stepped forth, in March 1640–41, five leading Puritan parish ministers, the initials of whose names, clubbed together on the title-page of their joint production, made the uncouth word "Smectymnuus." These were Stephen Marshall, Edmund Calamy, Thomas Young, Matthew Newcomen, and William Spurstow. The Thomas Young whose name

comes in the middle was no other than the Scottish Thomas Young who had been Milton's domestic preceptor in Bread Street. Having returned from Hamburg in 1628, he had been appointed to the vicarage of Stowmarket in Suffolk, in which living he had remained ever since, with the reputation of being one of the most solid and learned Puritans among the English parish clergy. The famous Smectymnuan pamphlet in reply to Hall was mainly Young's. What is more interesting is that his old pupil Milton was secretly in partnership with him and his brother-Smectymnuans. Milton's hand is discernible in a portion of the original Smectymnuan pamphlet; and he continued to aid the Smectymnuans in their subsequent rejoinders to Hall's defences of himself. It was more in Milton's way, however, to appear in print independently; and in May 1641, while the controversy between Hall and the Smectymnuans was going on, he put forth a pamphlet of his own. It was entitled *Of Reformation touching Church Discipline in England and the Causes that have hitherto hindered it*, and consisted of a review of English ecclesiastical history, with an appeal to his countrymen to resume that course of reformation which he considered to have been prematurely stopped in the preceding century, and to sweep away the last relics of papacy and prelacy. Among all the root-and-branch pamphlets of the time it stood out, and stands out still, as the most thorough-going and tremendous. It was followed by four others in rapid succession,—to wit, *Of Prelatical Episcopacy and whether it may be deduced from the Apostolical Times* (June 1641), *Animadversions upon the Remonstrant's Defence against Smectymnuus* (July 1641), *The Reason of Church Government urged against Prelaty* (February 1641–42), *Apology against a Pamphlet called a Modest Confutation of the Animadversions*, &c. (March 1641–42). The first of these was directed chiefly against that middle party which advocated a limited Episcopacy, with especial reply to the arguments of Archbishop Ussher, as the chief exponent of the views of that party. Two of the others, as the titles imply, belong to the Smectymnuan series, and were castigations of Bishop Hall. The greatest of the four, and the most important of all Milton's anti-Episcopal pamphlets after the first, is that entitled *The Reason of Church Government.* It is there that Milton takes his readers into his confidence, speaking at length of himself and his motives in becoming a controversialist. Poetry, he declares, was his real vocation; it was with reluctance that he had resolved to "leave a calm and pleasing solitariness, fed with cheerful and confident thoughts, to embark in a troubled sea of noises and hoarse disputes"; but duty had left him no option. The great poem or poems he had been meditating could wait; and meanwhile, though in prose-polemics he had the use only of his "left hand," that hand should be used with all its might in the cause of his country and of liberty.

The parliament had advanced in the root-and-branch direction so far as to have passed a bill for the exclusion of bishops from the House of Lords, and compelled the king's assent to that bill, when, in August 1642, the further struggle between Charles and his subjects took the form of civil war. All England was then divided into the Royalists, supporting the king, and the Parliamentarians, adhering to that majority of the Commons, with a minority of the Lords, which sat on as the parliament. While the first battles of the civil war were being fought with varying success, this parliament, less impeded than when it had been full, moved on more and more rapidly in the root-and-branch direction, till, by midsummer 1643, the abolition of Episcopacy had been decreed, and the question of the future non-prelatic constitution of the Church of England referred to a synod of divines, to meet at Westminster under parliamentary authority. Of Milton's life through those first months of the civil war little is known. He remained in his house in Aldersgate Street, teaching his nephews and other pupils; and the only scrap that came from his pen was the semi-jocose sonnet bearing the title *When the Assault was intended to the City.* In the summer of 1643, however, there was a great change in the Aldersgate Street household. About the end of May, as his nephew Edward Phillips remembered, Milton went away on a country journey, without saying whither or for what purpose; and, when he returned, about a month afterwards, it was with a young wife, and with some of her sisters and other relatives in her company. He had, in fact, been in the very headquarters of the king and the Royalist army in and round Oxford; and the bride he brought back with him was a Mary Powell, the eldest daughter of Richard Powell, Esq., of Forest Hill, near Oxford. She was the third of a family of eleven sons and daughters, of good standing, but in rather embarrassed circumstances, and was seventeen years and four months old, while Milton was in his thirty-fifth year. However the marriage came about, it was a most unfortunate event. The Powell family were strongly Royalist, and the girl herself seems to have been frivolous, unsuitable, and stupid. Hardly were the honeymoon festivities over in Aldersgate Street when, her sisters and other relatives having returned to Forest Hill and left her alone with her husband, she pined for home again and begged to be allowed to go back on a visit. Milton consented, on the understanding that the visit was to be a brief one. This seems to have been in July 1643. Soon, however, the intimation from Forest Hill was that he need not look ever to have his wife in his house again. The resolution seems to have been mainly the girl's own, abetted by her mother; but, as the king's cause was then prospering in the field, it is a fair conjecture that the whole of the Powell family had repented of their sudden connexion with so prominent a Parliamentarian and assailant of the Church of England as Milton. While his wife was away, his old father, who had been residing for three years with his younger and lawyer son at Reading, came to take up his quarters in Aldersgate Street.

Milton's conduct under the insult of his wife's desertion was most characteristic. Always fearless and speculative, he converted his own case into a public protest against the existing law and theory of marriage. *The Doctrine and Discipline of Divorce Restored, to the good of both Sexes*, was the title of a pamphlet put forth by him in August 1643, without his name, but with no effort at concealment, declaring the notion of a sacramental sanctity in the marriage relation to be a clerically invented superstition, and arguing that inherent incompatibility of character, or contrariety of mind, between two married persons, is a perfectly just reason for divorce. There was no reference to his own case, except by implication; but the boldness of the speculation roused attention and sent a shock through London. It was a time when the authors of heresies of this sort, or of any sort, ran considerable risks. The famous Westminster Assembly of Divines, called by the Long Parliament, had met on the appointed day, July 1, 1643; the Scots, in consenting to send an army into England to assist the parliament in their war with the king, had proposed, as one of the conditions, their Solemn League and Covenant, binding the two nations to endeavour after a uniformity of religion and of ecclesiastical discipline, with the extirpation of all "heresy, schism, and profaneness," as well as popery and prelacy; the Solemn League and Covenant had been enthusiastically accepted in England, and was being sworn to universally by the Parliamentarians; and one immediate effect was that four eminent Scottish

divines and two Scottish lay commissioners were added to the Westminster Assembly and became leaders there. Whether Milton's divorce tract was formally discussed in the Assembly during the first months of its sitting is unknown; but it is certain that the London clergy, including not a few members of the Assembly, were then talking about it privately with anger and execration. That there might be no obstacle to a more public prosecution, Milton threw off the anonymous in a second and much enlarged edition of the tract, in February 1643–44, dedicated openly to the parliament and the Assembly. Then, for a month or two, during which the gossip about him and his monstrous doctrine was spreading more and more, he turned his attention to other subjects. Among the questions in agitation in the general ferment of opinion brought about by the civil war was that of a reform of the national system of education and especially of the universities. To this question Milton made a contribution in June 1644, in a small *Tract on Education*, in the form of a letter to Mr Samuel Hartlib, a German then resident in London and interesting himself busily in all philanthropic projects and schemes of social reform. In the very next month, however, July 1644, he returned to the divorce subject in a pamphlet addressed specially to the clergy and entitled *The Judgment of Martin Bucer concerning Divorce.* The outcry against him then reached its height. He was attacked in pamphlets; he was denounced in pulpits all through London, and more than once in sermons before the two Houses of Parliament by prominent divines of the Westminster Assembly; strenuous efforts were made to bring him within definite parliamentary censure. In the cabal formed against him for this purpose a leading part was played, at the instigation of the clergy, by the Stationers' Company of London. That company, representing the publishers and booksellers of London, had a plea of their own against him, on the ground that his doctrine was not only immoral, but had been put forth in an illegal manner. His first divorce treatise, though published immediately after the "Printing Ordinance" of the parliament of June 14, 1643, requiring all publications to be licensed for press by one of the official censors, and to be registered in the books of the Stationers' Company, had been issued without licence and without registration. Complaint to this effect was made against Milton, with some others liable to the same charge of contempt of the printing ordinance, in a petition of the Stationers to the House of Commons in August 1644; and the matter came before committee both in that House and in the Lords. It is to this circumstance that the world owes the most popular and eloquent, if not the greatest, of all Milton's prose-writings, his famous *Areopagitica, a Speech of Mr John Milton for the Liberty of Unlicensed Printing to the Parliament of England.* It appeared in the end of November 1644, deliberately unlicensed and unregistered, as was proper on such an occasion, and was a remonstrance addressed to the parliament, as if in an oration to them face to face, against their ordinance of June 1643 and the whole system of licensing and censorship of the press. Nobly eulogistic of the parliament in other respects, it denounced their printing ordinance as utterly unworthy of them, and of the new era of English liberties which they were initiating, and called for its repeal. Though that effect did not follow, the pamphlet virtually accomplished its purpose. The licensing system had received its death-blow; and, though the Stationers returned to the charge in another complaint to the House of Lords, Milton's offence against the press ordinance was condoned. He was still assailed in pamphlets, and found himself "in a world of disesteem"; but he lived on through the winter of 1644–45 undisturbed in his house in Aldersgate Street. To this period there belong, in the shape of verse, only his sonnets ix. and x., the first to some anonymous lady, and the second "to the Lady Margaret Ley," with perhaps the Greek lines entitled *Philosophus ad Regem Quendam.* His divorce speculation, however, still occupied him; and in March 1644–45 he published simultaneously his *Tetrachordon, or Expositions upon the four chief places of Scripture which treat of Marriage,* and his *Colasterion, a Reply to a nameless Answer against the Doctrine and Discipline of Divorce.* In these he replied to his chief recent assailants, lay and clerical, with merciless severity.

It was not merely Milton's intellectual eminence that had saved him from prosecution for his divorce heresy. A new tendency of national opinion on the church question had operated in his favour, and in favour of all forms of free speculation. There had occurred in the Westminster Assembly itself, and more largely throughout the general community, that split of English Puritanism into the two opposed varieties of Presbyterianism on the one hand and Independency or Congregationalism on the other which explains the whole subsequent history of the Puritan revolution. Out of this theoretical discussion as to the constitution of the church there had grown the all-important practical question of toleration. The Presbyterians insisted that the whole population of England should necessarily belong to the one national Presbyterian Church, be compelled to attend its worship, and be subject to its discipline, while the Independents demanded that, if a Presbyterian Church should be set up as the national and state-paid church, there should at least be liberty of dissent from it, and toleration for those that chose to form themselves into separate congregations. Vehement within the Westminster Assembly itself, the controversy had attained wider dimensions out of doors, and had inwrought itself in a most remarkable manner with the conduct of the war. Orthodox Presbyterian Calvinists were still the majority of the Puritan body; but, in the new atmosphere of liberty, there had sprung up, from secret and long-suppressed seeds in the English mind, a wonderful variety of sects and denominations, mingling other elements with their Calvinism, or hardly Calvinistic at all,—most of them, it is true, fervidly Biblical and Christian after their different sorts, but not a few professing the most coolly inquisitive and sceptical spirit, and pushing their speculations to strange extremes of free-thinking. These sects, growing more and more numerous in the large towns, had become especially powerful in the English Parliamentary army. That army had, in fact, become a marching academy of advanced opinionists and theological debaters. Now, as all the new Puritan sects, differing however much among themselves, saw their existence and the perpetuity of their tenets threatened by that system of ecclesiastical uniformity which the Presbyterians proposed to establish, they had, one and all, abjured Presbyterianism, and adopted the opposite principle of Independency, with its appended principle of toleration. Hence an extraordinary conflict of policies among those who seemed to be all Parliamentarians, all united in fighting against the king. The auxiliary Scottish army, which had come into England in January 1643–44, and had helped the English generals to beat the king in the great battle of Marston Moor in July 1644, thought that he had then been almost sufficiently beaten, and that the object of the Solemn League and Covenant would be best attained by bringing him to such terms as should secure an immediate Presbyterian settlement and the suppression of the Independents and sectaries. In this the chief English commanders, such as Essex and Manchester, agreed substantially with the Scots. Cromwell, on the other hand, who was now the recognized head of the army Independents, did not think that the king had

been sufficiently beaten, even for the general purposes of the war, and was resolved that the war should be pushed on to a point at which a Presbyterian settlement should be impossible without guarantees for liberty of conscience and a toleration of non-Presbyterian sects. Through the latter part of 1644, accordingly, Milton had been saved from the penalties which his Presbyterian opponents would have inflicted on him by this general championship of liberty of opinion by Cromwell and the army Independents. Before the middle of 1645 he, with others who were on the black books of the Presbyterians as heretics, was safer still. Though the parliament had voted, in January 1644–45, that the future national church of England should be on the Presbyterian system, Cromwell and the Independents had taken care to have the question of toleration left open; and, within the next month or two, by Cromwell's exertions, a completely new face was put upon the war by the removal of all the chief officers that had been in command hitherto, and the equipment of the New Model army, with Fairfax as its commander-in-chief and Cromwell himself as lieutenant-general. The Scots and the stricter English Presbyterians looked on malignantly while this army took the field, calling it an "Army of Sectaries," and almost hoping it would be beaten. On June 14, 1645, however, there was fought the great battle of Naseby, utterly ruining the king at last, and leaving only relics of his forces here and there. Milton's position then may be easily understood. Though his first tendency on the church question had been to some form of a Presbyterian constitution for the church, he had parted utterly now from the Scots and Presbyterians, and become a partisan of Independency, having no dread of "sects and schisms," but regarding them rather as healthy signs in the English body-politic. He was, indeed, himself one of the most noted sectaries of the time, for in the lists of sects drawn out by contemporary Presbyterian writers special mention is made of one small sect who were known as *Miltonists* or *Divorcers*.

So far as Milton was concerned personally, his interest in the divorce speculation came to an end in July or August 1645, when, by friendly interference, a reconciliation was effected between him and his wife. The ruin of the king's cause at Naseby had suggested to the Powells that it might be as well for their daughter to go back to her husband after their two years of separation. It was not, however, in the house in Aldersgate Street that she rejoined him, but in a larger house, which he had taken in the adjacent street called Barbican, for the accommodation of an increasing number of pupils.

The house in Barbican was tenanted by Milton from about August 1645 to September or October 1647. Among his first occupations there must have been the revision of the proof sheets of the first edition of his collected poems. It appeared as a tiny volume, copies of which are now very rare, with the title *Poems of Mr John Milton, both English and Latin, composed at several times.* The title-page gives the date 1645, but January 1645–46 seems to have been the exact month of the publication. The appearance of the volume indicates that Milton may have been a little tired by this time of his notoriety as a prose-polemic, and desirous of being recognized once more in his original character of literary man and poet. But, whether because his pedagogic duties now engrossed him or for other reasons, very few new pieces were added in the Barbican to those that the little volume had thus made public. In English, there were only the four sonnets now numbered xi.–xiv., the first two entitled "On the Detraction which followed upon my writing certain Treatises," the third "To Mr Henry Lawes on his Airs," and the fourth "To the Religious Memory of Mrs Catherine Thomson," together with the powerful anti-Presbyterian invective or "tailed sonnet" entitled "On the New Forcers of Conscience under the Long Parliament"; and in Latin there were only the ode *Ad Joannem Rousium*, the trifle called *Apologus de Rustico et Hero*, and one interesting *Familiar Epistle* addressed to his Florentine friend Carlo Dati. Some family incidents of importance, however, appertain to this time of residence in Barbican. Oxford having surrendered to Fairfax in June 1646, the whole of the Powell family had to seek refuge in London, and most of them found shelter in Milton's house. His first child, a daughter named Anne, was born there on the 29th of July that year; on the 1st of January 1646–47 his father-in-law Mr Powell died there, leaving his affairs in confusion; and in the following March his own father died there, at the age of eighty-four, and was buried in the adjacent church of St Giles, Cripplegate. For the rest, the two years in Barbican are nearly blank in Milton's biography. The great Revolution was still running its course. For a time Charles's surrender of himself, in May 1646, to the auxiliary Scottish army rather than to Fairfax and Cromwell, and his residence with that Scottish army at Newcastle in negotiation with the Scots, had given the Presbyterians the advantage; but, after the Scots had evacuated England in January 1646–47, leaving Charles a captive with his English subjects, and especially after the English army had seized him at Holmby in June 1647 and undertaken the further management of the treaty with him, the advantage was all the other way. It was a satisfaction to Milton, and perhaps still a protection for him, that the "Army of Independents and Sectaries" had come to be really the masters of England.

From Barbican Milton removed, in September or October 1647, to a smaller house in that part of High Holborn which adjoins Lincoln's Inn Fields. His Powell relatives had now left him, and he had reduced the number of his pupils, or perhaps kept only his two nephews. But, though thus more at leisure, he did not yet resume his projected poem, but occupied himself rather with three works of scholarly labour which he had already for some time had on hand. One was the compilation in English of a complete history of England, or rather of Great Britain, from the earliest times; another was the preparation in Latin of a complete system of divinity, drawn directly from the Bible; and the third was the collection of materials for a new Latin dictionary. Milton had always a fondness for such labours of scholarship and compilation. Of a poetical kind there is nothing to record, during his residence in High Holborn, but an experiment in psalm-translation, in the shape of Psalms lxxx.–lxxxviii. done into service-metre in April 1648, and the *Sonnet to Fairfax*, written in September of the same year.—This last connects him again with the course of public affairs. The king, having escaped from the custody of the army chiefs, and taken refuge in the Isle of Wight, had been committed to closer custody there; all negotiation between him and parliament had been declared at an end; and the result would probably have been his deposition, but for the consequences of a secret treaty he had contrived to make with the Scots. By this treaty the Scots engaged to invade England in the king's behalf, rescue him from the English parliament and army, and restore him to his full royalty, while he engaged in return to ratify the Covenant, the Presbyterian system of church government, and all the other conclusions of the Westminster Assembly, throughout England, and to put down Independency and the sects. Thus, in May 1648, began what is called the Second Civil War, consisting first of new risings of the Royalists in various parts of England, and then of a conjunction of these with a great invasion

of England by a Royalist Scottish army, under the command of the duke of Hamilton. It was all over in August 1648, when the crushing defeat of the Scottish army by Cromwell in the three days' battle of Preston, and the simultaneous suppression of the English Royalist insurrection in the south-east counties by Fairfax's siege and capture of Colchester, left Charles at the mercy of the victors.—Milton's *Sonnet to Fairfax* was a congratulation to that general-in-chief of the parliament on his success at Colchester, and attested the exultation of the writer over the triumph of the Parliamentary cause. His exultation continued through what followed. After one more dying effort of the parliament at negotiation with Charles, the army took the whole business on itself. The king was brought from the Isle of Wight; the parliament, manipulated by the army officers, and purged of all members likely to impede the army's purpose, was converted into an instrument for that purpose; a court of high justice was set up for the trial of Charles; and on January 30, 1648–49, he was brought to the scaffold in front of Whitehall. By that act England became a republic, governed, without King or House of Lords, by the persevering residue or "Rump" of the recent House of Commons, in conjunction with an executive council of state, composed of forty-one members appointed annually by that House.

The first Englishman of mark out of parliament to attach himself openly to the new republic was John Milton. This he did by the publication of his pamphlet entitled *Tenure of Kings and Magistrates, proving that it is lawful, and hath been held so in all ages, for any who have the power, to call to account a Tyrant or wicked King, and, after due conviction, to depose and put him to death, if the ordinary Magistrate have neglected to do it.* It was out within a fortnight after the king's death, and was Milton's last performance in the house in High Holborn. The chiefs of the new republic could not but perceive the importance of securing the services of a man who had so opportunely and so powerfully spoken out in favour of their tremendous act, and who was otherwise so distinguished. In March 1648–49, accordingly, Milton was offered, and accepted, the secretaryship for foreign tongues to the council of state of the new Commonwealth. The salary was to be £288 a year, worth about £1000 a year now. To be near his new duties in attendance on the council, which held its daily sittings for the first few weeks in Derby House, close to Whitehall, but afterwards regularly in Whitehall itself, he removed at once to temporary lodgings at Charing Cross. In the very first meetings of council which Milton attended he must have made personal acquaintance with President Bradshaw, Fairfax, Cromwell himself, Sir Henry Vane, Whitlocke, Henry Marten, Hasilrig, Sir Gilbert Pickering, and the other chiefs of the council and the Commonwealth, if indeed he had not known some of them before. After a little while, for his greater convenience, official apartments were assigned him in Whitehall itself.

At the date of Milton's appointment to the secretaryship he was forty years of age. His special duty was the drafting of such letters as were sent by the council of state, or sometimes by the Rump Parliament, to foreign states and princes, with the examination and translation of letters in reply, and with personal conferences, when necessary, with the agents of foreign powers in London, and with envoys and ambassadors. As Latin was the language employed in the written diplomatic documents, his post came to be known indifferently as the secretaryship for foreign tongues or the Latin secretaryship. In that post, however, his duties, more particularly at first, were very light in comparison with those of his official colleague, Mr Walter Frost, the general secretary. Foreign powers held aloof from the English republic as much as they could; and, while Mr Frost had to be present in every meeting of the council, keeping the minutes, and conducting all the general correspondence, Milton's presence was required only when some piece of foreign business did turn up. Hence, from the first, his employment in very miscellaneous work. Especially, the council looked to him for everything in the nature of literary vigilance and literary help in the interests of the struggling Commonwealth. He was employed in the examination of suspected papers, and in interviews with their authors and printers; and he executed several great literary commissions expressly entrusted to him by the council. The first of these was his pamphlet entitled *Observations on Ormond's Articles of Peace with the Irish Rebels.* It was published in May 1649, and was in defence of the republic against a complication of Royalist intrigues and dangers in Ireland. A passage of remarkable interest in it is one of eloquent eulogy on Cromwell. More important still was the *Eikonoklastes* (which may be translated "Image-Smasher"), published by Milton in October 1649, by way of counterblast to the famous *Eikon Basilike* ("Royal Image"), which had been in circulation in thousands of copies since the king's death, and had become a kind of Bible in all Royalist households, on the supposition that it had been written by the royal martyr himself. A third piece of work was of a more laborious nature. In the end of 1649 there appeared abroad, under the title of *Defensio Regia pro Carolo I.*, a Latin vindication of the memory of Charles, with an attack on the English Commonwealth, intended for circulation on the Continent. As it had been written, at the instance of the exiled royal family, by Salmasius, or Claude de Saumaise, of Leyden, then of enormous celebrity over Europe as the greatest scholar of his age, it was regarded as a serious blow to the infant Commonwealth. To answer it was thought a task worthy of Milton, and he threw his whole strength into the performance through the year 1650, interrupting himself only by a new and enlarged edition of his *Eikonoklastes.* Not till April 1651 did the result appear; but then the success was prodigious. Milton's Latin *Pro Populo Anglicano Defensio*, as it was called, ran at once over the British Islands and the Continent, rousing acclamation everywhere, and received by scholars as an annihilation of the great Salmasius. Through the rest of 1651 the observation was that the two agencies which had co-operated most visibly in raising the reputation of the Commonwealth abroad were Milton's books and Cromwell's battles.—These battles of Cromwell, in the service of the Commonwealth he had founded, had kept him absent from the council of state, of which he was still a member, since shortly after the beginning of Milton's secretaryship. For nearly a year he had been in Ireland, as lord lieutenant, reconquering that country after its long rebellion; and then, for another year, he had been in Scotland, crushing the Royalist commotion there round Charles II., and annexing Scotland to the English republic. The annexation was complete on the 3d of September 1651, when Cromwell, chasing Charles II. and his army out of Scotland, came up with them at Worcester and gained his crowning victory. The Commonwealth then consisted of England, Ireland, and Scotland, and Cromwell was its supreme chief.—Through the eventful year 1651, it has been recently ascertained, Milton had added to the other duties of his secretaryship that of Government journalist. Through the whole of that year, if not from an earlier period, he acted as licenser and superintending editor of the *Mercurius Politicus*, a newspaper issued twice a week, of which Mr Marchamont Needham was the working editor and proprietor. Milton's hand is discernible in some of the leading articles.

About the end of 1651 Milton left his official rooms in

Whitehall for a house he had taken on the edge of St James's Park, in what was then called Petty France, Westminster, but is now York Street. The house existed till the other day, but has been pulled down. In Milton's time it was a villa-looking residence, with a garden, in a neighbourhood of villas and gardens. He had now more to do in the special work of his office, in consequence of the increase of correspondence with foreign powers. But he had for some time been in ailing health; and a dimness of eyesight which had been growing upon him gradually for ten years had been settling rapidly, since his labour over the answer to Salmasius, into total blindness. Actually, before or about May 1652, when he was but in his forty-fourth year, his blindness was total, and he could go about only with some one to lead him. Hence a re-arrangement of his secretarial duties. Such of these duties as he could perform at home, or by occasional visits to the Council Office near, he continued to perform; but much of the routine work was done for him by assistants, one of them a well-known German named Weckherlin, under the superintendence of Mr John Thurloe, who had succeeded Mr Walter Frost in the general secretaryship. Precisely to this time of a lull in Milton's secretaryship on account of his ill-health and blindness we have to refer his two great companion sonnets *To the Lord General Cromwell* and *To Sir Henry Vane the Younger*. To about the same time, or more precisely to the interval between May and September 1652, though the exact date is uncertain, we have to refer the death of his only son, who had been born in his official Whitehall apartments in the March of the preceding year, and the death also of his wife, just after she had given birth to his third daughter, Deborah. With the three children thus left him,—Anne, but six years old, Mary, not four, and the infant Deborah,—the blind widower lived on in his house in Petty France in such desolation as can be imagined. He had recovered sufficiently to resume his secretarial duties; and the total number of his dictated state letters for the single year 1652 is equal to that of all the state letters of his preceding term of secretaryship put together. To the same year there belong also three of his Latin *Familiar Epistles.* In December 1652 there was published *Joannis Philippi Angli Responsio ad Apologiam Anonymi Cujusdam Tenebrionis*, being a reply by Milton's younger nephew, John Phillips, but touched up by Milton himself, to one of several pamphlets that had appeared against Milton for his slaughter of Salmasius. The ablest and most scurrilous of these, which had just appeared anonymously at the Hague, with the title *Regii Sanguinis Clamor ad Cœlum adversus Parricidas Anglicanos* ("Cry of the Royal Blood to Heaven against the English Parricides"), Milton was reserving for his own attention at his leisure.

On the 20th of April 1653 there was Cromwell's great act of armed interference by which he turned out the small remnant of the Rump Parliament, dismissed their council of state, and assumed the government of England, Ireland, and Scotland into his own hands. For several months, indeed, he acted only as interim dictator, governing by a council of his officers, and waiting for the conclusions of that select body of advisers which he had called together from all parts of the country, and which the Royalists nicknamed "The Barebones Parliament." In December 1653, however, his formal sovereignty began under the name of the Protectorate, passing gradually into more than kingship. This change from government by the Rump and its council to government by a single military Lord Protector and his council was regarded by many as treason to the republican cause, and divided those who had hitherto been the united Commonwealth's men into the "Pure Republicans," represented by such men as Bradshaw and Vane, and the "Oliverians," adhering to the Protector. Milton, whose boundless admiration of Cromwell had shown itself already in his Irish tract of 1649 and in his recent sonnet, was recognized as one of the Oliverians. He remained in Oliver's service and was his Latin secretary through the whole of the Protectorate. For a while, indeed, his Latin letters to foreign states in Cromwell's name were but few,—Mr Thurloe, as general secretary, officiating as Oliver's right-hand man in everything, with a Mr Philip Meadows under him, at a salary of £200 a year, as deputy for the blind Mr Milton in foreign correspondence and translations. The reason for this temporary exemption of Milton from routine duty may have been that he was then engaged on an answer, by commission from the late Government, to the already-mentioned pamphlet from the Hague entitled *Regii Sanguinis Clamor.* Salmasius was now dead, and the Commonwealth was too stable to suffer from such attacks; but no Royalist pamphlet had appeared so able or so venomous as this in continuation of the Salmasian controversy. All the rather because it was in the main a libel on Milton himself did a reply from his pen seem necessary. It came out in May 1654, with the title *Joannis Miltoni Angli pro Populo Anglicano Defensio Secunda* ("Second Defence of John Milton, Englishman, for the People of England"). It is one of the most interesting of all Milton's writings. The author of the libel to which it replied was Dr Peter du Moulin the younger, a naturalized French Presbyterian minister, then moving about in English society, close to Milton; but, as that was a profound secret, and the work was universally attributed on the Continent to an Alexander Morus, a French minister of Scottish descent, then of much oratorical celebrity in Holland,—who had certainly managed the printing in consultation with the now deceased Salmasius, and had contributed some portion of the matter,—Milton had made this Morus the responsible person and the one object of his castigations. They were frightful enough. If Salmasius had been slaughtered in the former *Defensio*, Morus was murdered and gashed in this. His moral character was blasted by exposure of his antecedents, and he was blazoned abroad in Europe as a detected clerical blackguard. The terrific castigation of Morus, however, is but part of the *Defensio Secunda.* It contains passages of singular autobiographical and historical value, and includes laudatory sketches of such eminent Commonwealth's men as Bradshaw, Fairfax, Fleetwood, Lambert, and Overton, together with a long panegyric on Cromwell himself and his career, which remains to this day unapproached for elaboration and grandeur by any estimate of Cromwell from any later pen. From about the date of the publication of the *Defensio Secunda* to the beginning of 1655 the only specially literary relics of Milton's life are his translations of Psalms i.–viii. in different metres, done in August 1654, his translation of Horace's *Ode* i. 5, done probably about the same time, and two of his Latin *Familiar Epistles.* The most active time of his secretaryship for Oliver was from April 1655 onwards. In that month, in the course of a general revision of official salaries under the Protectorate, Milton's salary of £288 a year hitherto was reduced to £200 a year, with a kind of re-definition of his office, recognizing it, we may say, as a Latin secretaryship extraordinary. Mr Philip Meadows was to continue to do all the ordinary Foreign Office work, under Thurloe's inspection; but Milton was to be called in on special occasions. Hardly was the arrangement made when a signal occasion did occur. In May 1655 all England was horrified by the news of the massacre of the Vaudois Protestants by the troops of Emanuele II., duke of Savoy and prince of Piedmont, in consequence of their disobedience to an edict requiring them either to leave

their native valleys or to conform to the Catholic religion. Cromwell and his council took the matter up with all their energy; and the burst of indignant letters on the subject despatched in that month and the next to the duke of Savoy himself, Louis XIV. of France, Cardinal Mazarin, the Swiss cantons, the States-General of the United Provinces, and the kings of Sweden and Denmark, were all by Milton. His famous sonnet *On the late Massacre in Piedmont* was his more private expression of feeling on the same occasion. This sonnet was in circulation, and the case of the Vaudois Protestants was still occupying Cromwell, when, in August 1655, there appeared the last of Milton's great Latin pamphlets. It was his *Pro Se Defensio*, in answer to an elaborate self-defence which Morus had put forth on the Continent since Milton's attack on his character, and it consisted mainly of a re-exposure of that unfortunate clergyman. Thence, through the rest of Cromwell's Protectorate, Milton's life was of comparatively calm tenor. He was in much better health than usual, bearing his blindness with courage and cheerfulness; he was steadily busy with such more important despatches to foreign powers as the Protector, then in the height of his great foreign policy, and regarded with fear and deference by all European monarchs and states from Gibraltar to the Baltic, chose to confide to him; and his house in Petty France seems to have been, more than at any previous time since the beginning of his blindness, a meeting-place for friends and visitors, and a scene of pleasant hospitalities. The four sonnets now numbered xix.–xxii., one of them to young Mr Lawrence, the son of the president of Cromwell's council, and two of the others to Cyriack Skinner, belong to this time of domestic quiet, as do also no fewer than ten of his Latin *Familiar Epistles*. His second marriage belongs to the same years, and gleams even yet as the too brief consummation of this happiest time in the blind man's life. The name of his second wife was Katharine Woodcock. He married her on the 12th of November 1656; but, after only fifteen months, he was again a widower, by her death in childbirth in February 1657–58. The child dying with her, only the three daughters by the first marriage remained. The touching sonnet which closes the series of Milton's *Sonnets* is his sacred tribute to the memory on his second marriage and to the virtues of the wife he had so soon lost. Even after that loss we find him still busy for Cromwell. Mr Meadows having been sent off on diplomatic missions, Andrew Marvell had, in September 1657, been brought in, much to Milton's satisfaction, as his assistant or colleague in the Latin secretaryship; but this had by no means relieved him from duty. Some of his greatest despatches for Cromwell, including letters, of the highest importance, to Louis XIV., Mazarin, and Charles Gustavus of Sweden, belong to the year 1658.

One would like to know precisely in what personal relations Milton and Cromwell stood to each other. There is, unfortunately, no direct record to show what Cromwell thought of Milton; but there is ample record of what Milton thought of Cromwell. "Our chief of men," he had called Cromwell in his sonnet of May 1652; and the opinion remained unchanged. He thought Cromwell the greatest and best man of his generation, or of many generations; and he regarded Cromwell's assumption of the supreme power, and his retention of that power with a sovereign title, as no real suppression of the republic, but as absolutely necessary for the preservation of the republic, and for the safeguard of the British Islands against a return of the Stuarts. Nevertheless, under this prodigious admiration of Cromwell, there were political doubts and reserves. Milton was so much of a modern radical of the extreme school in his own political views and sympathies that he cannot but have been vexed by the growing conservatism of Cromwell's policy through his Protectorate. To his grand panegyric on Oliver in the *Defensio Secunda* of 1654 he had ventured to append cautions against self-will, over-legislation, and over-policing; and he cannot have thought that Oliver had been immaculate in these respects through the four subsequent years. The attempt to revive an aristocracy and a House of Lords, on which Cromwell was latterly bent, cannot have been to Milton's taste. Above all, Milton dissented *in toto* from Cromwell's church policy. It was Milton's fixed idea, almost his deepest idea, that there should be no such thing as an Established Church, or state-paid clergy, of any sort or denomination or mixture of denominations, in any nation, and that, as it had been the connexion between church and state, begun by Constantine, that had vitiated Christianity in the world, and kept it vitiated, so Christianity would never flourish as it ought till there had been universal disestablishment and disendowment of the clergy, and the propagation of the gospel were left to the zeal of voluntary pastors, self-supported, or supported modestly by their flocks. He had at one time looked to Cromwell as the likeliest man to carry this great revolution in England. But Cromwell, after much meditation on the subject in 1652 and 1653, had come to the opposite conclusion. The conservation of the Established Church of England, in the form of a broad union of all evangelical denominations of Christians, whether Presbyterians, or Independents, or Baptists, or moderate Old Anglicans, that would accept state-pay with state-control, had been the fundamental notion of his Protectorate, persevered in to the end. This must have been Milton's deepest disappointment with the Oliverian rule.

Cromwell's death on the 3d of September 1658 left the Protectorship to his son Richard. Milton and Marvell continued in their posts, and a number of the Foreign Office letters of the new Protectorate were of Milton's composition. Thinking the time fit, he also put forth, in October 1658, a new edition of his *Defensio Prima*, and, early in 1659, a new English pamphlet, entitled *Treatise of Civil Power in Ecclesiastical Causes*, ventilating those notions of his as to the separation of church and state which he had been obliged of late to keep to himself. To Richard's Protectorate also belongs one of Milton's Latin *Familiar Epistles*. Meanwhile, though all had seemed quiet round Richard at first, the jealousies of the army officers left about him by Oliver, and the conflict of political elements let loose by Oliver's death, were preparing his downfall. In May 1659 Richard's Protectorate was at an end. The country had returned with pleasure to what was called "the good old cause" of pure republicanism; and the government was in the hands of "the Restored Rump," consisting of the reassembled remains of that Rump Parliament which Cromwell had dissolved in 1653. To this change, as inevitable in the circumstances, or even promising, Milton adjusted himself. The last of his known official performances in his Latin secretaryship are two letters in the name of William Lenthall, as the speaker of the restored Rump, one to the king of Sweden and one to the king of Denmark, both dated May 15, 1659. Under the restored Rump, if ever, he seemed to have a chance for his notion of church-disestablishment; and, accordingly, in August 1659, he put forth, with a prefatory address to that body, a large pamphlet entitled *Considerations touching the likeliest means to remove Hirelings out of the Church*. The restored Rump had no time to attend to such matters. They were in struggle for their own existence with the army chiefs; and the British Islands were in that state of hopeless confusion and anarchy which, after passing through a brief phase of attempted military government (October to December 1659), and a second revival of the purely republican or Rump government (December 1659 to

the Restoration as one of "solitude." Nor was this the worst. His three daughters, on whom he ought now to have been able principally to depend, were his most serious domestic trouble. The poor motherless girls, the eldest in her seventeenth year in 1662, the second in her fifteenth, and the youngest in her eleventh, had grown up, in their father's blindness and too great self-absorption, ill-looked-after and but poorly educated; and the result now appeared. They "made nothing of neglecting him"; they rebelled against the drudgery of reading to him or otherwise attending on him; they "did combine together and counsel his maid-servant to cheat him in her marketings"; they actually "had made away some of his books, and would have sold the rest." It was to remedy this horrible state of things that Milton consented to a third marriage. The wife found for him was Elizabeth Minshull, of a good Cheshire family, and a relative of Dr Paget's. They were married on the 24th of February 1662–63, the wife being then only in her twenty-fifth year, while Milton was in his fifty-fifth. She proved an excellent wife; and the Jewin Street household, though the daughters remained in it, must have been under better management from the time of her entry into it. From that date Milton's circumstances must have been more comfortable, and his thoughts about himself less abject, than they had been through the two preceding years, though his feeling in the main must have been still that of his own Samson:—

> "Now blind, disheartened, shamed, dishonoured, quelled,
> To what can I be useful? wherein serve
> My nation, and the work from heaven imposed?
> But to sit idle on the household hearth,
> A burdenous drone, to visitants a gaze,
> Or pitied object."

That might be the appearance, but it was not the reality. All the while of his seeming degradation he had found some solace in renewed industry of various kinds among his books and tasks of scholarship, and all the while, more particularly, he had been building up his *Paradise Lost.* He had begun the poem in earnest, we are told, in his house in Petty France, in the last year of Cromwell's Protectorate, and then not in the dramatic form contemplated eighteen years before, but deliberately in the epic form. He had made but little way when there came the interruption of the anarchy preceding the Restoration and of the Restoration itself; but the work had been resumed in Jewin Street and prosecuted there steadily, by dictations of twenty or thirty lines at a time to whatever friendly or hired amanuensis chanced to be at hand. Considerable progress had been made in this way before his third marriage; and after that the work proceeded apace, his nephew Edward Phillips, who was then out in the world on his own account, looking in when he could to revise the growing manuscript.

It was not in the house in Jewin Street, however, that *Paradise Lost* was finished. Not very long after the third marriage, probably in 1664, there was a removal to another house, with a garden, not far from Jewin Street, but in a more private portion of the same suburb. This, which was to be the last of all Milton's London residences, was in the part of the present Bunhill Row which faces the houses that conceal the London artillery-ground and was then known as "Artillery Walk, leading to Bunhill Fields." Here the poem was certainly finished before July 1665; for, when, in that month, Milton and his family, to avoid the Great Plague of London, then beginning its fearful ravages, went into temporary country-quarters in a cottage in Chalfont St Giles, Buckinghamshire, about 23 miles from London, the finished manuscript was taken with him, in probably more than one copy. This we learn from his young Quaker friend, Thomas Ellwood, who had taken the cottage for him, and who was shown one of the manuscript copies, and allowed to take it away with him for perusal, during Milton's stay at Chalfont. Why the poem was not published immediately after his return to his Bunhill house in London, on the cessation of the Great Plague, does not distinctly appear, but may be explained partly by the fact that the official licenser hesitated before granting the necessary *imprimatur* to a book by a man of such notorious republican antecedents, and partly by the paralysis of all business in London by the Great Fire of September 1666. It was not till the 27th of April 1667 that Milton concluded an agreement with a publisher for the printing of his epic. By the agreement of that date, still extant, Milton sold to Samuel Simmons, printer, of Aldersgate Street, London, for £5 down, the promise of another £5 after the sale of a first edition of thirteen hundred copies, and the further promise of two additional sums of £5 each after the sale of two more editions of the same size respectively, all his copyright and commercial interest in *Paradise Lost* for ever. It was as if an author now were to part with all his rights in a volume for £17, 10s. down, and a contingency of £52, 10s. more in three equal instalments. The poem was duly entered by Simmons as ready for publication in the Stationers' Registers on the 20th of the following August; and shortly after that date it was out in London as a neatly printed small quarto, with the title *Paradise Lost: A Poem written in Ten Books: By John Milton.* The publishing price was 3s., equal to about 10s. 6d. now. It is worth noting as an historical coincidence that the poem appeared just at the time of the fall and disgrace of Clarendon.

The effect of the publication of *Paradise Lost* upon Milton's reputation can only be described adequately, as indeed it was consciously described by himself in metaphor, by his own words on Samson's feat of triumph over the Philistines:—

> But he, though blind of sight,
> Despised, and thought extinguished quite,
> With inward eyes illuminated,
> His fiery virtue roused
> From under ashes into sudden flame,
> And as an evening dragon came,
> Assailant on the perched roosts
> And nests in order ranged
> Of tame villatic fowl, but as an eagle
> His cloudless thunder bolted on their heads."

As the poem circulated and found readers, whether in the first copies sent forth by Simmons, or in subsequent copies issued between 1667 and 1669, with varied title-pages, and the latest of them with a prefixed prose "Argument," the astonishment broke out everywhere. "This man cuts us all out, and the ancients too" is the saying attributed to Dryden on the occasion; and it is the more remarkable because the one objection to the poem which at first, we are told, "stumbled many" must have "stumbled" Dryden most of all. Except in the drama, rhyme was then thought essential in anything professing to be a poem; blank verse was hardly regarded as verse at all; Dryden especially had been and was the champion of rhyme, contending for it even in the drama; and yet here was an epic not only written in blank verse, but declaring itself on that account to be "an example set, the first in English, of ancient liberty recovered to heroic poem from the troublesome and modern bondage of riming." That, notwithstanding this obvious blow struck by the poem at Dryden's pet literary theory, he should have welcomed the poem so enthusiastically and proclaimed its merits so emphatically, says much at once for his critical perception and for the generosity of his temper. An opinion proclaimed by the very chief of the Restoration literature could not but prevail among the contemporary scholars; and, though execration of the blind and unhanged regicide

had not ceased among the meaner critics, the general vote was that he had nobly redeemed himself. One consequence of his renewed celebrity was that visitors of all ranks again sought him out for the honour of his society and conversation. His obscure house in Artillery Walk, Bunhill, we are told, became an attraction now, "much more than he did desire," for the learned notabilities of his time.

The year 1669, when the first edition of *Paradise Lost* had been completely sold out, and Milton had received his second £5 on account of it, may be taken as the time of the perfect recognition of his pre-eminence among the English poets of his generation. He was then sixty years of age; and it is to about that year that the accounts that have come down to us of his personal appearance and habits in his later life principally refer. They describe him as to be seen every other day led about in the streets in the vicinity of his Bunhill residence, a slender figure, of middle stature or a little less, generally dressed in a grey cloak or overcoat, and wearing sometimes a small silver-hilted sword, evidently in feeble health, but still looking younger than he was, with his lightish hair, and his fair, rather than aged or pale, complexion. He would sit in his garden at the door of his house, in warm weather, in the same kind of grey overcoat, "and so, as well as in his room, received the visits of people of distinguished parts, as well as quality." Within doors he was usually dressed in neat black. He was a very early riser, and very regular in the distribution of his day, spending the first part, to his midday dinner, always in his own room, amid his books, with an amanuensis to read for him and write to his dictation. Music was always a chief part of his afternoon and evening relaxation, whether when he was by himself or when friends were with him. His manner with friends and visitors was extremely courteous and affable, with just a shade of stateliness. In free conversation, either at the midday dinner, when a friend or two happened, by rare accident, to be present, or more habitually in the evening and at the light supper which concluded it, he was the life and soul of the company, from his "flow of subject" and his "unaffected cheerfulness and civility," though with a marked tendency to the satirical and sarcastic in his criticisms of men and things. This tendency to the sarcastic was connected by some of those who observed it with a peculiarity of his voice or pronunciation. "He pronounced the letter *r* very hard," Aubrey tells us, adding Dryden's note on the subject: "*litera canina*, the dog-letter, a certain sign of a satirical wit." He was extremely temperate in the use of wine or any strong liquors, at meals and at all other times; and when supper was over, about nine o'clock, "he smoked his pipe and drank a glass of water, and went to bed." He suffered much from gout, the effects of which had become apparent in a stiffening of his hands and finger-joints, and the recurring attacks of which in its acute form were very painful. His favourite poets among the Greeks were Homer and the Tragedians, especially Euripides; among the Latins, Virgil and Ovid; among the English, Spenser and Shakespeare. Among his English contemporaries, he thought most highly of Cowley. He had ceased to attend any church, belonged to no religious communion, and had no religious observances in his family. His reasons for this were a matter for curious surmise among his friends, because of the profoundly religious character of his own mind; but he does not seem ever to have furnished the explanation. The matter became of less interest perhaps after 1669, when his three daughters ceased to reside with him, having been sent out, at considerable expense, "to learn some curious and ingenious sorts of manufacture that are proper for women to learn, particularly embroideries in gold or silver." After that the household in Bunhill consisted only of Milton, his wife, a single maid-servant, and the "man" or amanuensis who came in for the day.

The remaining years of Milton's life, extending through that part of the reign of Charles II. which figures in English history under the name of "The Cabal Administration," were by no means unproductive. In 1669 he published, under the title of *Accedence Commenced Grammar*, a small English compendium of Latin grammar that had been lying among his papers. In 1670 there appeared, in a rather handsome form, and with a prefixed portrait of him by Faithorne, done from the life, and the best and most authentic that now exists, his *History of Britain to the Norman Conquest*, being all that he had been able to accomplish of his intended complete history of England. In 1671 there followed his *Paradise Regained* and *Samson Agonistes*, bound together in one small volume, and giving ample proof that his poetic genius had not exhausted itself in the preceding great epic. His only publication in 1672 was a Latin digest of Ramist logic, entitled *Artis Logicæ Plenior Institutio*, of no great value, and doubtless from an old manuscript of his earlier days. In 1673, at a moment when the growing political discontent with the government of Charles II. and the conduct of his court had burst forth in the special form of a "No-Popery" agitation and outcry, Milton ventured on the dangerous experiment of one more political pamphlet, in which, under the title *Of True Religion, Heresy, Schism, Toleration, and what best means may be used against the growth of Popery*, he put forth, with a view to popular acceptance, as mild a version as possible of his former principles on the topics discussed. In the same year appeared the second edition of his *Minor Poems*. Thus we reach the year 1674, the last of Milton's life. One incident of that year was the publication of the second edition of *Paradise Lost*, with the poem rearranged as now into twelve books, instead of the original ten. Another was the publication of a small volume containing his Latin *Epistolæ Familiares*, together with the *Prolusiones Oratoriæ* of his student-days at Cambridge,—these last thrown in as a substitute for his Latin state letters in his secretaryship for the Commonwealth and the Protectorate, the printing of which was stopped by order from the Foreign Office. A third publication of the same year, and probably the very last thing dictated by Milton, was a translation of a Latin document from Poland relating to the recent election of the heroic John Sobieski to the throne of that kingdom, with the title *A Declaration or Letters Patents of the Election of this present King of Poland, John the Third.* It seems to have been out in London in August or September 1674. On the 8th of the following November, being a Sunday, Milton died, in his house in Bunhill, of "gout struck in," or gout-fever, at the age of sixty-five years and eleven months. He was buried, the next Thursday, in the church of St Giles, Cripplegate, beside his father, a considerable concourse attending the funeral.

Before the Restoration, Milton, what with his inheritance from his father, what with the official income of his Latin secretaryship, must have been a man of very good means indeed. Since then, however, various heavy losses, and the cessation of all official income, had greatly reduced his estate, so that he left but £900 (worth about or over £2700 now), besides furniture and household goods. By a word-of-mouth will, made in presence of his brother Christopher, he had bequeathed the whole to his widow, on the ground that he had done enough already for his "undutiful" daughters, and that there remained for them his interest in their mother's marriage portion of £1000, which had never been paid, but which their relatives, the Powells of Forest Hill, were legally bound for, and were now in circumstances to make good. The daughters, with the Powells probably abetting them, went to law with the widow to upset the will; and the decision of the court was that they should receive £100 each. With the £600 thus left, the widow, after some further stay in London, retired to Nantwich in her

native Cheshire. There, respected as a pious member of a local Baptist congregation, she lived till 1727, having survived her husband fifty-three years. By that time all the three daughters were also dead. The eldest, Ann Milton, who was somewhat deformed, had died not long after her father, having married "a master-builder," but left no issue; the second, Mary Milton, had died, unmarried, before 1694; and only the third, Deborah, survived as long as her step-mother. Having gone to Ireland, as companion to a lady, shortly before her father's death, she had married an Abraham Clarke, a silk-weaver in Dublin, with whom she returned to London about 1684, when they settled in the silk-weaving business in Spitalfields, rather sinking than rising in the world, though latterly some public attention was paid to Deborah, by Addison and others, on her father's account. One of her sons, Caleb Clarke, had gone out to Madras in 1703, and had died there as "parish-clerk of Fort George" in 1719, leaving children, of whom there are some faint traces to as late as 1727, the year of Deborah's death. Except for the possibility of further and untraced descent from this Indian grandson of Milton, the direct descent from him came to an end in his granddaughter, Elizabeth Clarke, another of Deborah's children. Having married a Thomas Foster, a Spitalfields weaver, but afterwards set up a small chandler's shop, first in Holloway and then in Shoreditch, she died at Islington in 1754, not long after she and her husband had received the proceeds of a performance of *Comus* got up by Dr Johnson for her benefit. All her children had predeceased her, leaving no issue.—Milton's brother Christopher, who had always been on the opposite side in politics, rose to the questionable honour of a judgeship and knighthood in the latter part of the reign of James II. He had then become a Roman Catholic,—which religion he professed till his death in retirement at Ipswich in 1692. Descendants from him are traceable a good way into the 18th century.—Milton's two nephews and pupils, Edward and John Phillips, both of them known as busy and clever hack-authors before their uncle's death, continued the career of hack authorship, most industriously and variously, though not very prosperously, through the rest of their lives, Edward in a more reputable manner than John, and with more of enduring allegiance to the memory of his uncle. Edward died about 1695; John was alive till 1706. Their half-sister, Ann Agar, the only daughter of Milton's sister by her second husband, had married, in 1673, a David Moore, of Sayes House, Chertsey; and it has so happened that the most flourishing of all the lines of descent from the poet's father is in this Agar-Moore branch of the Miltons.

Of masses of manuscript that had been left by Milton, some portions saw the light posthumously. Prevented, in the last year of his life, as has been mentioned, from publishing his Latin *State Letters* in the same volume with his Latin *Familiar Epistles*, he had committed the charge of the *State Letters*, prepared for the press, together with the completed manuscript of his Latin *Treatise of Christian Doctrine*, to a young Cambridge scholar, Daniel Skinner, who had been among the last of his amanuenses, and had, in fact, been employed by him specially in copying out and arranging those two important MSS. Negotiations were on foot, after Milton's death, between this Daniel Skinner and the Amsterdam printer, Daniel Elzevir, for the publication of both MSS., when the English Government interfered, and the MSS. were sent back by Elzevir, and thrown aside, as dangerous rubbish, in a cupboard in the State Paper Office. Meanwhile, in 1676, a London bookseller, named Pitt, who had somehow got into his possession a less perfect, but still tolerably complete, copy of the *State Letters*, had brought out a surreptitious edition of them, under the title *Literæ Pseudo-Senatus Anglicani, necnon Cromwelli, nomine et jussu conscriptæ.* No other posthumous publication of Milton's appeared till 1681, when another bookseller put forth a slight tract entitled *Mr John Milton's Character of the Long Parliament and Assembly of Divines*, consisting of a page or two, of rather dubious authenticity, said to have been withheld from his *History of Britain* in the edition of 1670. In 1682 appeared *A Brief History of Moscovia and of other less-known Countries lying eastward of Russia as far as Cathay*, undoubtedly Milton's, and a specimen of those prose compilations with which he sometimes occupied his leisure. Of the fate of his collections for a new Latin *Dictionary*, which had swelled to three folio volumes of MS., all that is known is that, after having been used by Edward Phillips for some of *his* pedagogic books, they came into the hands of a committee of Cambridge scholars, and were used for that Latin dictionary of 1693, called *The Cambridge Dictionary*, on which Ainsworth's *Dictionary* and all subsequent Latin dictionaries of English manufacture have been based. In 1698 there was published in three folio volumes, under the editorship of John Toland, the first collective edition of Milton's prose works, professing to have been printed at Amsterdam, though really printed in London. A very interesting folio volume, published in 1743 by "John Nickolls, junior," under the title of *Original Letters and Papers of State addressed to Oliver Cromwell*, consists of a number of intimate Cromwellian documents that had somehow come into Milton's possession immediately after Cromwell's death, and were left by him confidentially to the Quaker Ellwood. Finally, a chance search in the London State Paper Office in 1823 having discovered the long-lost parcel containing the MSS. of Milton's Latin *State Letters* and his Latin *Treatise of Christian Doctrine*, as these had been sent back from Amsterdam a hundred and fifty years before, the *Treatise on Christian Doctrine* was, by the command of George IV., edited and published in 1825 by the Rev. C. R. Sumner, keeper of the Royal Library, and afterwards bishop of Winchester, under the title of *Joannis Miltoni Angli De Doctrina Christiana Libri Duo Posthumi.* An English translation, by the editor, was published in the same year.

Information, rather than criticism, has seemed proper in such an article as the present. What little of closing remark is necessary will best connect itself with the obvious fact of the division of Milton's literary life into three almost mechanically distinct periods, viz.:—(1) the time of his youth and minor poems, (2) his middle twenty years of prose polemics, and (3) the time of his later Muse and greater poems.

Had Milton died in 1640, when he was in his thirty-second year, and had his literary remains been then collected, he would have been remembered as one of the best Latinists of his generation and one of the most exquisite of minor English poets. In the latter character, more particularly, he would have taken his place as one of that interesting group or series of English poets, coming in the next forty years after Spenser, who, because they all acknowledged a filial relationship to Spenser, may be called collectively The Spenserians. In this group or series, counting in it such other true poets of the reigns of James I. and Charles I. as Phineas and Giles Fletcher, William Browne, and Drummond of Hawthornden, Milton would have been entitled, by the small collection of pieces he had left, and which would have included his *Ode on the Nativity*, his *L'Allegro* and *Il Penseroso*, his *Comus*, and his *Lycidas*, to recognition as indubitably the very highest and finest. There was in him that peculiar Spenserian something which might be regarded as the poetic faculty in its essence, with a closeness and perfection of verbal finish not to be found in the other Spenserians, or even in the master himself. A very discerning critic might have gone deeper, as we can now. Few as the pieces were, and owning discipleship to Spenser as the author did, he was a Spenserian with a difference belonging to his own constitution,—which prophesied, and indeed already exhibited, the passage of English poetry out of the Spenserian into a kind that might be called the Miltonic. This Miltonic something, distinguishing the new poet from other Spenserians, was more than mere perfection of literary finish. It consisted in an avowed consciousness already of the *os magna soniturum*, "the mouth formed for great utterances," that consciousness resting on a peculiar substratum of personal character that had occasioned a new theory of literature. "He who would not be frustrate of his hope to write well hereafter on laudable things ought himself to be a true poem" was Milton's own memorable expression afterwards of the principle that had taken possession of him from his earliest days; and this principle of moral manliness as the true foundation of high literary effort, of the inextricable identity of all literary productions in kind, and their coequality in worth, with the personality in which they have their origin, might have been detected, in more or less definite shape, in all or most of the minor poems. It is a specific form of that general Platonic doctrine of the invincibility of virtue which runs through his *Comus*, and which is summed up in the Miltonic motto of the closing lines:—

> "Mortals that would follow me,
> Love Virtue: she alone is free.
> She can teach ye how to climb
> Higher than the sphery chime;
> Or, if Virtue feeble were,
> Heaven itself would stoop to her."

That a youth and early manhood of such poetical promise should have been succeeded by twenty years of all but incessant prose polemics has been a matter of regret with many. Why should the author of *Comus* and *Lycidas*, instead of keeping to the poetic craft, have employed himself for twenty years in the drudgery and turmoil of prose pamphleteering on questions of church and state, with nothing in verse to glitter across the long morass but a slight chain of biographical and historical sonnets? Surely this is a most shallow and most unmasculine judgment. Is nothing due to Milton's own explanation of the reasons that drew him, at the beginning of the English Revolution, out of his literary projects and dreamings, into active partisanship with the cause which his reason favoured? Hear what he says would have been the reproach of his own conscience to him, evening and morning, if he had abstained from such partisanship and persisted in his poetic privacy. "Ease and leisure was given thee for thy retired thoughts out of the sweat of other men. Thou hadst the diligence, the parts, the language of a man, if a vain subject were to be adorned or beautified; but, when the cause of God and His church was to be pleaded, for which purpose that tongue was given thee which thou hast, God listened if He could hear thy voice among His zealous servants, but thou wert dumb as a beast: from henceforward *be* that which thine own brutish silence hath made thee." Or, if this should be in too high a strain for the ordinary modern apprehension, may not one ask, more

simply, whether such controversial work as Milton did plunge into, and persevere in for twenty years, was unworthy, after all, of him or his powers? Do not hundreds of men, accounted among the ablest in the world, spend their lives precisely in such work of controversy on contemporary questions; and are not some of the men of noblest reputation in the world's history remembered for nothing else? If Burke, whose whole public career consisted in a succession of speeches and pamphlets, is looked back upon as one of the greatest men of his century on their account, why should there be such regret over the fact that Milton, after having been the author of *Comus* and *Lycidas*, became for a time the prose orator of *his* earlier and more tumultuous generation? The truth is that it is not his exchange of poetry for prose oratory that is objected to, so much as the nature of his prose oratory, the side he took, the opinions he advocated. English scholarship and English literary criticism have not yet sufficiently recovered from that inherited sycophancy to the Restoration which has covered with a cloud the preceding twenty years of the "Great Rebellion," voting that period of English history to be unrespectable, and all its phenomena of Presbyterianism, the Solemn League and Covenant, Independency, the sects, English republicanism, &c., to be matters of obsolete jargon, less worthy of attention than a Roman agrarian law or the names of Horace's mistresses. When this unscholarly state of temper has passed, there will be less disposition to distinguish between Milton as the poet and Milton as the prose writer. While some may recognize, with the avidity of assent and partisanship, the fact that there are in Milton's prose writings notions of much value and consequence that have not yet been absorbed into the English political mind, there will be a general agreement at least as to the importance of those pamphlets historically. It will be perceived that he was not only the greatest pamphleteer of his generation, head and shoulders above the rest, but also that there is no life of that time, not even Cromwell's, in which the history of the great Revolution in its successive phases, so far as the deep underlying ideas and speculations were concerned, may be more intimately and instructively studied than in Milton's. Then, on merely literary grounds, what an interest in those prose remains! Not only of his *Areopagitica*, admired now so unreservedly because its main doctrine has become axiomatic, but of most of his other pamphlets, even those the doctrine of which is least popular, it may be said confidently that they answer to his own definition of "a good book," by containing somehow "the precious life-blood of a master-spirit." From the entire series there might be a collection of specimens, unequalled anywhere else, of the capabilities of that older, grander, and more elaborate English prose of which the Elizabethans and their immediate successors were not ashamed, though it has fallen into disrepute now in comparison with the easier and nimbler prose which came in with Dryden. Nor will readers of Milton's pamphlets continue to accept the hackneyed observation that his genius was destitute of humour. Though his prevailing mood was the severely earnest, there are pages in his prose writings, both English and Latin, of the most laughable irony, reaching sometimes to outrageous farce, and some of them as worthy of the name of humour as anything in Swift. Here, however, we touch on what is the worst feature in some of the prose pamphlets,—their measureless ferocity, their boundless licence in personal scurrility. With all allowance for the old custom of those days, when controversy was far more of a life-and-death business than it is now, as well as for the intrinsic soundness of Milton's rule of always discerning the *man* behind the *book*, it is impossible for the most tolerant of modern readers to excuse Milton in this respect to the full extent of his delinquencies.

While it is wrong to regard Milton's middle twenty years of prose polemics as a degradation of his genius, and while the fairer contention might be that the youthful poet of *Comus* and *Lycidas* actually promoted himself, and became a more powerful agency in the world and a more interesting object in it for ever, by consenting to lay aside his "singing robes" and spend a portion of his life in great prose oratory, who does not exult in the fact that such a life was rounded off so miraculously at the close by a final stage of compulsory calm, when the "singing robes" could be resumed, and *Paradise Lost, Paradise Regained*, and *Samson Agonistes* could issue in succession from the blind man's chamber? Of these three poems, and what they reveal of Milton, no need here to speak at length. *Paradise Lost* is one of the few monumental works of the world, with nothing in modern epic literature comparable to it except the great poem of Dante. This is best perceived by those who penetrate beneath the beauties of the merely terrestrial portion of the story, and who recognize the coherence and the splendour of that vast symbolic phantasmagory by which, through the wars in heaven and the subsequent revenge of the expelled archangel, it paints forth the connexion of the whole visible universe of human cognizance and history with the grander, pre-existing, and still environing world of the eternal and inconceivable. To this great epic *Paradise Regained* is a sequel, and it ought to be read as such. The legend that Milton preferred the shorter epic to the larger is quite incorrect. All that is authentic on the subject is the statement by Edward Phillips that, when it was reported to his uncle that the shorter epic was "generally censured to be much inferior to the other," he "could not hear with patience any such thing." The best critical judgment now confirms Milton's own, and pronounces *Paradise Regained* to be not only, within the possibilities of its briefer theme, a worthy sequel to *Paradise Lost*, but also one of the most edifying and artistically perfect poems in any language. Finally, the poem in which Milton bade farewell to the Muse, and in which he reverted to the dramatic form, proves that to the very end his right hand had lost none of its power or cunning. *Samson Agonistes* is the most powerful drama in our language after the severe Greek model, and it has the additional interest of being so contrived that, without strain at any one point, or in any one particular, of the strictly objective incidents of the Biblical story which it enshrines, it is yet the poet's own epitaph and his condensed autobiography. All in all, now that those three great poems of Milton's later life have drawn permanently into their company the beautiful and more simple performances of his youth and early manhood, so that we have all his English poetry under view at once, the result has been that this man, who would have had to be remembered independently as the type of English magnanimity and political courage, is laurelled also as the supreme poet of his nation, with the single exception of Shakespeare.

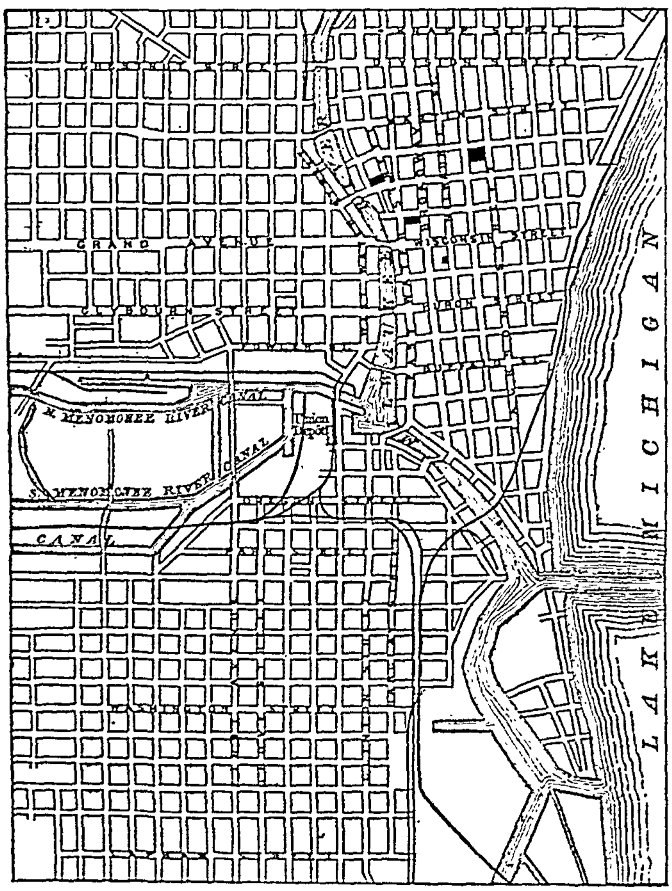
Much light is thrown upon Milton's mind in his later life, and even upon the poems of that period, by his posthumous Latin *Treatise of Christian Doctrine*. It differs from all his other prose writings of any importance in being cool, abstract, and didactic. Professing to be a system of divinity derived directly from the Bible, it is really an exposition of Milton's metaphysics and of his reasoned opinions on all questions of philosophy, ethics, and politics. The general effect is to show that, though he is rightly regarded as the very genius of English Puritanism, its representative poet and idealist, yet he was not a Puritan of what may be called the first wave, or that wave of Calvinistic orthodoxy which broke in upon the absolutism of Charles and Laud, and set the English Revolution agoing. He belonged distinctly to that larger and more persistent wave of Puritanism which, passing on through Independency, included at length an endless variety of sects, many of them rationalistic and free-thinking in the extreme, till, checked by the straits of the Restoration, it had to contract its volume for a while, and to reappear, so far as it could reappear at all, in the new and milder guise of what has ever since been known as English Liberalism. For example, the treatise shows that Milton in his later life was not an orthodox Trinitarian, but an anti-Trinitarian of that high Arian order, counting Sir Isaac Newton among its subsequent English adherents, which denied the coessentiality or coequality of Christ with absolute Deity, but regarded him as clothed with a certain derivative divinity of a high and unfathomable kind. It shows him also to have been Arminian, rather than Calvinistic, in his views of free will and predestination. It shows him to have been no Sabbatarian, like the Puritans of the first wave, but most strenuously anti-Sabbatarian. Indeed one of its doctrines is that the Decalogue is no longer the standard of human morality, and that Christian liberty is not to be bounded by its prohibitions or by any sacerdotal code of ethics founded on these. Hence, in the treatise, not only a repetition of Milton's views on the marriage subject and of other peculiar tenets of his that had been set forth in his pamphlets, but some curious and minute novelties of opinion besides. By far the most important revelation of the treatise, however, consists in the very definite statement it makes of Milton's metaphysical creed and of the connexion of that creed in his mind with the revealed theology of Christianity. While, ontologically, he starts from a pure spiritualistic theism, or from the notion of one infinite and eternal Spirit as the self-subsisting God and author of all being, cosmologically his system is that of a pantheistic materialism, which conceives all the present universe, all that we call creation, as consisting of diverse modifications, inanimate or animate, of one primal matter, which was originally nothing else than an efflux or emanation from the very substance of God. Angels and men, no less than the brute world and the things we call lifeless, are formations from this one original matter, only in higher degrees and endowed with soul and free will. Hence any radical distinction between matter and spirit, body and soul, is, Milton holds, fallacious. The soul of man, he holds, is not something distinct from the body of man and capable of existing apart, but is actually bound up with the bodily organism. Therefore, when the body dies, the soul dies also, and the whole man ceases to exist. The immortality revealed in Scripture is, therefore, not a continued existence of the soul in an immaterial condition immediately after death, but a miraculous revival of the whole man, soul and body together, at the resurrection, after an intermediate sleep. In such a resurrection, with a final judgment, a reign of Christ, and a glorification of the saints in a new heaven and a new earth, Milton declares his absolute belief. But, indeed, throughout the treatise, with all its differences from the orthodox interpretations of the Bible, nothing is more remarkable than the profoundness of the reverence avowed for the Bible itself. The very initial

principle of the treatise is that, as the Bible is a revelation from God of things that man could not have found out for himself, all that the Bible says on any matter is to be accepted implicitly, in the plain sense of the words, and without sophistication, however strange it may seem to the natural human reason. Hence, in all those essentials of Christianity which consist in the doctrines of the fall of man, atonement by Christ, and restoration and sanctification through Christ only, Milton is at one with the great body of Christians. Altogether, what the treatise makes clear is that, while Milton was a most fervid theist and a genuine Christian, believing in the Bible, and valuing the Bible over all the other books in the world, he was at the same time one of the most intrepid of English thinkers and theologians.

For further information reference may be made to Masson's *Life of Milton and History of his Time*, 6 vols. (1859–80), and to his editions of Milton's *Poetical Works* (Cambridge edition in 3 vols., 1874, and smaller 3 vol. ed., 1882), as well as to Todd's variorum edition of the *Poetical Works*, with Life (5th ed., 1852), to Keightley's *Life, Opinions, and Writings of Milton* (1855), to *Milton und Seine Zeit*, by Alfred Stern (1877-79), and to Mr Mark Pattison's *Milton* in Mr Morley's series of "English Writers." Collective editions of the prose works since that of 1698 are—Symmons's (7 vols., 1806); Pickering's, with *Life* by Mitford (8 vols., prose and verse together, 1851); and St John's, in Bohn's Standard Library (5 vols., 1848–53). This last includes a revised edition of Bishop Sumner's translation of the *Treatise of Christian Doctrine*, originally published in 1825. (D. MA.)

MILWAUKEE, the largest city in the State of Wisconsin, United States, is situated on the west shore of Lake Michigan, 100 miles north of its southern end, 80 miles north of Chicago, and 1000 miles north-west of New York by rail, in 43° 3′ N. lat., 87° 56′ W. long. (44 min. W. of Washington). The shore of the lake is 600 feet above the level of the sea.

The Milwaukee and Menomonee rivers unite in the centre of the business portion of the city, about half a mile from their entrance to Lake Michigan, where they are joined by a third and smaller stream—the Kinnikinnic. A bay 6 miles from cape to cape, and 3 miles broad,



Plan of Milwaukee.

stretches in front of the city, which commands a fine water view, the ground rising along the shore 80 feet above the level of the lake, then gradually sloping westward to the Milwaukee river, and again rising on the west and north to a height of 125 feet. The ground also rises to a commanding elevation south of the valley of the Menomonee. Few cities present so many natural attractions of site, as indeed its Indian name indicates ("the beautiful hollow or bay"); and art has added to nature. In the residence parts of the city there are miles of avenues from 70 to 100 feet wide, lined on both sides with elms and maples, behind which stand handsome houses with spacious lawns, fountains, and evergreens, giving the appearance of a continuous park. The material used for building is largely the cream-coloured brick made in the vicinity, from which Milwaukee is sometimes called the "Cream City." The climate, tempered by the great lake, is remarkably pleasant and healthy. The mean temperature, as shown by the records of twenty years, is 46°·7 Fahr. The coldest month is January (average 22°·37), the hottest July (70°·4).[1] During the last nine years the average death-rate has been but 20 per 1000, showing it to be one of the healthiest of American cities. Besides a full complement of the usual religious and charitable institutions, there is adjoining the city the national home for disabled United States volunteer soldiers, consisting of several buildings situated in grounds of 400 acres extent, which serve the purpose of a city park. There are numerous lodges belonging to the freemasons and other guilds; and the Turners' societies, which embrace a large membership and own some valuable buildings, have done much to create and keep up the practice of athletic exercises among the citizens. Two excellent musical societies are also established here.

Before the year 1835 Milwaukee was known only as an Indian trading-post occupied by a Frenchman named Solomon Juneau, who is generally spoken of as the founder of the city. The total inhabitants in 1838 numbered only 700; in 1840 there were 1712; but in 1846 the population amounted to 9666, in 1850 to 20,061, in 1855 to 30,118, in 1860 to 45,246, in 1870 to 71,440, and in 1880 to 115,578 (57,475 males, 58,103 females). In 1882 the population was estimated at 130,000,—more than one half of them of foreign parentage, a very large majority being Germans. Notwithstanding the multitude of nationalities represented in the population, there are few cities more orderly and law-abiding, the number of police employed being less than one for every 1500 inhabitants. Another feature worthy of mention is the large proportion of families who own their own houses, and this is true not only as to the mercantile and professional classes, but especially as to the labouring population. Although the grain trade, formerly very large here, has now greatly diminished, the growth and prosperity of the city have not materially suffered, owing to the development of manufacturing industries, for which the low rents, healthy climate, and advantageous location make it well adapted. About a sixth of the population are engaged in the manufacture of clothing, cigars, cooperage, leather, bricks, sashes, doors, and blinds, machinery, and flour (of which one million of barrels are annually made), and in meat-packing. Milwaukee has become famous for its "lager beer," of which there are one million of barrels annually produced, valued at $8,000,000. The lake commerce is very large. The tonnage entered and cleared in 1880 was 5,322,373 tons, being about as large as that of Baltimore, Boston, or Philadelphia. The Wisconsin Central, the Milwaukee and Lake Shore, the Milwaukee and Northern, and the Chicago, Milwaukee, and St Paul Railways have their head offices here, and the last-named, owning 4000 miles of lines, has immense workshops in the Menomonee valley near the city.

Milwaukee is governed by a mayor and a common council of thirty-nine aldermen. The streets and public buildings are under the charge of the board of public works,

[1] The monthly averages for twenty years are:—January, 22°·37; February, 25°·13; March, 33°·35; April, 43°·94; May, 53°·75; June, 64°·39; July, 70°·04; August, 67°·89; September, 61°·68; October, 48°·48; November, 36°·27; December, 25°·53.

composed of three commissioners and the city engineer, all subject to the common council. A bountiful supply of water is obtained from the lake, and the streets are well supplied with sewers. The value of property as assessed for taxation was $62,000,000 in 1882,—the city debt being $2,500,000, mostly for the water-works, which are city property.

There is an efficient system of public schools under a superintendent and board of school commissioners, the value of the buildings with their sites being estimated at $700,000. For the higher education there are a high school, a normal school, and three commercial colleges, while the Roman Catholics and Lutherans have several excellent denominational seminaries and colleges. A public library belonging to the city contained 20,000 volumes in 1882. (J. J.)

MIMICRY is the name given in biology to the advantageous resemblance (usually protective) which one species of animal or plant often shows to another. The word was first applied in this metaphorical sense by Mr W. H. Bates, and it has since been accurately defined and limited, in its biological application, by Mr A. R. Wallace. Briefly put, the essence of the phenomenon of mimicry consists in the following relation. A certain species of plant or animal possesses some special means of defence from its enemies, such as a sting, a powerful and disagreeable odour, a nauseous taste, or a hard integument. Some other species inhabiting the same district or a part of it, and not itself provided with the same special means of defence, closely resembles the first species in all external points of form and colour, though often very different in structure and unrelated in the biological order. For example, a South-American family of butterflies, the *Heliconidæ*, are distinguished by their very varied and beautiful colours, and their slow and weakly flight; they might easily be captured by insectivorous birds, but their remains are never found on the ground amongst the rejected wings of other butterflies which cover the soil in many places. They also possess a strong pungent odour, which clings to the fingers for many days; and this fact led Mr Wallace to suspect that they have a disagreeable taste, and would not therefore be eaten by birds after a single trial. Mr Belt has since experimentally proved the truth of that belief. But among the totally distinct family of the *Pieridæ*, most of which are white, there is a genus of small butterflies, known as *Leptalis*, edible by birds, some species of which are white like their allies, while the greater number exactly resemble one or other of the *Heliconidæ* in the peculiar shape and colouring of their wings. As regards structure, the two families are widely different; yet the resemblance of a species of one family to a species of the other is often so close that Mr Bates and Mr Wallace, experienced entomologists, frequently mistook them for one another at the time of capture, and only discovered their mistake upon nearer examination. Mr Bates observed several species or varieties of *Leptalis* in the Amazons valley, each of which more or less exactly copied one of the *Heliconidæ* in its own district. Accordingly, they seem to be mistaken by birds for the uneatable insects they mimic, and so to be benefited by their resemblance. This, which may perhaps be regarded as the most typical instance of true mimicry, is also the first to which the word was applied.

In considering the phenomena under review, it may be well to give first the chief observed facts, which are quite independent of any particular explanation, and then the theory which has been started to account for them by Mr Bates and Mr Wallace. Before doing so, however, true mimicry should be carefully discriminated from one or two superficially similar modes of resemblance among organic beings, whose real implications are very different. It must not be confused with mere accidental or adaptive resemblance, due either to simple chance or to similarity of external conditions. As a case of the first sort, we may adduce the real or fancied resemblance between certain orchids and flies or spiders; as a case of the second sort, we may take certain African *Euphorbiaceæ*, which, growing in dry deserts, have acquired a very close likeness to the cactuses that cover the equally dry deserts of Mexico; or again the sub-Antarctic gallinaceous bird, *Chionis alba*, which, living on the sea-shore, has acquired a coloration like that of the gulls, together with the legs of a wader. These resemblances, however, do not as such subserve any function. The species apparently mimicking and the species apparently mimicked either do not inhabit the same district or do not come into any definite relation with one another. The likeness is either accidental, or else it is due to similar adaptation to similar circumstances. In cases of true mimicry, on the other hand, the mimicking species derives a direct advantage from its likeness to the species mimicked; the resemblance is deceptive; and this is equally true whether we suppose the mimicry to be produced by creative design or by natural selection. On either hypothesis, however it came by its likeness, the mimicking species escapes certain enemies or obtains certain sorts of food by virtue of its resemblance to some other kind.

It should also be added that the word mimicry, as applied to such cases, is used only in a metaphorical sense. It is not intended to imply any conscious or voluntary imitation by one species of the appearance or habits of another. All that is meant is the fact of an advantageous resemblance, a delusive similarity, which gives the mimicking animal or plant some extra protection or some special means of acquiring food which it would not otherwise have possessed but for its likeness to the creature mimicked.

Taking animals first, mimicry does not occur very frequently among the higher classes. In the vertebrates it is comparatively rare, and among mammals probably only one good case has yet been adduced. This is that of *Cladobates*, an insectivorous genus of the Malayan region, many species of which closely resemble squirrels in size, in colour, and in the bushiness and posture of the tail. It has been suggested by Mr Wallace (from whom most of the following examples have been borrowed) that *Cladobates* may thus be enabled to approach the insects and small birds which form its prey under the disguise of the harmless fruit-eating squirrel. In this case, as in some others, the resemblance is not protective, but is apparently useful to the animal in the quest for food.

Among birds, Mr Wallace has pointed out that the general likeness of the cuckoo, a weak and defenceless group, to the hawks and gallinaceous tribe makes some approach to real mimicry. But besides such vague resemblances there are one or two very distinct cases of true mimicry in this class of vertebrates. In Australia and the Moluccas lives a genus of dull-hued honey-suckers, *Tropidorhynchus*, consisting of large, strong, active birds, with powerful claws and sharp beaks. They gather together in noisy flocks, and are very pugnacious, driving away crows and even hawks. In the same countries lives a group of orioles, forming the genus *Mimeta*; and these, which are much weaker birds, have not the usual brilliant colouring of their allies the golden orioles, but are usually olive-green or brown. In many cases species of *Mimeta* closely resemble the *Tropidorhynchi* inhabiting the same island. For example, on the island of Bouru are found the *Tropidorhynchus bouruensis* and *Mimeta bouruensis*, the latter of which mimics the former in the particulars thus noted by Mr Wallace:—"The upper and under surfaces of the two birds are exactly of the same tints of dark and light brown. The *Tropidorhynchus* has a large

bare black patch round the eyes; this is copied in the *Mimeta* by a patch of black feathers. The top of the head of the *Tropidorhynchus* has a scaly appearance from the narrow scale-formed feathers, which are imitated by the broader feathers of the *Mimeta* having a dusky line down each. The *Tropidorhynchus* has a pale ruff formed of curious recurved feathers on the nape (which has given the whole genus the name of friar-birds); this is represented in the *Mimeta* by a pale band in the same position. Lastly, the bill of the *Tropidorhynchus* is raised into a protuberant keel at the base, and the *Mimeta* has the same character, although it is not a common one in the genus. The result is that on a superficial examination the birds are identical, although they have important structural differences, and cannot be placed near each other in any natural arrangement." Allied species of *Tropidorhynchus* in Ceram and Timor are similarly mimicked by the local *Mimeta* of each island. Mr Osbert Salvin has likewise noticed a case of mimicry among the birds of prey near Rio Janeiro. An insect-eating hawk, *Harpagus diodon*, is closely resembled by a bird-eating hawk, *Accipiter pileatus*. Here the advantage seems to be that the small birds have learned not to fear the *Harpagus*, and the *Accipiter* is able to trade upon the resemblance by catching them unawares, both birds being reddish-brown when seen from beneath. But the *Accipiter* has the wider range of the two; and where the insect-eating species is not found it no longer resembles it, but varies in the under wing-coverts to white. Here again the resemblance, though advantageous, is not protective.

Among reptiles, Mr Wallace has instanced some curious cases where a venomous tropical American genus of snakes, *Elaps*, with brightly-banded colours, is closely mimicked by several genera of harmless snakes, having no affinity with it, but inhabiting the same region. Thus the poisonous *Elaps fulvus* of Guatemala has black bands on a coral-red ground; the harmless *Pliocerus æqualis* of the same district is coloured and banded precisely like it. The likeness affords the unarmed snakes a great protection, because other animals probably will not touch them, mistaking them for the venomous kinds.

It is among the invertebrates, however, and especially among insects, that cases of mimicry are most frequent and were first observed. In the order *Lepidoptera*, besides the classical instance of *Leptalis* and the *Heliconidæ*, a genus of another family, the *Erycinidæ*, also mimics the same group. The flocks of one species of *Ithomia*, an uneatable butterfly, often have flying with them a few individuals of three other widely different genera, quite indistinguishable from them when on the wing. In the tropics of the Old World, the *Danaidæ* and *Acræidæ* possess a similar protective odour, and are equally abundant in individuals; they are closely mimicked by various species of *Papilio* and *Diadema*. Mr Trimen, in a paper on "Mimetic Analogies among African Butterflies," gives a list of sixteen species or varieties of *Diadema* or its allies, and ten species of *Papilio*, each of which mimics a *Danais* or *Acræa* of the same region in the minutest particulars of form and colour. The *Danais tytia* of India has semi-transparent bluish wings, and a border of reddish-brown; this coloration is exactly reproduced in *Papilio agestor* and *Diadema nama*, all three insects frequently coming together in collections from Darjiling. In the Malay Archipelago the common and beautiful *Euplæa midamus* is so exactly mimicked by two rare species of *Papilio* that Mr Wallace generally mistook the latter at first for the ordinary insect. An immense number of other instances among the *Lepidoptera* have been quoted from other parts of the world.

Occasionally species of *Lepidoptera* also imitate insects of other orders. Many of them take on the appearance of bees or wasps, which are of course protected by their stings. Thus the *Sesiidæ* and *Ægeriidæ*, two families of diurnal moths, have species so like hymenopterous insects that they are known by such names as *apiformis*, *vespiforme*, *ichneumoniforme*, *sphegiforme*, and so forth. The British *sesia bombiliformis* closely resembles the humble bee; the *Sphecia craboniformis* is coloured like a hornet, and carries its wings in the same fashion. Some Indian *Lepidoptera* have the hind legs broad and densely hairy, so as exactly to imitate the brush-legged bees of the same country. Mr Belt mentions a Nicaraguan moth, *Pionia lycoides*, which closely mimics a distasteful coleopterous genus, *Calopteron*; and Professor Westwood pointed out that the resemblance to the beetle is still further increased in the moth by raised lines of scales running lengthwise down the thorax.

Among the *Coleoptera*, or beetles, and other orders, similar disguises are not uncommon. Mr Belt noticed species of *Hemiptera* and *Coleoptera*, as well as spiders, in Nicaragua, which exactly resemble stinging ants, and thus no doubt escape the attacks of birds. The genus *Calopteron* is mimicked by other beetles, as well as by the moth *Pionia*. In the same country, one of the *Hemiptera*, *Spiniger luteicornis*, has every part coloured like the hornet, *Priocnemis*, which it mimics; "in its vibrating coloured wing-cases it departs greatly from the normal character of the *Hemiptera*, and assumes that of the hornets." Mr Wallace mentions the longicorn beetle, *Cyclopeplus batesii*, which "differs totally in outward appearance from every one of its allies, having taken upon itself the exact shape and colouring of a globular *Corynomalus*, a little stinking beetle, with clubbed antennæ." *Erythroplatis corallifer*, another longicorn, almost exactly resembles *Cephalodonta spinipes*, one of the common South-American *Hispidæ*, which possesses a disagreeable secretion; and Mr Bates also found a totally different longicorn, *Streptolabis hispoides*, which resembles the same insect with equal minuteness. Some of the large tropical weevils have the elytra so hard that they cannot be pierced by a bird's beak; and these are mimicked by many other comparatively soft and eatable insects. In southern Brazil, *Acanthotritus dorsalis* closely resembles a *Curculio* of the hard genus *Heiliplus*; and Mr Bates found *Gymnocerus cratosomoides*, a longicorn, on the same tree with the hard weevil, *Cratosomus*, which it mimics. Other beetles resemble bees, wasps, and shielded bugs. Hairy caterpillars are well known to be distasteful to birds, and comparatively free from attack; and Mr Belt found a longicorn, *Desmiphora fasciculata*, covered with long brown and black hairs, and exactly mimicking some of the short, thick, woolly caterpillars common on the bushes around.

Amongst other orders, one of the most interesting cases is that of certain *Diptera* or two-winged flies which mimic wasps and bees. Sometimes this likeness only serves to protect the insect from attack, by inspiring fear of a sting. But there are also a number of parasitic flies whose larvæ feed upon the larvæ of bees, as in the British genus *Volucella*; and these exactly mimic the bees, so that they can enter the nests or hives to deposit their eggs without being detected even by the bees themselves. In every country where such flies occur they resemble the native bees of the district. Similarly, Mr Bates found a species of *Mantis* on the Amazons which exactly mimicked the white ants on which it fed. On the other hand, the defenceless species itself may mimic its persecutor, as in the case of several crickets, *Scaphura*, that exactly resemble various sand-wasps, and so escape the depredations of those cricket-killing enemies. Another cricket from the Philippine Islands, *Condylodera tricondyloides*, so closely copies a tiger-beetle, *Tricondyla*, that even Professor Westwood long retained it among that group in his cabinet,

and only slowly discovered his mistake. The cases here mentioned form but a small part of all those that have hitherto been observed and described in the insect world. They amount altogether to many hundreds.

Among plants, though included in the above definition for the sake of formal completeness, instances of true mimicry are rare or almost unknown. Perhaps the nearest approach to this phenomenon in the vegetal world is found in the resemblance borne by the dead-nettle, *Lamium album*, and a few other labiates, to the stinging nettle, *Urtica dioica* and *U. urens*. The true nettles are strikingly protected from animal foes by their stinging hairs; and the general appearance of the dead-nettle is sufficiently like them to prevent human beings from plucking it, and therefore probably to deter herbivorous mammals from eating it down. Mr Mansel Weale mentions another labiate, *Ajuga ophrydis*, of South Africa, which closely resembles an orchid, and may thus induce insects to fertilize its flowers. Mr Worthington Smith has found three rare British fungi, each accompanying common species which they closely resembled; and one of the common species possesses a bitter and nauseous taste; so that this would seem to be a case of true mimicry. Many diverse instances alleged by Mr A. W. Bennett, Dr Cooke, and others cannot be considered as genuine mimetic resemblances in the sense here laid down. They are mere coincidences or similar adaptations to similar needs; and the word ought to be applied strictly to such likenesses alone as benefit the organism in which they occur by causing it to be mistaken for another possessing some special advantage of its own.

The theoretical explanation of mimicry on evolutionary principles may best be considered in connexion with the general subject of protective coloration and variation in form, of which it is a very special case. There are two ways in which imitative colouring may benefit a species. It may help the members of the species to escape the notice of enemies, or it may help them to deceive prey. In the first case imitative hues enable the animal or plant to avoid being itself devoured; in the second case they enable it to devour others more easily, and so to secure a larger amount of food than less deceptively coloured compeers. In the former instance we must suppose that such individuals as did not possess the deceptive colouring have been discovered and destroyed by enemies with highly developed sight, while those which possessed it have survived. In the latter instance we must suppose that the individuals which have no protective colouring have failed to secure sufficient prey, through too readily betraying their presence, and that only those which possessed such colouring have become the parents of future generations. It is difficult, however, to separate these two cases, and in many instances the same colouring may aid a species both in escaping its peculiar enemies and in deceiving its peculiar prey. They may therefore most conveniently be considered together.

Colour is always liable to vary from individual to individual, as we see in the case of domesticated fowls, rabbits, dogs, and other animals, as well as in most cultivated flowers, wherever natural selection cannot act to keep the typical specific hues pure and true. But in a wild state certain conspicuous colours are sure to prove disadvantageous by betraying the individual, and these will sooner or later get weeded out, under certain circumstances, either through the action of enemies or by starvation resulting from the inability to escape the notice of prey. On the other hand, certain other colours are sure to benefit the individual by harmonizing with the tints of the environment and these will be spared by natural selection, so that the individuals possessing them will pair with one another, and will hand down their peculiarities to their descendants. In this way many species will acquire and retain a coloration that harmonizes with their environment as a whole or with some special part of it. The degree to which the protective coloration will be carried, however, must depend upon the sharpness of the senses in those other organisms which it is desirable to deceive. Large dominant herbivorous or frugivorous mammals or birds, with relatively few enemies, would not be benefited by protective coloration, and so they seldom exhibit it. The grasses or fruits on which they feed cannot make any attempt to escape them. But carnivores generally require to deceive their prey, and therefore a large number of them exhibit marked deceptive colouring. Still more especially do small defenceless birds or mammals need to escape the notice of the carnivores, and they accordingly very generally possess dull colours, because any variation in the direction of conspicuousness is certain to be promptly cut off. Above all, among insects, which are so largely the prey of birds, of reptiles, and of other animals possessing highly developed vision, protective coloration in one form or other is almost universal, except where a nauseous taste, hairy skin, or hard external coverings afford a different kind of protection. In every case the weeding out of ill-protected forms must depend upon the relative keenness of vision in the various enemies or of the prey, be they mammals, birds, reptiles, insects, or spiders. Hence the existence of protective coloring and of mimicry incidentally affords us valuable hints as to the perceptive faculties of the various classes against which each organism is thus unconsciously guarded.

Where the general aspect of the environment is most uniform, and where little but a vague impression of colour without individual form can be conveyed, the hues of animals are also usually uniform, to match their surroundings, and no special imitative adaptations of form occur. Thus, among the Arctic snows, a brown or black animal would immediately be perceived, and if defenceless at once devoured, while if a carnivore it would seldom or never approach unperceived near enough to its prey to effect a capture. Hence all such variations are at once repressed, and almost all Arctic animals, like the American polar hare, are pure white. Elsewhere bears are black or brown; in the polar region the native species is nearly indistinguishable from the snow in which it lives. Where the environment undergoes a regular change from season to season the colour of the fauna varies with it. The Arctic fox, the ermine, the alpine hare, the ptarmigan and many other birds, are all more or less brown among the brown hill-sides of autumn, and snow-white among the winter snows. Almost equally general is the sandy colour of deserts, though this, instead of being uniform, is slightly varied from grain to grain; and nearly all the birds, reptiles, and insects of Sahara exactly copy the sandy grey hue of the desert around them. Soles and other flat-fish (*Pleuronectidæ*) closely imitate the colour and speckled appearance of the sand on which they lie. The fishes and crustaceans which inhabit the sargasso weed are coloured the same yellow as the masses of algæ to which they cling. Aphides and many small leaf-eating caterpillars are bright green like the neighbouring foliage.

Where the environment is somewhat more diverse, the resemblance begins to show more specialized features. The lion, a large ground-cat of desert or rocky districts, is uniformly brown; but the tiger and other jungle-cats have perpendicular stripes which harmonize with the bamboos and brown grass of their native haunts; while the leopards, jaguars, and other tree-cats have ocellated spots which conceal them among the mingled light and shade of the forests. Large marine animals have the back black, because the water looks dark when seen from above, but their bellies are white, so as to harmonize with the colour of the surface when seen from below. Dr Weismann has shown that most edible unprotected caterpillars imitate the stripes and shades of the leaves among which they feed. Those which live upon grasses are longitudinally striped like the blades, those which live among small leaves are spotted and varied so as to resemble the distribution of light and shade in the bushes, and those which live upon large veined leaves with oblique ribs have oblique lines to harmonize with them. In some cases even the unripe berries are represented on the caterpillar by small reddish spots. A specialized form of this particular protective device is found in the chameleon, the chameleon-shrimp, many flat-fish, and some amphibians, all of which can vary their coloration to suit that of the surface on which they rest. The action is reflex, and ceases if the animal is blinded.

Where the environment is very varied, as in tropical forests, we find the greatest variety of colouring as well as actual imitation of particular forms; and the protective resemblances become at once closer and more common. Birds, reptiles, spiders, monkeys, and other active predaceous creatures are constantly hunting for insects and similar small prey amongst the fallen sticks or leaves; and among the most powerless classes of insects only those which very closely resemble specific objects in the environment can easily escape them. A gradual passage can be traced from the most general to the most special resemblances under such circumstances. Many forestine birds have a ground-tone of green in their plumage, which occurs nowhere but in the tropics. Some tree-lizards are green like the leaves on which they sit, others are marbled to resemble the bark where they lie in wait for their prey. Arboreal snakes often hang like lianas or other creepers. Insects which cling to the trunks of trees can seldom be distinguished from the bark. A Sumatran butterfly, *Kallima paralecta*, always settles on dry bushes among dead leaves, and can then hardly be perceived among the brown foliage, which it imitates even in the apparent blotches and mildew with which its wings are covered. The family of *Phasmidæ*, including the leaf and stick insects, carries such forms of imitation very far indeed. Most of them are large, soft, defenceless creatures; but some, like *Phyllium*, closely resemble green leaves, so as to be almost indistinguishable while feeding; and others exactly imitate short broken twigs of bamboo. Mr Wallace found one such insect, *Ceroxylus laceratus*, in Borneo,

apparently overgrown with a creeping moss or jungermannia; and Mr Belt discovered a larval form in Nicaragua whose body was prolonged into thin green filaments, precisely like the moss in which it lurked. In other instances the insect probably uses its disguise rather to deceive its prey than to escape its enemies. Sir Joseph Hooker believes that an Indian *Mantis* deludes the little creatures which .. . its food by its singular likeness to a leaf; while Sir Charles Dilke found one which had its head and fangs moulded into the deceptive appearance of an orchid, so that small flies were actually attracted in search of honey into its very jaws. Outside the class of insects, similar phenomena sometimes occur. Thus, according to Mr Bates, many showy little tropical spiders double themselves up at the base of leaf stalks so as to resemble flower buds, and thus delude the flies on which they prey. Even among the vertebrates Mr Belt mentions a green Nicaraguan lizard looking like the herbage by which it is surrounded, and decked with leaf-like expansions, which hide its predaceous nature from passing beetles or butterflies.

These last instances are divided from true mimicry by a very narrow line. But they differ in the fact that some vague object only in the general environment is simulated, not a particular protected species, as in genuine mimetic resemblance. If we allow, however, that natural selection can produce the white colour of Arctic animals, and the sandy hue of the sole and the flounder, it is easy enough to extend the same principle to the leaf-insect and the stick-insect, or even to real mimicry, as in the case of the *Leptalis* and the *Heliconidæ*. Certain *Phasmidæ* may at first have varied in the direction of green coloration, and these would naturally escape the eyes of birds more readily than their fellows. After the lapse of many generations, all the *Phasmidæ* of that special group would have become green, and the birds which preyed upon them would have learned in many cases to penetrate the disguise; for, as Mr Belt has observed, each fresh deceptive resemblance in the prey is sure to be followed by increased keenness of discrimination in the enemies of the species. At this stage the ordinary green *Phasmidæ* would often be killed, while only those which happened to approximate rudely in the venation of their wings to leaves would now escape the sharper and more experienced eyes of the birds. Thus step by step the disguise would become more and more perfect, only the best-protected of each generation escaping on the average, while all the worse-protected would be discovered and devoured. Given the usual luxuriance of tropical life, it is not difficult to understand how favourable variations might continually occur, until at length we get such perfect deceptions as those of the leaf-insects, the stick-insects, and the moss-grown larvæ.

The phenomena of true mimicry may be explained by a parallel genesis. Suppose, to begin with, a group of large and brilliant butterflies like the South-American *Heliconidæ*, protected by a nauseous taste and odour, and therefore never eaten by birds. To such insects slow flight and conspicuous hues are a positive protection, because they enable birds readily to discriminate them, and therefore prevent attacks, just as the banded body of the wasp and the hum of the bee prevent us from catching and killing them upon a window pane. Suppose, again, that in the same district there lives a widely different species of edible butterfly presenting some very slight and remote resemblance to the protected species. At first, no doubt, the resemblance will be merely an accidental one of general hue; it may even be so slight as to deceive nobody except upon the most distant and casual glance. Now, suppose these edible butterflies to be devoured in large quantities by birds, then a few of them may happen to gain safety by associating with the flocks of inedible butterflies which the birds refuse. After a time, even if the habit of consorting with the protected species becomes fixed in the race, the birds will begin to recognize the edible insects amongst the flocks, especially such as vary most in the opposite direction from the protected species. On the other hand, they will overlook such as vary most in the same direction as the inedible kind; and thus the least mimetic individuals will be destroyed, while the most mimetic will be left to pair with one another and to produce young, most of whom will present the like peculiarities. From generation to generation the birds will go on picking out every bad copy, and sparing all the best ones, till at last the two species become absolutely indistinguishable upon the wing. But the mimicry will never of course affect any but the most external and noticeable parts of the organism; it will be to the last a mere matter of colour, shape of wing, visible appearance of legs or antennæ, and so forth. The underlying structural differences will remain as great as ever, though externally masked by the deceptive resemblance in form and hue.

In like manner we may explain the genesis of the mimetic resemblance borne by *Volucella* to the humble bee. Suppose an undisguised fly to enter the bees' nest, it would be at once attacked and killed. But if it presented some very slight resemblance to the bee it might manage to lay its eggs undisturbed, and its larvæ would then be able to feed quietly upon the larvæ of the bee. With each new generation the more flimsy disguises would be more and more readily detected, and only those flies which varied most in the direction of resembling the bees would survive or lay their eggs in peace. On the other hand, those which actually succeeded would possess great advantages over their neighbours, because their larvæ would thus obtain a safe and certain supply of food, and be guaranteed the protection of the bees' nest. In this way the flies would at last, by constant survival of the best-adapted, come exactly to imitate the bees amongst which they lived.

The theory of the origin of mimetic forms thus briefly sketched out is due to Mr Bates and Mr Wallace, and it explains all the facts more fully than any other. It shows us, first, why the mimicking organism always imitates a specially protected species; secondly, why the two always inhabit the same district; thirdly, why the mimicking species is always much rarer than the species mimicked; fourthly, why the phenomenon is confined to a few groups only; and fifthly, why several different mimicking species often imitate the same protected form. It also accounts for the absence of mimicry amongst large or dominant animals, and its comparative commonness amongst small and defenceless kinds. And by affiliating the whole of the phenomena upon the general principles of protective colouring it reduces a seemingly strange and marvellous fact to a particular case of a well-known law.

Whatever theory be adopted, however, the facts and most of their implications remain the same. For, whether we suppose these imitative resemblances to be due to direct creative design or to survival of favourable variations, it is at least clear that the disguise subserves a function—that it is purposive and not accidental. Hence we may draw from the phenomena of mimicry certain important psychological implications. On the hypothesis of evolution, it is obvious that the mimicry can never go further than the senses of the creatures against whom the disguise is advantageous would naturally carry it; and even on the hypothesis of special design it is not likely that the imitation would be made more accurate than would be necessary for practical purposes of deception. There is much evidence in favour of this view. Mr B. T. Lowne, for example, who has carefully measured the curvature of the facets in the compound eyes of insects, upon which depends the minimum size of apprehensible objects, finds that the mimicry in the case of the flies parasitic upon bees' nests has proceeded just so far as the structure of the bee's eye would lead us to expect, and no further. In other words, so far as measurements of angular distance subtended can guide us, such a fly seems to be absolutely indistinguishable by a bee from one of his own species, within the limits of ordinary vision. The pictures cast upon the sensorium by the fly and by a brother bee are simply identical. In many other cases it can be shown that the mimicry seems specially intended to deceive the eyes of a particular class of animals; while there is no case of mimicry where the only enemies or prey consist of plants or eyeless animals. Naturally there can be no mimicry without a creature to deceive; the very conception implies an external nervous system to be acted upon, and to be acted upon deceptively. Thus mimicry in plants must have reference to the eyes of animals, in animals themselves to the eyes of one another. We may conclude, accordingly, that if a leaf-insect is green with faint violet-brown veins to the wings, exactly like a certain leaf, in order to deceive sundry tropical birds then those birds are capable of perceiving the forms and colours imitated to that particular degree. So the presence of mimicry in any group may guide us to a rough idea of the perceptive powers of those creatures whom the mimicry serves to deceive. The exact imitation of sand and coloured pebbles in the flat-fish is a fairly safe indication that the predaceous fish by whose selection they have been developed (through the weeding out of ill-protected variations) can pretty accurately distinguish form and colour. The long green pipe fish which cling around green sea-weed have probably acquired their existing hues to deceive the eyes of small sharks; the *Phyllopteryx eques*, a hippocampus which looks precisely like a piece of tangled and waving fucus (see figure, vol. xi. p. 852), has doubtless in the same way taken on its delusive likeness to the algæ among which it lives. So the cricket which resembles its foe the sand-wasp must have gained its present shape and hue by deceiving its enemy, and therefore it suggests the probability of highly developed vision on the part of the wasps. There seems every reason to believe that in many instances insects, spiders, and even lizards have developed mimetic or other deceptive resemblances in order to delude the eyes of insects; while in other cases the disguise has been unconsciously adopted to deceive fish, amphibians, reptiles, birds, and mammals. Moreover, we have some grounds for believing that the sense of colour is exceptionally strong in birds and in one or two insect orders; and the mimicry of colour seems to have proceeded to the greatest length amongst animals which are most exposed to the attacks of these classes, or which would find it advantageous to deceive them. It may be added that these same classes have been most effective in producing the bright hues of flowers and fruits, on Mr Darwin's hypothesis, or are at least in any case most intimately correlated with such vegetable structures as fertilizers of blossoms and dispersers of seed. Mimicry is thus to some extent a rough gauge of the perceptive faculties of the species deceived by it.

The vocal mimicry which occurs among certain birds, such as the mocking-bird, starling, parrot, and bullfinch, must of course be placed in a wholly different category from these biological cases. It is a direct volitional result, and it is mimicry in a literal not in a figurative sense. The faculty seems to be due to the play-instinct alone, and not to subserve any directly useful function. (G. A.)

MIMNERMUS, a Greek elegiac poet, born at Smyrna, lived about 600 B.C. His life fell in the troubled time when the old Greek city of Smyrna was struggling to maintain itself against the rising power of the Lydian kings. One of the extant fragments of his poems refers to the struggle and contrasts the present effeminacy of his countrymen with the bravery of those who had once defeated the Lydian king Gyges. The poet mentions in another fragment that he belonged to the stock of the Colophonians who had seized the Æolic Smyrna. But his most important poems were a set of elegies addressed to a flute-player named Nanno; they were collected in two books called after her name. Hermesianax mentions his love for Nanno, and implies that it was unfortunate. Only a few fragments of these poems have been preserved; and their soft melancholy tone and delicate language give some idea of the poet's character. His ideal is the sweet soft luxurious Ionian life, and he would enjoy it free from sorrow and die as soon as he could no longer enjoy it. Yet there is apparent some of the old stronger strain of character which in early time raised the Ionian cities to greatness, pride in the glories of his race and scorn for those that are unworthy of their fathers' renown. His experience of life was evidently sad; he felt that his country was gradually yielding to the enemy it had once defeated, and he knew that his own hopes were disappointed. The sun himself has endless toils from rising to setting and again from setting to rising. The life of man is as transitory as the leaves of spring, he says, referring to a passage in the popular epic poetry of Ionia (*Iliad*, vi. 146). He wishes to die in his sixtieth year, a wish to which Solon replied bidding him reconsider and rather long to die when he was eighty years old. Mimnermus was the first to make the elegiac verse, which had previously had more of the epic character, the vehicle for love-poetry, and to impart to it the colour of his own mind. He found the elegy devoted to objective themes; he made it subjective. He set his own poems to the music of the flute, and the poet Hipponax says that he used the melancholy νόμος Κραδίας. He bears the epithet Λιγυαστάδης, by which Solon addresses him. It is doubtful whether this epithet is peculiar to himself or whether it marks him as belonging to a musical and poetic family or school; it is evidently akin to the epithet λίγειαι Μοῦσαι.

MIMOSA. The *Mimoseæ* (so named from their mimicry of animal movements) form one of the three suborders of *Leguminosæ*, and are characterized by their (usually small) regular flowers and valvate corolla. Their 28 genera and 1100 species are arranged by Baillon in four series, of which the acacias (see ACACIA) and the true mimosas are the most important. They are distributed throughout almost all tropical and subtropical regions, the acacias preponderating in Australia and the true mimosas in America. The former are of considerable importance as sources of timber, gum, and tannin, but the latter are of much less economic value, though a few, like the talh (*M. ferruginea*) of Arabia and Central Africa, are important trees. Most are herbs or undershrubs, but some South-American species are tall woody climbers. They are often prickly. The roots of some Brazilian species are poisonous, and that of *M. pudica*, L., has irritating properties. *M. sensitiva* has been used in America in the treatment of fistula, &c., probably as an astringent. The mimosas, however, owe their interest and their extensive cultivation, partly to the beauty of their usually bipinnate foliage, but still more to the remarkable development in some species of the sleep movements manifested to some extent by most of the pinnate *Leguminosæ*, as well as many other (especially seedling) plants. In the so-called "sensitive plants" these movements not only take place under the influence of light and darkness, but can be easily excited by mechanical and other stimuli. When stimulated, say at the axis of one of the secondary petioles, the leaflets move upwards on each side until they meet, the movement being propagated centripetally. It may then be communicated to the leaflets of the other secondary petioles, which close (the petioles, too, converging), and thence to the main petiole, which sinks rapidly downwards towards the stem, the bending taking place at the pulvinus, or swollen base of the leafstalk. See BOTANY, vol. iv. p. 113, fig. 117. When shaken in any way, the leaves close and droop simultaneously, but if the agitation be continued, they reopen as if they had become accustomed to the shocks. The common sensitive plant of hot-houses is *M. pudica*, L., a native of tropical America but now naturalized in corresponding latitudes of Asia and Africa; but the hardly distinguishable *M. sensitiva* and others are also cultivated. The common wild sensitive plants of the United States are two species of the closely allied genus *Schrankia*.

MINDANAO, MINDORO. See PHILIPPINE ISLANDS.

MINDEN, the chief town of a district of the same name in Prussia, province of Westphalia, is situated about 22 miles to the west-south-west of Hanover, on the left bank of the Weser, which is spanned there by two bridges. The older parts of the town retain an old-fashioned appearance, with narrow and crooked streets; the modern suburbs occupy the site of the former fortifications. The most interesting building is the Roman Catholic cathedral, the tower of which, dating from the 11th century, illustrates the first step in the growth of the Gothic spire in Germany. The nave was erected at the end of the 13th century, and the choir in 1377–79. Among the other chief edifices are the old church of St Martin; the town-house, with a Gothic façade; the extensive court-house; and the Government offices, constructed, like many of the other buildings, of a peculiar veined brown sandstone found in the district. Minden contains a gymnasium and several hospitals, besides other charitable institutions. Its industries include linen and cotton weaving, dyeing, calico printing, and the manufacture of tobacco, leather, lamps, chicory, and chemicals. There is also some activity in the building of small craft. In 1881 107 vessels of an aggregate burden of 12,569 tons entered and cleared the river-harbour of Minden. The population in 1880 was 17,869.

Minden (Mindun, Mindo), apparently a trading place of some importance in the time of Charlemagne, was made the seat of a bishop by that monarch, and subsequently became a flourishing member of the Hanseatic League. In the 13th century it was surrounded with a wall. Punished by military occupation and a fine for its reception of the Reformation in 1547, Minden underwent similar trials in the Thirty Years' War and the wars of the French occupation. In 1648 the bishopric was converted into a secular principality under the elector of Brandenburg. From 1807 to 1814 Minden was included in the kingdom of Westphalia, and in the latter year it passed to Prussia. In 1816 the fortifications, which had been razed by Frederick the Great after the Seven Years' War, were restored and strengthened, and as a fortress of the second rank it remained the chief military place of Westphalia down to 1872, when the works were finally demolished. At Todtenhausen, 3 miles to the north of Minden, the allied English and German troops under the duke of Brunswick gained a decisive victory over the French in 1759. About 3 miles to the south of Minden is the so-called "Porta Westfalica," a narrow and picturesque defile by which the Weser quits the mountains and reaches the plain.

Minden is not to be confounded with the Hanoverian Münden, also sometimes written Minden (population 6355), at the confluence (*Mündung*) of the Werra and Fulda.

MINE. See MINING.

MINERALOGY

NATURAL objects which are homogeneous in their mass, and in which no parts formed for special purposes can be distinguished, are termed "minerals"; and the branch of natural science which treats of these is termed mineralogy. Minerals differ from the structures treated of in botany and zoology in the three following particulars. (1) They differ in the mode of their formation; this has been accomplished, not by assimilation of matter, producing growth from within, but by augmentation of bulk through accretion of particles from without. (2) Minerals are not heterogeneous. While the objects treated of in the other departments of natural history consist of beings possessed of life, and having parts which, being mutually dependent, cannot be separated from one another without a more or less complete destruction of the individual, the objects treated of under the department of mineralogy have so uniformly consistent an individuality that they are not destroyed by any separation of parts,—each portion or fragment possessing the same properties and the same composition as the whole. And (3), while those beings which are possessed of life have their component elements grouped into complexes, for the most part capable of more or less freedom of motion and susceptible of change, minerals have a constitution resulting from chemical attractions alone and an arrangement of their parts, under physical influences, which has resulted in rigidity and an absence of all tendency to change.

FORM OF MINERALS—CRYSTALLOGRAPHY.

Definition of a mineral.

The most precise definition of a mineral would be—an inorganic body possessed of a definite chemical composition, and usually of a regular geometric form. Of these, the second is in one respect the direct outcome of the first; while many of the most important physical properties possessed by minerals are outcomes of the second.

Both the geometric form and the composition of minerals are produced and modified under the influence of general laws.

Mineral bodies occur in the three physical conditions of solid, liquid, and gas. Those now found in the last two states are few in number, and are of altogether inferior interest to those which occur as solids; but there is reason to believe that the minerals we know as solids once existed in the liquid or gaseous state, and that their present structure was determined in the process of solidification. All bodies thus formed may be divided into two great classes:—

Amorphous bodies.

1. Amorphous bodies, or such as do not possess a definite and characteristic geometrical form. These (when transparent) refract light singly in every direction (except when under stress); they are equally easy or equally difficult to break in all directions; when broken they exhibit a conchoidal or an earthy fracture; they are equally hard throughout all their parts; they are equally elastic in all directions; they conduct heat with equal rapidity and in equal amount in all directions.

Crystals.

2. Crystalline bodies, or such as occur in definite geometrical forms bounded by flat surfaces. These present greater facilities of separation of their particles, or "cleavage," in certain directions lying in determinate planes than they do in others; most of them are neither equally hard nor equally elastic in all directions, conduct heat more rapidly in certain directions than they do in others, and, when transparent, refract light doubly except in certain directions.

Mineral bodies are found in both of the above classes; and the same mineral body may occur in both the amorphous and the crystalline condition. This is seen in the piece of gold shown in fig. 1, where the upper portion has a sharply angular and a well-defined shape, while the lower presents curvilinear and rugged outlines, similar to one another in no part. Under favouring circumstances, it is possible that every substance whose composition is capable of being represented by a definite chemical formula—*i.e.*, which has an unvarying composition—may be capable of assuming a definite crystalline form.

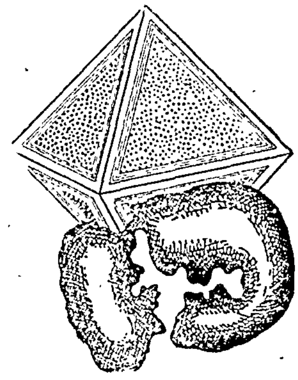


Fig. 1.

Size of crystals.

Size and Form of Crystals.—They are of every size from over a yard in diameter to mere specks requiring a high power of the microscope to reveal their existence. Beryls have been obtained in America more than 4 feet in length by 2½ in thickness, weighing 2½ tons. Equally large crystals of apatite have been found in Canada. There is a rock crystal at Milan 3¼ feet long by 5½ in circumference, weighing 870 lb. The highest perfection of form, and hence of other properties, is only found, however, in crystals of moderate or of small size.

Variety of form.

Variety of Form, and Constancy of Form.—The same mineral may be found in different localities, or sometimes in the same locality, exhibiting an almost endless variety of forms. Calc-spar occurs at a Scottish locality in acicular pyramidal crystals of which the length may be ten or more times as great as the width (fig. 2); in flat plates as thin as paper, in which the length is not the hundredth part of the width; also in prisms, pyramids, and rhombohedra, which at first sight (as in figs. 3, 4) seem

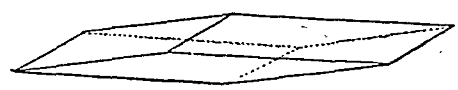

Fig. 3.

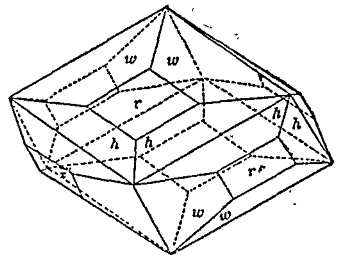

Fig. 4.

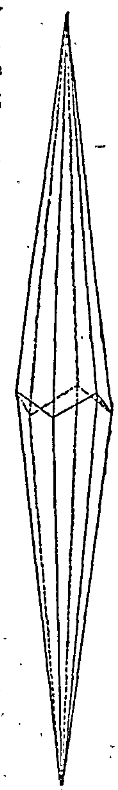

Fig. 2.

destitute of any relationship to each other. This substance has elsewhere been noted in several hundred forms. The minerals fluorite, pyrite, and baryte have each been observed in over a hundred diverse forms. Nevertheless, however great the number, all the forms, in the case of each mineral, may be reduced or referred to a single type, by the simple process of examining its internal structure or the mode of arrangement of its molecules. This is

Relation to parent form.

accomplished in two ways—(1) by finding the weak joints in that arrangement, through splitting the crystal, and (2) by measuring the angular inclination of the outside surfaces which bound the form and, from these measurements, by simple mathematical laws, arriving at what has been termed its "primitive" or simplest form.

Invariability of angles.

As regards the mere recognition of a substance, such measurement in itself suffices,—the angular inclination, if the same surfaces be measured, being unvarying in each species. It can, moreover, be shown that the possible range of external variety of form is governed by fixed mathematical laws, which determine precisely what crystalline forms are or may be produced for each species. Comparatively few of these actually occur in nature; but crystallographic laws can point out the range of those which can possibly occur, can delineate them even before they are found, and can in all cases show the relationship which subsists between them and the simple or fundamental form from which or out of which they all originate. It must be observed that in crystalline bodies the internal structure—that is, the arrangement of the molecules—is as regular in an outwardly shapeless mass as in the modelled crystal which presents itself as a perfect whole.

Properties and parts of crystals.

Definitions of Crystals, and their Members or Parts.—A crystal is a symmetrical solid, either opaque or transparent, contained within surfaces which theoretically are flat, and of a perfect polish, but which are actually frequently curved, striated, or pitted. These surfaces are called "planes," or "faces." The external planes of a crystal are called its "natural planes"; the flat surfaces obtained by splitting a crystal are called its "cleavage planes." The intersections of the bounding planes are called "edges," and planes are said to be similar when their corresponding edges are proportional and their corresponding angles equal. Crystals bounded by equal and similar faces are termed "simple forms." The cube, bounded by six equal squares, the octahedron, bounded by eight equilateral triangles, and the rhombohedron, bounded by six equal rhombs, are thus simple forms. Crystals of which the faces are not all equal and similar are termed compound forms, or "combinations," being regarded as produced by the union or combination of two or more simple forms. Edges are termed rectangular, obtuse, or acute, according as the angle at which the faces which form the edge meet is equal to, or greater or less than, a right angle. Edges are similar when the planes by the intersection of which they are formed are respectively equal and equally inclined to one another; otherwise they are unlike or dissimilar.

Interferences.

When a figure is bounded by only one set of planes, it is said to be "developed." When an edge is cut off by a new plane, it is said to be "replaced"; when cut off by a plane which forms an equal angle with each of the original faces which formed the edge, it is said to be "truncated." When an edge is cut off by two new faces equally inclined to the two original faces respectively, it is said to be "bevelled." When a solid angle is cut off by a new face which forms equal angles with all the faces which went to form the solid angle, it is said to be truncated.

Axes.

In classifying crystals and studying their properties, it is found convenient to introduce certain imaginary lines called "axes." Axes are imaginary lines connecting points in the crystal which are diametrically opposite,—such as the centres of opposite faces, the apices of opposite solid angles, the centres of opposite edges. Different sets of axes may thus be drawn through the same crystal; but there is always one set, usually of three, but in one special class of crystals of four, axes, by reference to which the geometrical and physical properties of a crystal can be most simply explained. These axes intersect one another, either at right angles, producing "orthometric" forms, or at oblique angles, producing "clinometric" forms. The axes may be all equal, or only two equal, or all unequal.

"Positioning" of crystals.

There is a definite conventional position in which for purposes of description a crystal is always supposed to be held. With reference to this position one of the axes,—that which is erect or most erect,—is termed the "vertical," and the others the "lateral." The planes in which any two of the axes lie are called the "axial" or "diametral planes,"—sometimes "sections." By these the space around the centre is divided into "sectants." If there are, as is generally the case, only two lateral axes, the space is divided into eight sectants, or octants; but, if there are three lateral axes, it is divided into twelve sectants.

Primitive forms

Primitive Forms of Crystals.—If we attempt to arrive, through a study of the internal structure of crystals, as evidenced by directions of weakness of cohesion, at the total number of primitive or parent forms which can exist, we find that there are thirteen such forms and no more.

Nine of these may be regarded as prisms standing upon a base, three as octahedra standing upon a solid angle; and there is one twelve-sided figure, or dodecahedron.

Prisms

Prisms.—Of the prisms eight have a four-sided base.

If the base is square and the prism stands erect—that is, if its sides or lateral planes, as they are called, are perpendicular to the base—the form is termed a "right square prism" (fig. 6). In this the four lateral planes are rectangular and equal; they may be either oblong or square; in the latter case the form is the "cube" (fig. 5). When the base is a rectangle instead of a square, the form is a "right rectangular prism" (fig. 7). In each of the

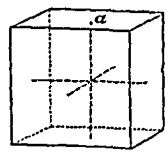

Fig. 5.

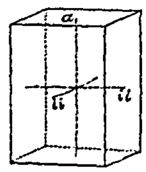

Fig. 6.

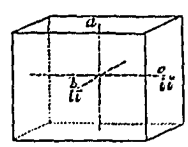

Fig. 7.

above three forms the edges are twelve in number. In the cube all the edges are equal. In the square prism the lateral edges are all equal, but are different from the four equal edges of the base. In the rectangular prism, two at each base differ in length from the other two, while both differ from the lateral; hence there are here three sets of edges, four in each. In each of the three forms, however, the solid angles are eight in number, all equal, and each enclosed by three right angles.

When the base is a rhombus, and the prism stands erect, the form is a "right rhombic prism" (fig. 8). Two of the angles in the base being here acute and two obtuse, two of the solid angles corresponding each with each must differ from the others. So also must two of the lateral angles be acute and two obtuse. The four lateral faces are equal.

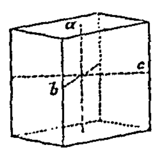

Fig. 8.

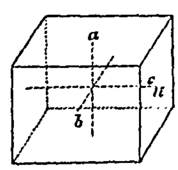

Fig. 9.

When the base is a rhomboid, and the prism stands erect, it is only the opposite lateral faces that can be equal. The form is called a "right rhomboidal prism" (fig. 9).

When the base is a rhombus, but the prism stands obliquely on its base, the form is called an "oblique rhombic prism" (fig. 10). Here the basal edges of the lateral planes are all equal in length, but on account of the inclination of the prism the angles which these edges form with the lateral edges of the lateral planes are two acute and two obtuse.

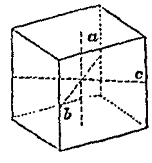

Fig. 10.

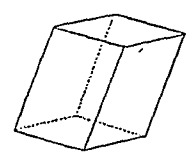

Fig. 11.

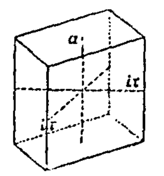

Fig. 12.

If all the edges of an oblique rhombic prism are equal in length to the breadth of the base, and if the lateral planes are rhombi equal in all respects to the basal, the form is called a "rhombohedron" (fig. 11). This is included within six equal planes, like

the cube, but these planes have oblique angles. The rhombohedron thus bears the same relation to the oblique rhombic prism which the cube does to the right square prism. Of the eight solid angles of a rhombohedron only two are contained by three equal plane angles, and these two "apices," as they may be called, are opposite one another. According as the apices are acute or obtuse, we have an acute or obtuse rhombohedron.

When the base of an oblique prism is a rhomboid, the prism becomes an "oblique rhomboidal prism" (fig. 12). In this form, only diagonally opposite edges are similar, as regards equality of length and the value of the included angle. Only opposite solid angles are equal, as are also the opposite and parallel faces.

A right prism may have an equilateral six-sided base; it is then called an "hexagonal prism." This form may be developed in two positions relatively to each other,—one in which the transverse axes pass from the centres of opposite faces (fig. 13), the other in which they pass from the centres of opposite edges of the planes (fig. 14). The faces of the one set mutually truncate the edges of the other. If a rhombohedron be positioned so as to rest upon one of its apices, the faces of one hexagonal prism would truncate the lateral *edges* of the rhombohedron, while the faces of the other hexagonal prism would truncate its lateral *solid angles*. Hexagonal prisms may be longer or shorter than the width of their bases. The interfacial lateral angles are 120°. The angle between the lateral and terminal faces is 90°.

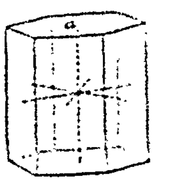

Fig. 13.

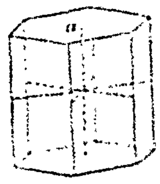

Fig. 14.

Octahedra.

Octahedra.—The planes of these eight-faced solids are triangular, and they may be regarded as made up of two four-sided pyramids applied to each other, base to base. They are always positioned so that they stand upon a solid angle with the "basal plane"—that is, the plane which is the common base of the two pyramids—horizontal. In the primitive forms now under consideration the vertices of the two pyramids will in this position be vertically above and below the centre of the base. The upper and lower solid angles are then termed the "vertical solid angles," and the four lateral solid angles are called the basal solid angles.

There are three octahedrons. In the "regular" octahedron (fig. 15) the base is a square, and the eight faces are equilateral triangles of equal size. There are twelve edges, which are all equal. The faces incline to each other at an angle of 109° 28' 16", and have the plane angles all 60°. There are six equal solid angles. When the base of the octahedron is square, but the other edges, although

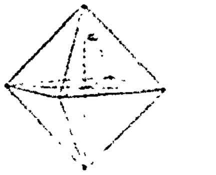

Fig. 15.

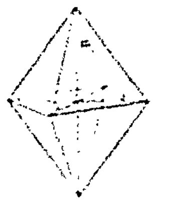

Fig. 16.

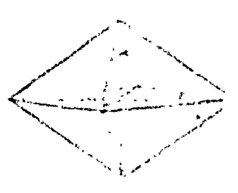

Fig. 17.

equal to one another, are either longer or shorter than the edges of the base, the form is a "right square octahedron" (fig. 16). In this the faces are isosceles triangles, the equal angles being at the basal edge of the planes. These basal edges are equal and similar, but differ in length and in angles from the eight equal pyramidal edges. When the base of an octahedron is a rhombus, it is called a "right rhombic octahedron" (fig. 17).

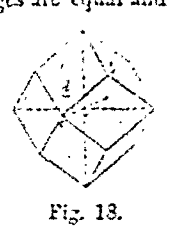

Fig. 18.

Dodecahedron.

Dodecahedron.—This (fig. 18) has each of its twelve faces a rhombus. It is, like the cube and the octahedron, a solid which is symmetrical. The interfacial angles are all 120°, the plane angles are 109° 28' 16" and 70° 31' 44". The edges are twenty-four, and similar. There are fourteen solid angles, of which six are formed each by the meeting of four acute plane angles, and eight by the meeting of three obtuse plane angles.

Determination of parent forms.

It has been said that the above simple forms were arrived at through a study of the internal structure of crystals, chiefly as disclosed by cleavage. Inasmuch, however, as there are some minerals which cleave in only one direction, and many which cannot be cleaved in any direction, this method of investigation fails. Its employment, moreover, frequently led to conflicting or embarrassing results. A conflicting result is when a substance has more than one set of cleavages,—that is, splits up in directions which would result in the production of more than one of the above primary or simple forms. Thus the mineral fluorite occurs with much the greatest frequency in the form of the cube, and it might very consistently be held that its frequent occurrence in this form was a clear natural indication that the cube was the primary or simplest form of fluorite; but it splits up into an octahedron. Galena crystallizes frequently in the form of the octahedron; yet to cleavage galena yields a cubic primary form. It might be conceived that there had been, in each case, some special tendency to assume the cubic form and the octahedral form; but one and the same piece of rock may bear on its surface cubic crystals of fluor and octahedral crystals of galena,—each of the minerals having here assumed the primitive cleavage form of the other in preference to its own. The mineral blende crystallizes not unfrequently in octahedra, which yield the dodecahedron on cleavage. Fluor crystallizes in dodecahedra, yet yields the octahedron to cleavage. Argyrite crystallizes in cubes and in octahedra, but yields the dodecahedron on cleavage. Pyrite crystallizes in cubes, octahedra, and dodecahedra, and yields both the cube and the octahedron on cleavage.

These are most embarrassing results, but they clearly indicate so intimate a relationship to subsist between three of the above simple forms that it is obvious that one alone would serve as a type form for representing the others. The selection of that one should be based upon grounds of most eminent simplicity, and this again is to be arrived at by a consideration of the smallness of number of parts, *i.e.*, of faces, edges, and solid angles. In such a consideration we find that the dodecahedron, with its higher number of each of these, at once gives place. The cube has six faces, the octahedron eight; simplicity here is in favour of the cube. The cube has twelve edges, the octahedron has twelve; in this respect they are equal. The cube has eight solid angles, the octahedron six; here the greater simplicity is on the side of the octahedron. So that this method of adjudicating by simplicity fails, and we are thrown back upon the relationships which may be unfolded through a consideration of the other elements of crystals,—their axes.

Systems of Crystals and Laws of Crystallization.

This consideration led, first, to the remarkable discovery that several of the above primary forms are mere modifications of each other, and ultimately showed that all crystals found in nature may be referred to six systems, based on certain relations of their axes, and that every face which could occur upon a crystal bears a definite and simple relation, in position and in angular inclination, to these axes. Relation of faces to axes.

As regards mere geometric measurement, there are several directions in which axes may with nearly equal advantage be projected. For example, in the cube (fig. 19) they may be drawn from the centres of opposite faces, as lettered O; or from opposite solid angles, as lettered C; or from the centres of opposite edges, as lettered D. There is abundance of evidence that each of these directions must be regarded as lines of dominant accretion of molecules. Axes directions of dominant accretion.

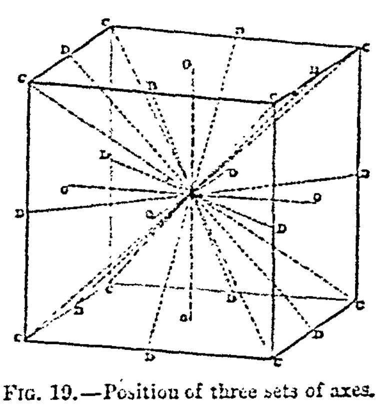

Fig. 19.—Position of three sets of axes.

But the accretion may be not only dominant but overwhelmingly so in one only of these directions in certain cases, or existent along one set of axes alone in certain others. In a specimen of native silver from Alva in Scotland (fig. 20), along O this is so much the case that the concreting molecules have done little more than delineate the form of an octahedron, and this they have only been able to do by

aggregating themselves in lines of minute crystals of the very shape of which they were projecting the skeleton form. Moreover, a polar aggregation at the terminal ends of these octahedral axes is here shown by the amount of concreting and crystallizing

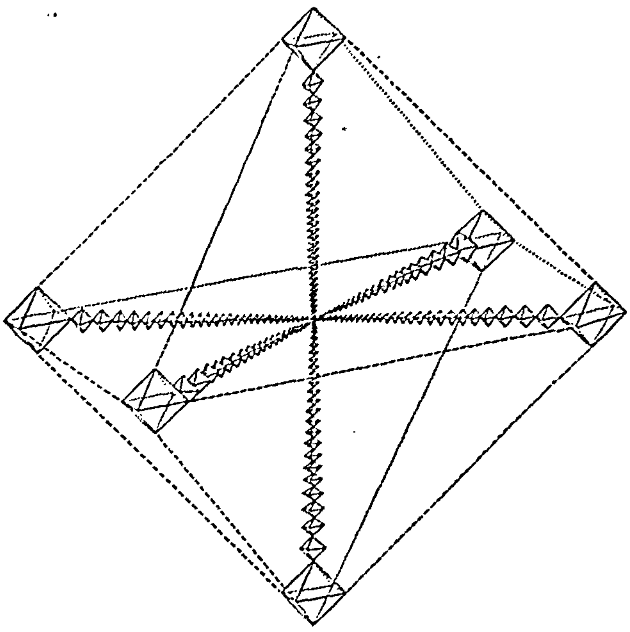

Fig. 20.

material being larger at the terminations of these axes than elsewhere. In the hollow-faced cube again (fig. 21), an aggregation of molecules in the direction of the lines D and C has filled the edges and solid angles, while none have been deposited along O.

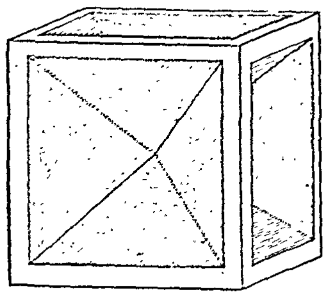

Fig. 21.

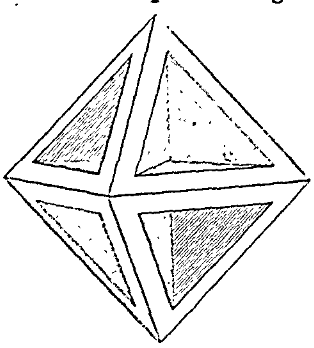

Fig. 22.

This occurs in crystals of salt. In the hollow-faced octahedron, again (fig. 22), there has been no deposition of matter along the line C. Cuprite often shows this form; and it as frequently occurs in hollow-faced dodecahedra, wherein the vacuity is in the direction of D.

In the specimen of pyrite from Elba (fig. 23), a deposition along D and C would ultimately have erected the scaffolding of a hollow cube, in twelve lines of minute combinations of the cube and octahedron. Such directional arrangements may, moreover, not only be intermittent but often alternate. The pyrite from Traversella (fig. 24) is an illustration of the first. A large pentagonal dodecahedron having been completed, a new accession of material has been attached, not uniformly spread over the pre-existent crystal, to enlarge it, but locally arranged, in equal amount, at the poles of O. But here the special method of the arrangement has determined the formation of a number of small crystals of the same form as that originally projected.

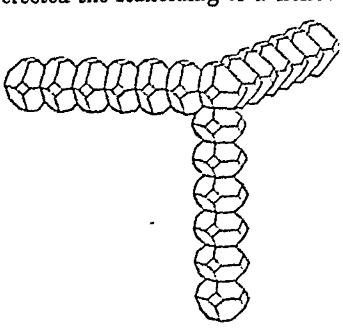

Fig. 23.

An alternation, as it were, in plan is shown in such a crystal of calcite as that in fig. 25. Here a scalenohedron is seen in the centre of the figure; then a rhombohedron has been perched upon its summit, and lastly both have been sheathed in a six-sided prism with trihedral summits. Different as these three forms are, it is found that they all here stand in a definite position one to the other; that definite position is the relation which they bear to one of the sets of axes, and this set may be assigned, not only to all the three crystals here combined, but also to all the crystals belonging to the same mineral, wherever occurring. This general applicability constitutes one of the respects in which one special set of axes is, in each of the systems, preferred to the others.

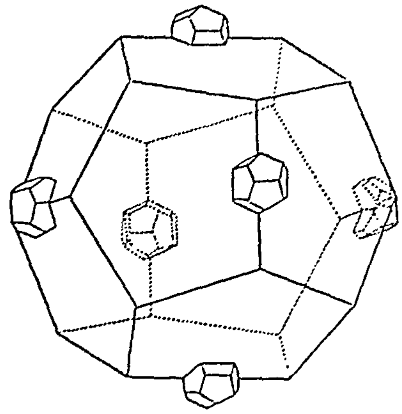

Fig. 24.

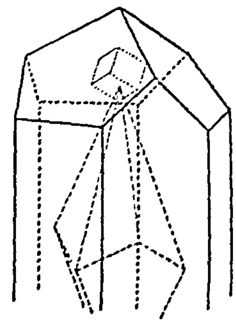

Fig. 25.

Another respect is the intensity with which the molecules cohere in the different parts of the crystal, as referred to these axes, and the resultant different hardness of certain parts of crystals. It will be afterwards found that this obtains in a very limited manner in the crystals which belong to the first of the following systems, on account of its regularity and sameness as a whole. It may be laid down as a general rule that the edges of crystals are harder than the centres of their faces, and the solid angles harder than the edges. This is markedly the case in the diamond. But, apart from this, there is no distinctive hardness in any one part, side, or end of the crystals of the first system. It is otherwise with the crystals which fall to be considered in all the other systems. So different is the hardness of the various portions of these, so diverse the appearance of their parts in lustre, colour, polish, &c., so varying the amount of the recoil of these when struck, so unequal their power of conducting heat, so dissimilar their power of resisting the agencies of decay, and so irreconcilable their action upon transmitted light, that we cannot but conclude that the molecules which build them up are packed with greater force, if not in greater number, in certain directions in preference to others. There thus remains no question that these nature-indicated sets of axes are those along which there has been a specially selective or "polar" arrangement.

Coherence of particles not equal in all directions.

The six systems are founded upon the relationships of the axes in number, in length, and in angular inclination. All crystals may be divided into "orthometric" or erect forms and "clinometric" or inclined forms; and in similar manner may the systems be, through a consideration of the relative lengths of their axes, divided into three classes. In the first, or most regular, of these the axes are all equal, that is, they are of one length; in the second there is one axis which differs in length from the others, and therefore they are of two lengths; while in the third the axes are all unequal, and therefore they are of three lengths. Of the six systems one belongs to the first class, two to the second, and three to the third. Hence they are thus classed:—

Systems of crystals.

Monometric.	*Dimetric.*	*Trimetric.*
Cubic.	Tetragonal.	Right Prismatic.
	Hexagonal.	Oblique Prismatic.
		Anorthic.

Though the grouping of the systems into three classes in virtue of axial dimensions is markedly borne out by optical and other properties, yet it is altogether insufficient for determining the relationships of the myriad forms in which bodies crystallize. Such knowledge is only attained by combining the consideration of axial length with axial inclination; and it is through a due regard of both of these that the six systems are instituted.

The above table may be read in two different ways,—either across or consecutively up and down the page. The six systems may be treated of in either of these ways;

and there are certain advantages in considering them at least first by the former method.

We consider first, as the more essential, the relative lengths of the axes, and, secondly, the angular inclination of these.

1. In the cubic system the axes are all equal, and all intersect at right angles. Here is the most perfect simplicity, and the most perfect regularity.

2. In the tetragonal system two only of the axes are equal; but all still intersect at right angles. Here is a departure from simplicity as regards the length of one axis, but no departure as regards the angular inclination.

3. In the right prismatic system none of the axes are equal, but all still intersect at right angles. Here is total loss of regularity in the first particular, but still none in the second.

4. In the oblique prismatic system none of the axes are equal, and only two intersect at right angles. Here there is again a total loss of simplicity in the first particular, and a certain amount of departure from it in the second.

5. In the anorthic system none of the axes are equal, and none of them intersect at right angles,—so that here, as expressed by the name, there is a total departure from regularity in both particulars.

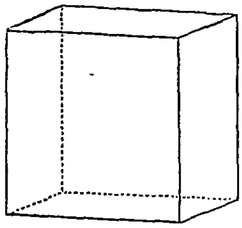

Fig. 26.

6. The hexagonal system is anomalous in relation to this mode of consideration. It is regarded as having four axes, three of which lie in one plane, parallel to the base, and intersect each other at equal angles (necessarily angles of 60°). The fourth axis intersects these at right angles, and may be longer, shorter, or equal to them. This system is generally considered after the tetragonal system, as having one axis which differs in length from the others, and only one which cuts the others at right angles. By some a rhombohedron is considered as the primary of this system; it then comes to have three axes, all equal, but none intersecting at right angles.

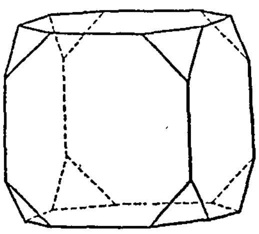

Fig. 27.

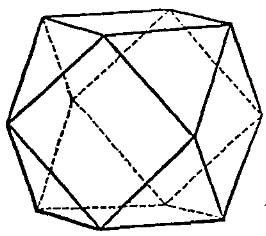

Fig. 28.

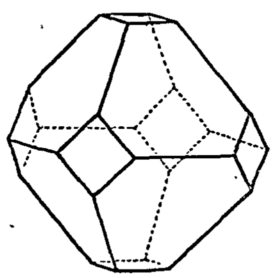

Fig. 29.

Unique axis made vertical.

In considering these systems, or in describing the form of a crystal, the vertical or erect axis is named the principal axis of the figure, and that axis is chosen as the vertical which is the only one of its kind. In the cubic system there is no such axis, so that any one may be chosen as the vertical.

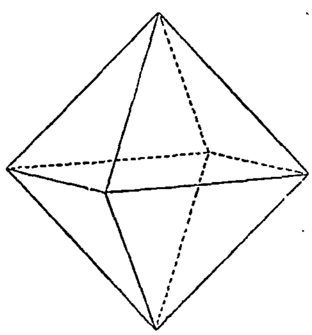

Fig. 30.

It will be convenient, before proceeding to the consideration of the laws of crystallography and the combinations of forms,—especially in view of the terminology that must be employed in illustrating those general aspects of the subject,—to give an outline of one of the six systems here. For this preliminary description the cubic system, as the simplest and most regular, naturally suggests itself as the most suitable.

Cubic system.

I. *The Cubic System.*—Here the axes are all equal, and all intersect at right angles. The "cube" (fig. 26), "octahedron" (fig. 30), and "rhombic dodecahedron" (fig. 33), which are here included, are alike in their perfect symmetry; the height, length, and breadth are equal; and their axes are equal, and are rectangular in their intersections.

Relations of simple forms.

In the cube (fig. 5) these axes connect the centres of opposite faces; in the octahedron (fig. 15) the apices of opposite solid angles; in the dodecahedron (fig. 18) the apices of opposite acute solid angles. The relation of these forms to each other, and the correspondence in their axes, will be made manifest through a consideration of the transition between the forms. If a cube be projected with the axes in the above position, or if a model of it in any sectile material be employed, and if the eight angles are sliced off evenly, keeping the planes thus formed equally inclined to the original faces, we first obtain the form in fig. 27, then that in fig. 28 and fig. 29, and finally a regular octahedron (fig. 30); and the last disappearing point of each face of the cube is the apex of each solid angle of the octahedron. Hence the axes of the former, being in no way displaced, necessarily connect the apices of the solid angles of the latter. By cutting off as evenly the twelve edges of another cube, the knife being equally inclined to the faces, we have the form in fig. 31, then fig. 32, and finally the rhombic dodecahedron (fig. 33), with the axes of the cube connecting the acute angles of the new form. These forms are thus mutually derivable. Moreover, they are often presented by the same mineral species, as is exemplified in galena, pyrites, and the diamond.

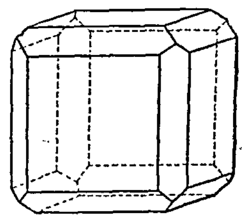

Fig. 31.

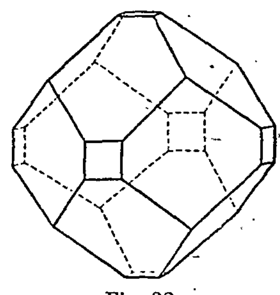

Fig. 32.

The process may be reversed, and the cube made from the octahedron, as will be readily understood from a comparison, in reverse order, of figs. 26 to 30. Or the cube may be similarly derived from the dodecahedron, as seen by inspecting figs. 33, 32, 31, 26.

The octahedron also is changed to a rhombic dodecahedron by removing its twelve edges (figs. 34, 35), and continuing the removal till the original faces are obliterated, thus producing the dodecahedron.

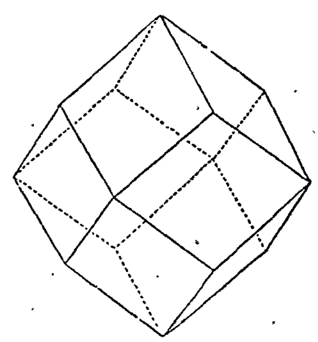

Fig. 33.

It will be observed that throughout all these changes the position of the axes, as determinants of dimensions, need not be altered,—that, in fact, one set of axes has served for all the forms.

The relationships of the principal forms of this system being thus disclosed, the forms themselves have next to be considered.

Parts of the cube. The cube (fig. 26) is bounded by six equal squares, has twelve edges formed by faces meeting at 90°, and eight solid trigonal angles. The axes are taken as joining the centres of each two opposite faces. Examples are hallite, galena, and fluor.

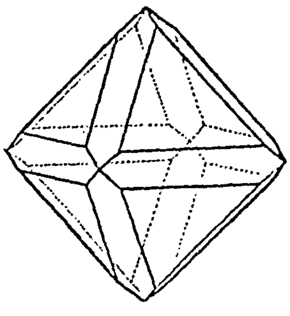

Fig. 34.

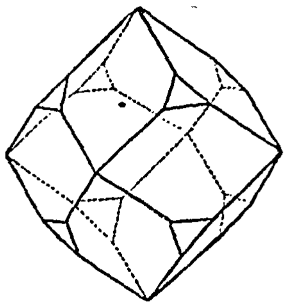

Fig. 35.

Octahedron. The octahedron (fig. 30), bounded by eight equilateral triangles, has twelve equal edges with planes meeting at 109° 28′ 16″, and six tetragonal angles. The principal axes join the opposite solid angles. Examples: magnetite, gold, cuprite.

Dodecahedron. The rhombic dodecahedron (fig. 33) is bounded by twelve equal and similar rhombi, has twenty-four equal edges of 120°, and has six tetragonal and eight trigonal angles. Each of the principal axes joins two opposite tetragonal angles. Examples: garnet, cuprite, blende.

Tetrakishexahedron. The tetrakishexahedrons (figs. 36, 37, 38, varieties of icositetrahedron) are bounded by twenty-four isosceles triangles, placed so as to form four-sided pyramids on the faces of the cube, arranged in six groups of four each. They have twelve longer edges, which correspond to those of the primitive or inscribed cube, and twenty-four shorter edges placed over each of its faces. The angles are eight hexagonal and six tetragonal, the latter joined two and two by the principal axes. Examples: fluorite, gold. This form varies much in general aspect. The four-sided pyramid which rests on the edges of each face of the cube may be so low as almost to fall into it (fig. 36); or it may rise so high that each side forms a level surface with that which is adjacent to it upon the nearest cubic face (fig. 38). In the latter case the form has become the rhombic dodecahedron; so that the more or less acute varieties of the form are but stages of a passage of the cube into the latter figure, through an increasing accretion of matter in the lines of the axes of the cube. This is termed a "transition by increment."

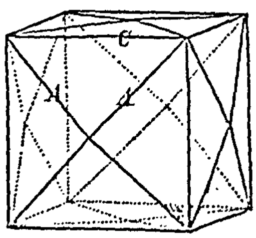

Fig. 36.

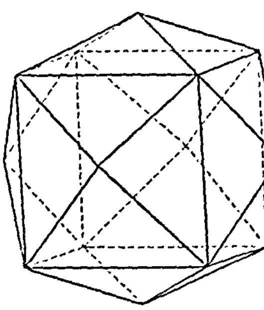

Fig. 37.

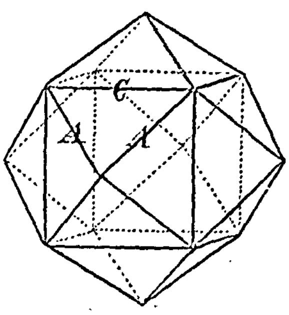

Fig. 38.

Triakisoctahedron. The triakisoctahedrons, fig. 39 (variety of icositetrahedron, fig. 40), are bounded by twenty-four isosceles triangles, in eight groups of three, arranged as pyramids on the edges of the faces of the octahedron. Like the previous form they vary in general aspect, the variation here being from the octahedron on one side to the rhombic dodecahedron on the other; while the increased accretion here is in the direction of lines joining the centres of the faces of the octahedron or the solid angles of the cube. The passage of the forms is similar to that illustrated in the last-considered form. The edges are twelve longer, corresponding with those of the inscribed octahedron, and twenty-four shorter, three and three over each of the faces. The angles are eight trigonal and six ditetragonal (formed by eight faces), the latter angles joined two and two by the principal axes. Examples: galena, diamond.

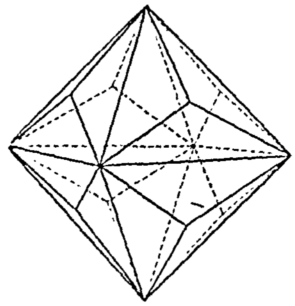

Fig. 39.

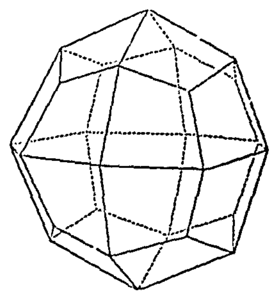

Fig. 40.

Icositetrahedron. The icositetrahedrons (fig. 40) are bounded by twenty-four deltoids. This form varies from the octahedron to the cube, sometimes approaching the former and sometimes the latter in general aspect. A *four-sided pyramid* rests on the angles of the faces of the cube. When increased accretion takes place along the cubic axes, an octahedron results. When it is along lines joining the solid angles of the cube, that form itself results. The edges are twenty-four longer and twenty-four shorter. The solid angles are six tetragonal joined by the principal axes, eight trigonal, and twelve rhombic or tetragonal with unequal angles. Examples: analcime, garnet.

Hexakisoctahedron. The hexakisoctahedrons (fig. 41), bounded by forty-eight scalene triangles, vary much in general aspect, approaching more or less to all the preceding forms, into all of which they may pass; but most frequently they have the faces arranged either in six groups of eight on the faces of the cube, or eight of six on the faces of the octahedron, or twelve of four on the faces of the dodecahedron. There are twenty-four long edges, often corresponding to those of the rhombic dodecahedron or bisecting the long diagonal of the trapezohedron, twenty-four intermediate edges lying in pairs over each edge of the inscribed octahedron, and twenty-four short edges in pairs over the edges of the inscribed cube. There are six ditetragonal angles joined by the principal axes, eight hexagonal, and twelve rhombic angles. Examples: diamond, fluorite.

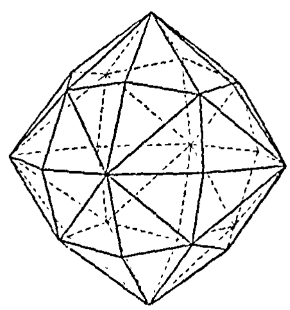

Fig. 41.

Laws of crystallography. *General Laws of Crystallography.*—The seven forms of crystals now described are related to each other in the most intimate manner. This will appear more distinctly from the account which is to follow of the mode of derivation of the forms, with which is conjoined an explanation of the crystallographic signs or symbols by which they are designated. These symbols were introduced by Naumann, in the belief that they not only mark the forms in a greatly abbreviated manner, but also exhibit the relations of the forms and combinations in a way which words could hardly accomplish. In order to follow out this

derivation of forms, it is necessary to state briefly the following laws, which have been established in crystallography. It is to be remembered that these laws apply, not merely to the cubic system just described, but to all the systems.

Invariability of angles.

1. *The Law of the Invariability of the Angles of Crystals*, which was established by Romé de l'Isle, may be thus stated:—the angles of inclination of the faces of a crystal are constant, however unequally the faces may be developed. The corresponding angles of different crystalline specimens of the same body do not, however, always absolutely agree. Differences have been found, amounting sometimes even to 10′.

Symmetry.

2. *The Law of Symmetry*, discovered by Haüy, may be thus expressed:—(1) similar parts of crystals—faces, edges, angles, and consequently axes—are all modified in the same manner, and dissimilar parts are modified separately or differently; (2) the modifications produce the same effect on the faces or edges which form the modified part, when they are equal; when they are not equal, they produce a different effect. That is, if an edge be truncated or bevelled, every similar edge will be similarly truncated or bevelled; if an angle be truncated or acuminated, every similar angle will be similarly truncated or acuminated; and consequently every similar axis will be equally affected by the modifications. Thus the cube has eight similar angles and twelve similar edges. In the physical production of the cube, if one of the angles or edges be modified, all will be similarly modified. This, which is the most important law of crystallography, is, however, subject to an exception which was fully formulated by Weiss. The law was—all the similar parts of crystals, faces, edges, angles, and consequently axes, are modified at the same time and in the same manner; the forms resulting from this law are termed "holohedral." The exception is that half of them or one-fourth of them only may be similarly modified. When only half of the similar parts are modified, we get the "hemihedral" forms; when one-fourth only are modified, which occurs only rarely, we get "tetartohedral" forms.

Parallelism of faces.

3. *The Law of the Parallelism of the Faces of a Crystal*, discovered by Romé de l'Isle, may be expressed as follows:—every face of a crystal has a similar face parallel to it; or every figure is bounded by pairs of parallel faces (with the exception of certain hemihedral forms).

Zones.

4. *The Law of Zones*, first established by Weiss, may be thus enunciated:—the lines in which several faces of a crystal intersect each other (or would do so if they were produced until they met) frequently form a system of parallels. Such a series of faces is termed a "zone." Sometimes the zones are parallel to one of the symmetrical axes. Thus, in every prism, the faces of the prism constitute a zone which encircles the axis of the prism. Faces may be in a zone although they do not actually intersect on the form.

Rationality of the parameters.

5. *The Law of the Rationality of the Parameters* of the faces of crystalline series, first indicated by Malus, is that the position of planes may be assigned by numbers bearing some simple ratio to the relative lengths of the axes of the crystal. This law was the outcome of investigations into the relationship of forms glanced at in commencing the consideration of the cubic system, and was arrived at through the study of the mode of derivation of forms.

Derivation of forms.

The derivation of forms is that process by which, from one form chosen for the purpose, and considered as the type,—the fundamental or primary form,—all the other forms of a system may be produced, according to fixed principles or general laws. In order to understand this process or method of derivation, it must be noted that the position of any plane is fixed when the position of any three points in it, not all in one straight line, is known. To determine the position, therefore, of the face of a crystal, it is only necessary to know the distance of three points in it from the centre of the crystal, which is the point in which the axes intersect each other. As the planes of all crystals are referred to their axes, the points in which the face (or its supposed extension) meets the three axes of the crystal are chosen, and the portions of the axes between these points and the centre are named parameters of the face; and the position of the face is sufficiently known when the relative length or proportion of these parameters is ascertained. When the position of one face of a simple form is thus fixed or described, all the other faces of the form are in like manner fixed in accordance with law 2, since they are all equal and similar, and have equal parameters—that is, intersect the axis in the same proportions. Hence the expression which marks or describes one face marks and describes the whole figure, with all its faces.

Parameters.

The octahedron is adopted as the primary or fundamental form of the cubic system, and distinguished by the first letter of the name, O. Its faces cut the half-axes at equal distances from the centre; so that these semiaxes, the parameters of the faces, have to each other the proportion 1 : 1 : 1. In order to derive the other forms from the octahedron, the following construction is employed.

Proportion of parameters expressed by symbols. Notation of Naumann.

Suppose a plane to be laid down perpendicular to one axis, and consequently parallel to the two other axes (or to cut them at an infinite distance, expressed by ∞, the sign of infinity); then the hexahedron or cube is produced, designated by the crystallographic sign $\infty O \infty$,—expressing the proportion of the parameters of its faces, or $\infty : 1 : \infty$. If a plane is supposed placed on each edge, parallel to one axis, and cutting the two other axes at equal distances, the resulting figure is the rhombic dodecahedron, designated by the sign ∞O, the proportion of the parameters of its faces being $\infty : 1 : 1$. The triakisoctahedron arises when, on each edge of the octahedron, planes are placed cutting the axis not belonging to that edge at a distance from the centre m, which is a rational number greater than 1. The proportion of its parameters is therefore $m : 1 : 1$, and its sign mO; the most common varieties are $\frac{3}{2}O$, $2O$, and $3O$, seen in diamond and fluorite. When, on the other hand, from a similar distance m in each two semiaxes prolonged a plane is drawn to the other semiaxis, or to each angle, an icositetrahedron is formed; the parameters of its faces have consequently the proportion $m : m : 1$, and its sign is mOm; the most common varieties are $2O2$ and $3O3$,—the former very frequent in leucite, analcime, and garnet, the latter in gold and amalgam. When, again, planes are drawn from each angle, or the end of one semiaxis of the octahedron, parallel to a second axis, and cutting the third at a distance n, greater than 1, then the tetrakishexahedron is formed; the parameter of its faces is $\infty : n : 1$; its sign is ∞On; and the most common varieties in nature are $\infty O\frac{3}{2}$, $\infty O2$, and $\infty O3$. Finally, if in each semiaxis of the octahedron two distances m and n be taken, each greater than 1, and m also greater than n, and planes be drawn from each angle to these points, so that the two planes lying over each edge cut the second semiaxis belonging to that edge at the smaller distance n, and the third axis at the greater distance m, then the hexakisoctahedron is produced; the parameters are $m : n : 1$, its sign mOn, and the most common varieties $3O\frac{3}{2}$, $4O2$, and $5O\frac{5}{3}$, seen in diamond and fluorite.

It must be observed that the numbers in the above signs refer to the parameters of the faces,—not to the axes of the crystal, which are always equal. One parameter also has always been, in the above, assumed $=1$, and then, either one only of the two other parameters, marked by the number before O, or both of them, marked by the numbers before and after O, have been changed.

In the above consideration of the mode of derivation of these forms actually found in nature, which belong to the cubic system, it will be observed (though the illustrations were limited) that the value of m and n in these indicated, by the precision of the proportions $\frac{3}{2}$, 2, or 3, a definite numerical relationship. This at once led up to the extended observations which established the law above stated of proportionality in the modification of crystals, or the rationality of the parameters, which gives a mathematical basis to the science, adding to symmetry of arrangement a numerical relation in the position of the planes.

To illustrate this in a general form (and not merely with special reference to the mode of notation or expression of Naumann, which is that adopted in the subsequent descriptions), let AOA′, BOB′, COC′ (fig. 42) be the three axes of a crystal, drawn in perspective, and cutting one another in the centre O. The semiaxes OA, OB, OC are three parameters. Now in the line OA take $Oa_2 = \frac{1}{2}OA$, and $Oa_3 = \frac{1}{3}OA$,—making as many points as may be necessary between OA, *rational fractions* of OA. Subdivide OB and OC in a similar manner. Further produce OA, OB, OC to *Ao*, *Bo*, *Co*, in each direction to an infinite distance, or to a supposed infinite distance, as expressed by the arrow-head; and suppose these extended axes to be divided in a manner similar to the subdivisions of the parameters, by rational multiples of OA, OB, and OC. *All the planes of a crystal will be parallel to one or other of the planes which pass through three of the points thus determined.*

First, in order to apprehend the relationship of faces to these axes, or to the half axes,—the parameters of the faces,—let us suppose one

plane of a crystal to be so situated as to cut the three parameters OA, OB, OC at their extremities A, B, C, which it must be remembered are points equidistant from the centre; or let it be supposed that a glass plate rests upon three intersecting wires at such points. It is evident that such a plane or plate will have a definite inclination or slope. Suppose further a second plane or plate to exist, which cuts the three semiaxes in the points a_2, b_2, c_2, which have been measured off (along with a_1, b_1, c_1) as equidistant from O. It will be evident that such a plane, though smaller, will be parallel to the first, seeing that, like it, it cuts the three parameters at equal distances from O.

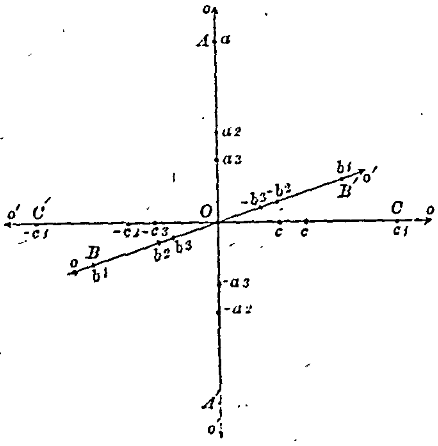

Fig. 12.

A little consideration will show that, whatever the absolute distances from the centre may be, so long as the supporting subdivisions are equal, no new slope of the glass plates or planes is possible; planes so situated must be parallel and similar. Any sign which may be adopted to express the slope of one of such planes must be applicable to all. A plane, however, cutting the points a_1, b_1, c_2 will have quite a different slope.

Let us now suppose a plane to cut a different set of the semiaxes, namely, OA′, OB′, OC′, in the points $-a_1$, $-b_1$, $-c_1$. Such a plane would be parallel to one cutting the points $-a_2$, $-b_2$, $-c_2$, and also to the set of planes first described, but on the opposite side of the centre of the crystal. If again, however, we had a plane cutting the semiaxes OA′ and OB′ in $-a_1$, $-b_1$, but the semiaxis OC′ in the point $-c_2$, it is clear that the slope of this plane would be quite different from that of the planes just described, but it would be parallel to the plane cutting the points a_1, b_1, c_2. This slope, like the other, evidently depends, not on the absolute lengths of the portions of OA′, OB′, OC′ cut off, but upon their proportions or ratios; and such is the case with all the planes which are referred to the same axes.

As there are three axes, and each or all of them may be cut at any points and at any ratios, it is evident that the number of planes which is possible is infinite; and it must be also evident that the inclinations of all are fixed or determinate if we know the ratios. While, however, the possible number of planes is infinite, the actual number occurring among minerals is either small or moderate, in virtue of the fact that the ratios of subdivision of the axes are always simple, and not numerous.

Other modes of notation. Naumann's symbols for the notation or individualizing of planes have been glanced at. A simpler method is that of employing as indices the denominators (if simple fractions) of the fractional parts of the axis cut. Thus 111 is used for any plane parallel to that cutting the axes in a_1, b_1, c_1; 122 for those parallel to a_1, b_2, c_2; 313 for a_3, b_1, c_3; and so on.

When any of the points referred to have negative signs, the corresponding indices have negative signs placed over them. Thus $\bar{1}22$ is the index for a plane parallel to $a'_1 b_2 c_2$. $\bar{1}0\bar{3}$ is the index of the plane a'_1, $b\infty$, c'_3. ∞ here indicates infinity; that is, the plane never would cut the axis B however far it were extended; in other words, it is parallel to it. The necessity for elongating the axes is brought about by the occurrence of highly acuminating planes, which in many cases would not meet the axes at all unless these were prolonged.

If the axes are unequal, as in the trimetric forms, then the ratio is of the same character, except that the relative lengths of the axes come into consideration; but here, as in the regular system, irrational values cannot occur, and in even the most complex crystals they seldom exceed seven, either as aliquot parts or multiples.

It will thus be seen that in crystals there is no haphazard scattering of faces, but a complete subserviency to law, a law which may be said to be the linear equivalent to the law of multiple proportions by weight, and Gay Lussac's law of multiple proportions in combination by volume.

In abbreviation of all the systematic modes of notation, letters of the Latin and Greek alphabets are frequently employed in a more or less arbitrary manner, and with advantage in the case of highly complex forms.

Symmetry of combination. 6. *The Law of Symmetry of Crystalline Combination* is the consequence of the law of symmetry and the law of the rationality of the parameters, and has been partially stated in enunciating these laws. It is thus expressed:—(1) a substance can only crystallize in forms, whether simple or compound, which have the same relative symmetry, that is, belong to the same crystalline system, and the parameters of the faces of which bear a simple relation to each other, that is, belong to the same axis; (2) a form cannot be modified by faces belonging to a different system, or a different series.

Apparent exceptions. Certain exceptions to the first part of this law occur. The element carbon occurs as the diamond, which is cubic, and as graphite, which is hexagonal. Sulphur occurs near volcanoes in needle crystals belonging to the oblique prismatic system, and also in caves (deposited apparently from solution) in crystals belonging to the right prismatic system. Titanic acid is tetragonal in rutile, and right prismatic in brookite. Carbonate of lime is hexagonal in calcite, and prismatic in aragonite. These are probably only apparent exceptions. The elementary substances which go to form them occur in different allotropic states, with different amounts of specific heat; and it is probable that in these different states they go to form the above modifications, which are therefore, in every respect, except in their chemical composition, different mineral bodies. The physical differences between diamond and graphite may suffice as an illustration. The diamond is transparent, colourless, brittle, and extremely hard; graphite is opaque, black, tough, and so soft as to be utilized as a lubricant.

Spheres of Projection.—The foregoing scheme for the development of the relation which subsists between faces of crystals and their axes affords but slight aid in displaying the position of the faces, or their mutual relationships. The delineation even of a considerable series of crystal forms does not indeed go far in effecting this,—on account, first, of very unequal development in the size of the faces of crystals, and, secondly, on account of the *habit* of development of these faces not only differing largely, but being special to certain localities,—as in the entire absence of some faces, and in the preponderance of others.

Spheres of projection. Maps of the whole domain occupied by the forms of each mineral have been happily projected for such display. The projection is laid down as on a globe, in accordance with stereographic projection, and admitting of calculation according to the laws of spherical trigonometry. These globe maps are called "spheres of projection." The centre O is the common centre of the crystal and of the sphere in which the axes intersect. The three axes will of course meet the circumference of the sphere in six points, called the "poles of the axes." From the centre radii are supposed to be drawn, meeting each plane perpendicularly. It is evident that such radii will have fixed inclinations to each other. They are called "normals" to the planes, and the points in which when produced they meet the circumference of the sphere of projection are called the "poles" of the corresponding faces. A face and its pole thus call for only one symbol. The angle included by any two normals is the supplement of that included by the two corresponding faces.

It is thus easy to determine the angles of any two normals when that of the corresponding faces is known, or *vice versa*. Thus, if the angle between two faces is 125°, that of the normals will be 55°. The spheres of projection are specially adapted to enable us to avail ourselves of the aid to calculation afforded by the forenoted fact that sets of faces lie parallel to each other, forming zones; for, when

Zones. projected on such a sphere, the normals of the parallel faces will all lie in one plane; and the poles, all cutting its surface in the direction of one line, may be connected, and so form a great circle on the sphere. This is called the "zone circle." A line drawn through the centre of the

zone plane, cutting it at right angles, is the "zone axis"; it is parallel to all the faces, and intersections of the faces (if they are extended enough to intersect), of the zone. A face may be common to two or more zones; its normals will then coincide with the intersections of the several zone planes.

In the absence of actual spheres upon which to detail the facts which go to form the "sphere of projection" of each substance, the hemisphere is represented on a plane surface. This has of necessity the disadvantage, except as regards the circumferential zone, of introducing spherical distance-distortion—foreshortening of all parts lying near the circumference; but the eye soon gets accustomed to this. Fig. 43 presents the principal zones of the cubic system, and

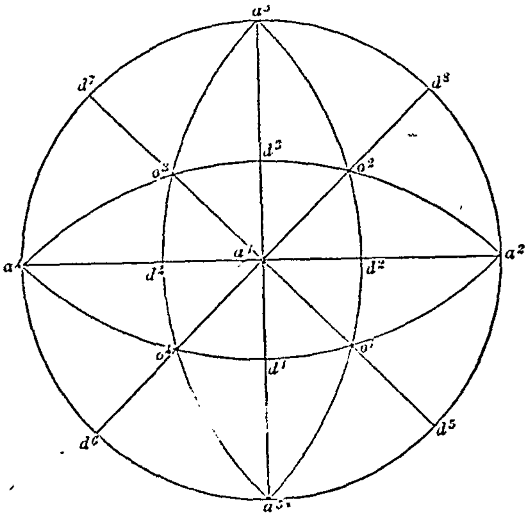

Fig. 43.

shows the position of the poles of the faces of the cube, the octahedron, and the rhombic dodecahedron. o_1, o_2, o_3, &c., are the poles of the octahedral faces; a_1, a_2, a_3, &c., those of the faces of the cube; and d_1, d_2, d_3, &c., those of the rhombic dodecahedron. It will be observed that the faces of the cube fall into the zone circles of the octahedron and dodecahedron, while those of the octahedron fall into those

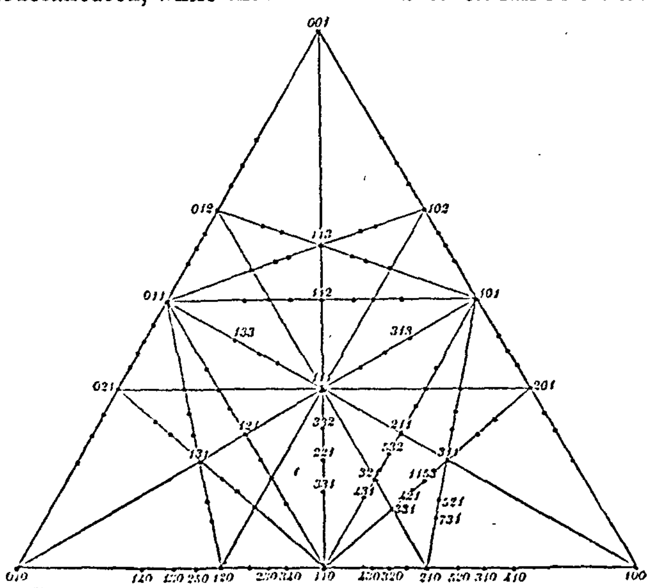

FIG 44.—Principal Poles of Cubic System in Octant of Sphere.

of the rhombic dodecahedron. Considering this as a delineation of a globe, these zone circles come to represent latitude and longitude; and, as almost all the faces in this system fall into some zone circle, it is clear that the latitude and longitude of all normals may be readily laid down, and their relations at once determined by spherical trigonometry. Fig. 44 shows the arrangement of the poles of all the forms belonging to the cubic system noticed above, or referred to in the present article,—delineated on an octant of the sphere of projection. It displays the perfect regularity of the system.

Hemihedral and Tetartohedral Forms.—The exception to the second law (that of symmetry), which was formulated by Weiss, was to the effect that one-half or even one-fourth only of the faces which go to form a holohedral crystal may be present. When but one-half of the faces present themselves, the form is termed hemihedral; when only one-fourth, it is tetartohedral. These restrained developments have now to be considered. In hemihedral forms the development is restrained, but symmetry is not deranged; half the similar parts are still alike, though unlike the other half.

There are two classes of hemihedral forms:—

I. Those forms in which half the similar angles or edges are modified independently of the other half ("hemi-holohedral"), producing—

1. In the monometric and dimetric systems "tetrahedral" and "sphenoidal" forms, by the independent replacement of the alternate angles; their opposite faces are not parallel, and they are hence called "inclined" hemihedrons; as in chalcopyrite, boracite.[1] The replacement in the dimetric system of two opposite basal edges at one base and the other two at the opposite base is of the same kind; as in edingtonite.

2. In the trimetric system "monoclinic" forms, by the replacement of half the similar parts of one base and the diagonally opposite of the other, unlike the other half; as in datholite, humite.

3. In the trimetric and hexagonal systems "hemimorphic" forms, by independent replacements at the opposite extremities of the crystal; as in topaz, calamine, tourmaline.

4. In the rhombohedral system, by the replacements of the alternate basal edges or angles of the rhombohedron, forms usually called "tetartohedral" or quarter forms, on the ground that mathematically the rhombohedron is a hemihedral form derived from the hexagonal prism, which is the type of the hexagonal system. Rock crystal is usually developed according to this law.

II. Those forms in which all the similar angles or edges are modified, but by half the full or normal number of planes ("holo-hemihedral"), producing—

1. In the monometric system "pyritohedral" forms, by a replacement of the edges or angles; as in pyrites. Such forms have opposite faces parallel, and are often called parallel hemihedrons.

2. In the dimetric system "pyramidal" and "scalenoidal" forms, by a replacement of the eight solid angles of the primary prism, according to two methods.

3. In the hexagonal system "pyramoidal" and "gyroidal" forms, by a replacement of the solid angles of the hexagonal prism, or of the six lateral angles of the rhombohedron, according to two methods, as in quartz and apatite.

The above illustrations show that hemihedrism is not only divided into two classes, but is of various kinds, and these have been systematized as follows:—"holomorphic," in which the occurring planes pertain equally to the upper and lower (or opposite) ranges of sectants, as in ordinary hemihedrons; and (2) "hemimorphic," in which each set of planes pertains to either the upper or the lower range, but not to both. As to the relative position of the sectants which contain the planes, the forms may be vertically direct, as in baryte; vertically alternate, as in the tetrahedron, the rhombohedron, and the plagihedral faces of quartz; and vertically oblique, as in many forms of chondrodite.

In hemimorphic forms symmetry is deranged; the crystals are bounded at the opposite ends of their main axes by faces belonging to distinct forms or modifications,—always, however, of the same system; hence only the upper or the under half of each crystal can be regarded as complete, as regards the form there seen; and so for each end it is half formed.

Fig. 45 represents a crystal of tourmaline, which is bounded on the upper end by the planes of the rhombohedrons R (P) and -2R (o), and on the lower end by the basal pinacoid (k'). In fig. 46 of smithsonite the upper extremity shows the base k, two brachydomes o and p, and two macrodomes m and l;

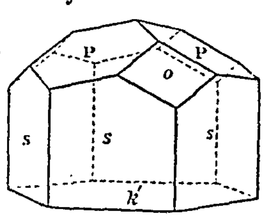

Fig. 45.

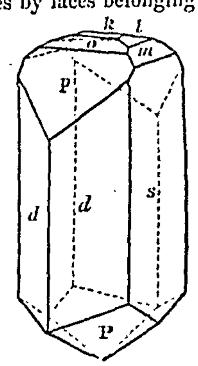

Fig. 46.

[1] As the parts of either half are alternate, there still results a symmetrical solid. As either one or other half may be the one thus modified, there may result two such symmetric solids, which stand in an inverse position to one another. When the modifications affect the upper right-hand solid angle, the resulting form is called +; when the upper left hand angle it is −.

whilst on the lower end it is bounded by the faces P of the primary alone.

It has been found that all hemimorphic crystals become electrically polar when heated, that is, exhibit opposite kinds of electricity at opposite ends of the crystal. The subject will be more fully considered under the electricity of minerals.

emi- edral rms. The hemihedral forms of the cubic system are the following :—

1. The *tetrahedron (fig. 47), hemihedral of the octahedron, is* bounded by *four equilateral triangles.* It has six equal edges with *faces meeting at* 70° 32′, and four trigonal angles. The principal axes join the middle points of each two opposite edges. Examples: fahlore, boracite, and helvine.

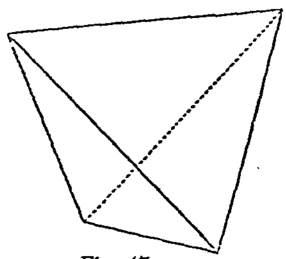

Fig. 47.

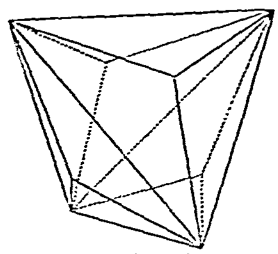

Fig. 48.

2. The trigonal dodecahedrons (fig. 48), hemihedral of the icositetrahedron, are bounded by twelve isosceles triangles, and vary in general form from the tetrahedron to the cube. There are six longer edges corresponding to those of the inscribed tetrahedron, and twelve shorter, placed three and three over each of its faces, and four hexagonal and four trigonal angles. Example : tetrahedrite.

3. The deltoid dodecahedrons (fig. 49), hemihedral of the triakisoctahedron, are bounded by twelve deltoids, and vary in general form from the tetrahedron on the one hand to the rhombic dodecahedron on the other. They have twelve longer edges lying in pairs over the edges of the inscribed tetrahedron, and twelve shorter edges, three and three over each of its faces. There are six tetragonal (rhombic), four acute trigonal, and four obtuse trigonal angles. The principal axes join, two and two, opposite rhombic angles. Example : tetrahedrite.

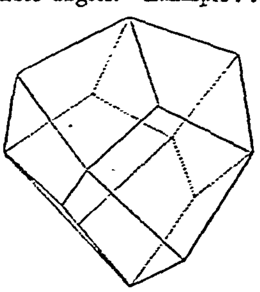

Fig. 49.

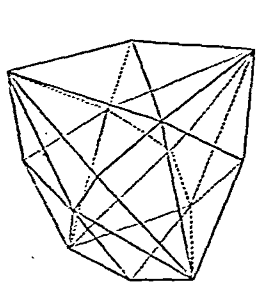

Fig. 50.

4. The hexakistetrahedrons (fig. 50), hemihedral of the hexakisoctahedron, are bounded by twenty-four scalene triangles, and most commonly have their faces grouped in four systems of six each. The edges are twelve shorter and twelve longer, lying in groups of three over each face of the inscribed tetrahedron, and twelve intermediate in pairs over its edges. The angles are six rhombic, joined in pairs by the principal axes, and four acuter and four obtuser hexagonal angles. Example : diamond.

In these forms, often named "tetrahedral," the faces are oblique to each other. Their derivation and signs are as follows. The tetrahedron arises when four alternate faces of the octahedron, two opposite above and two intermediate below, are enlarged so as to obliterate the other four; and its sign is hence $\frac{O}{2}$. But, as either four faces may be thus enlarged or obliterated, two tetrahedrons can be formed, similar in all respects except in position, and together making up the octahedron. These are distinguished by the signs + and −, added to the above symbol, but only the latter in general expressed, thus $-\frac{O}{2}$. In all hemihedric systems two forms similarly related occur, which may thus be named complementary forms. The trigonal dodecahedron is derived from the icositetrahedron by the expansion of the alternate trigonal groups of faces. Its sign is $\frac{mOm}{2}$, the most common variety being $\frac{2O2}{2}$. The deltoid dodecahedron is in like manner the result of the increase of the alternate trigonal groups of faces of the triakisoctahedron, and its sign is $\frac{mO}{2}$. Lastly, the hexakistetrahedron arises in the development of alternate hexagonal groups of faces in the hexakisoctahedron, and its sign is $\frac{mOn}{2}$.

Two semitesseral forms with parallel faces occur. (1) The pentagonal dodecahedrons (fig. 51), bounded by twelve *symmetrical* pentagons, vary in general aspect between the cube and the rhombic dodecahedron. They have six regular (and in general longer) edges, lying over the faces of the inscribed cube, and twenty-

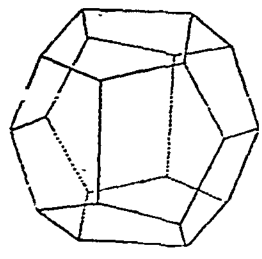

Fig. 51.

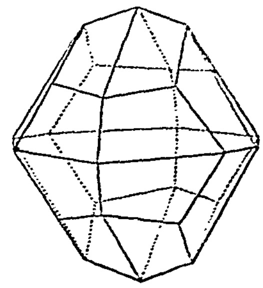

Fig. 52.

four, generally shorter (seldom longer), edges, usually lying in pairs over its edges. The solid angles are eight of three equal interfacial angles, and twelve of three interfacial angles, of which only two are equal. Each principal axis unites two opposite regular edges. This form is derived from the tetrakishexahedron, and its sign is $\frac{\infty On}{2}$. It is found frequently in iron pyrites and cobaltine.

(2) The dyakisdodecahedron (fig. 52), bounded by twenty-four trapezoids with two sides equal, has twelve short, twelve long, and twenty-four intermediate edges. The angles are six equiangular rhombic, united in pairs by the principal axes, eight trigonal, and twenty-four irregular tetragonal angles. It is derived from the hexakisoctahedron, and its sign is $\left[\frac{mOn}{2}\right]$, the brackets being used to distinguish it from the hexakistetrahedron, also derived *from the same primary form. It occurs in iron pyrites and* cobaltine. The two other semitesseral forms, the pentagonal

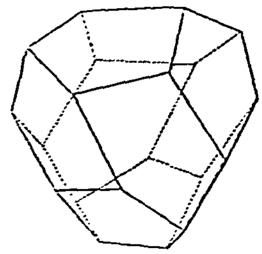

Fig. 53.

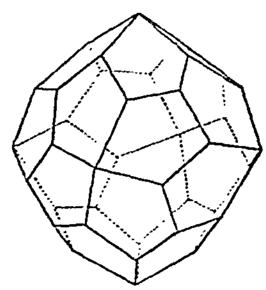

Fig. 54.

dodecahedron (fig. 53), and the pentagonal icositetrahedron (fig. 54), both bounded by *irregular* pentagons, have not yet been observed in nature.

Combinations.—The above-mentioned forms of the tesseral system (and this is true also of the five other systems of crystallization) not only occur singly, but often two, three, or more occur united in the same crystal, forming what are named combinations. Combinations.

In this case it is evident that no one of the individual forms can be complete, because the faces of one form must interfere with, by diminishing, the faces of other forms. A combination therefore implies that the faces of one form shall appear symmetrically disposed between the faces of other forms, and consequently take the place of certain of their edges and angles. These edges and angles are thus, as it were, cut off, and a greater number of new ones produced in their place, which properly belong neither to the one form nor the other, but are angles of combination. These new faces are hence termed modifications, and the original or primary or simple form is said to be modified. Usually one form predominates more than the others, or has more influence on the general aspect of the crystal, and hence is distinguished as the predominant form, the others being considered subordinate.

The sign of the combination consists of those of its constituent forms, written in the order of their influence or importance in the combination, with a point between each pair.

It will be readily seen that such combinations may be exceedingly numerous, or rather infinite; and only a few of the more common

zone plane, cutting it at right angles, is the "zone axis"; it is parallel to all the faces, and intersections of the faces (if they are extended enough to intersect), of the zone. A face may be common to two or more zones; its normals will then coincide with the intersections of the several zone planes.

In the absence of actual spheres upon which to detail the facts which go to form the "sphere of projection" of each substance, the hemisphere is represented on a plane surface. This has of necessity the disadvantage, except as regards the circumferential zone, of introducing spherical distance-distortion—foreshortening of all parts lying near the circumference; but the eye soon gets accustomed to this. Fig. 43 presents the principal zones of the cubic system, and

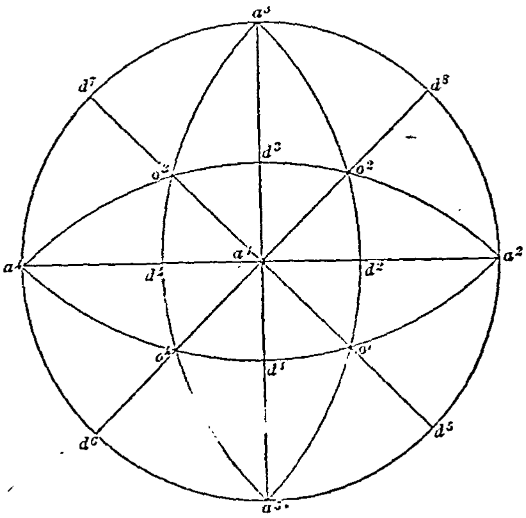

Fig. 43.

shows the position of the poles of the faces of the cube, the octahedron, and the rhombic dodecahedron. o_1, o_2, o_3, &c., are the poles of the octahedral faces; a_1, a_2, a_3, &c., those of the faces of the cube; and d_1, d_2, d_3, &c., those of the rhombic dodecahedron. It will be observed that the faces of the cube fall into the zone circles of the octahedron and dodecahedron, while those of the octahedron fall into those

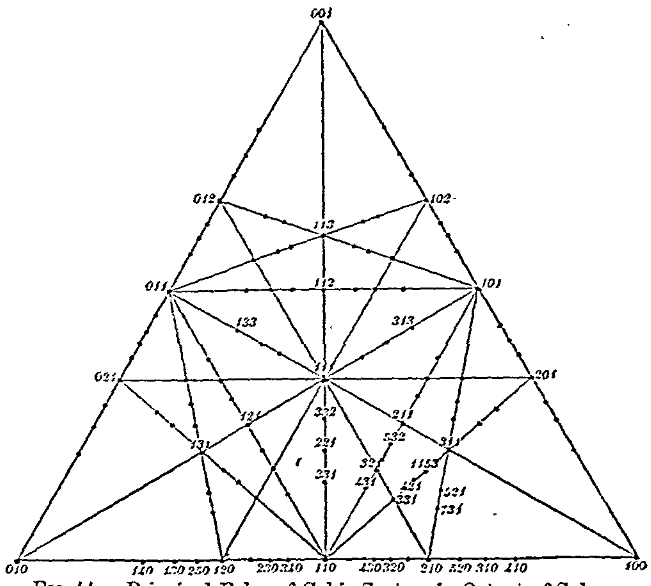

Fig 44.—Principal Poles of Cubic System in Octant of Sphere.

of the rhombic dodecahedron. Considering this as a delineation of a globe, these zone circles come to represent latitude and longitude; and, as almost all the faces in this system fall into some zone circle, it is clear that the latitude and longitude of all normals may be readily laid down, and their relations at once determined by spherical trigonometry. Fig. 44 shows the arrangement of the poles of all the forms belonging to the cubic system noticed above, or referred to in the present article,—delineated on an octant of the sphere of projection. It displays the perfect regularity of the system.

Hemihedral and Tetartohedral Forms.—The exception to the second law (that of symmetry), which was formulated by Weiss, was to the effect that one-half or even one-fourth only of the faces which go to form a holohedral crystal may be present. When but one-half of the faces present themselves, the form is termed hemihedral; when only one-fourth, it is tetartohedral. These restrained developments have now to be considered. In hemihedral forms the development is restrained, but symmetry is not deranged; half the similar parts are still alike, though unlike the other half.

There are two classes of hemihedral forms:—

I. Those forms in which half the similar angles or edges are modified independently of the other half ("hemi-holohedral"), producing—

1. In the monometric and dimetric systems "tetrahedral" and "sphenoidal" forms, by the independent replacement of the alternate angles; their opposite faces are not parallel, and they are hence called "inclined" hemihedrons; as in chalcopyrite, boracite.[1] The replacement in the dimetric system of two opposite basal edges at one base and the other two at the opposite base is of the same kind; as in edingtonite.

2. In the trimetric system "monoclinic" forms, by the replacement of half the similar parts of one base and the diagonally opposite of the other, unlike the other half; as in datholite, humite.

3. In the trimetric and hexagonal systems "hemimorphic" forms, by independent replacements at the opposite extremities of the crystal; as in topaz, calamine, tourmaline.

4. In the rhombohedral system, by the replacements of the alternate basal edges or angles of the rhombohedron, forms usually called "tetartohedral" or quarter forms, on the ground that mathematically the rhombohedron is a hemihedral form derived from the hexagonal prism, which is the type of the hexagonal system. Rock crystal is usually developed according to this law.

II. Those forms in which all the similar angles or edges are modified, but by half the full or normal number of planes ("holo-hemihedral"), producing—

1. In the monometric system "pyritohedral" forms, by a replacement of the edges or angles; as in pyrites. Such forms have opposite faces parallel, and are often called parallel hemihedrons.

2. In the dimetric system "pyramidal" and "scalenoidal" forms, by a replacement of the eight solid angles of the primary prism, according to two methods.

3. In the hexagonal system "pyramoidal" and "gyroidal" forms, by a replacement of the solid angles of the hexagonal prism, or of the six lateral angles of the rhombohedron, according to two methods, as in quartz and apatite.

The above illustrations show that hemihedrism is not only divided into two classes, but is of various kinds, and these have been systematized as follows:—"holomorphic," in which the occurring planes pertain equally to the upper and lower (or opposite) ranges of sectants, as in ordinary hemihedrons; and (2) "hemimorphic," in which each set of planes pertains to either the upper or the lower range, but not to both. As to the relative position of the sectants which contain the planes, the forms may be vertically direct, as in baryte; vertically alternate, as in the tetrahedron, the rhombohedron, and the plagihedral faces of quartz; and vertically oblique, as in many forms of chondrodite.

Hemimorphic forms.

In hemimorphic forms symmetry is deranged; the crystals are bounded at the opposite ends of their main axes by faces belonging to distinct forms or modifications,—always, however, of the same system; hence only the upper or the under half of each crystal can be regarded as complete, as regards the form there seen; and so for each end it is half formed.

Fig. 45 represents a crystal of tourmaline, which is bounded on the upper end by the planes of the rhombohedrons R (P) and -2R (o), and on the lower end by the basal pinacoid (k'). In fig. 46 of smithsonite the upper extremity shows the base k, two brachydomes o and p, and two macrodomes m and l;

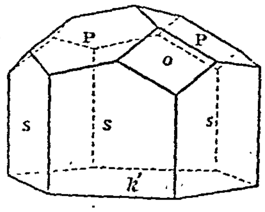

Fig. 45.

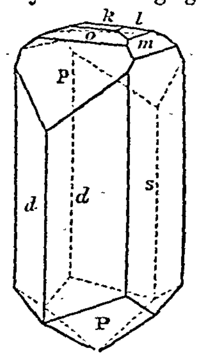

Fig. 46.

[1] As the parts of either half are alternate, there still results a symmetrical solid. As either one or other half may be the one thus modified, there may result two such symmetric solids, which stand in an inverse position to one another. When the modifications affect the upper right-hand solid angle, the resulting form is called +; when the upper left hand angle it is −.

whilst on the lower end it is bounded by the faces P of the primary alone.

It has been found that all hemimorphic crystals become electrically polar when heated, that is, exhibit opposite kinds of electricity at opposite ends of the crystal. The subject will be more fully considered under the electricity of minerals.

Hemihedral forms.

The hemihedral forms of the cubic system are the following:—

1. The tetrahedron (fig. 47), hemihedral of the octahedron, is bounded by four equilateral triangles. It has six equal edges with faces meeting at 70° 32′, and four trigonal angles. The principal axes join the middle points of each two opposite edges. Examples: fahlore, boracite, and helvine.

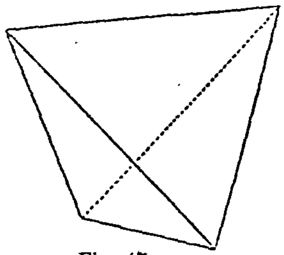

Fig. 47.

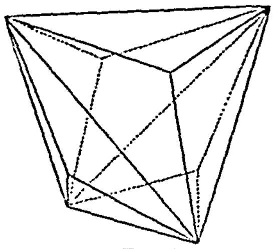

Fig. 48.

2. The trigonal dodecahedrons (fig. 48), hemihedral of the icositetrahedron, are bounded by twelve isosceles triangles, and vary in general form from the tetrahedron to the cube. There are six longer edges corresponding to those of the inscribed tetrahedron, and twelve shorter, placed three and three over each of its faces, and four hexagonal and four trigonal angles. Example: tetrahedrite.

3. The deltoid dodecahedrons (fig. 49), hemihedral of the triakisoctahedron, are bounded by twelve deltoids, and vary in general form from the tetrahedron on the one hand to the rhombic dodecahedron on the other. They have twelve longer edges lying in pairs over the edges of the inscribed tetrahedron, and twelve shorter edges, three and three over each of its faces. There are six tetragonal (rhombic), four acute trigonal, and four obtuse trigonal angles. The principal axes join, two and two, opposite rhombic angles. Example: tetrahedrite.

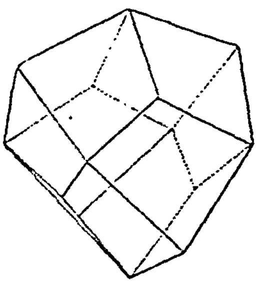

Fig. 49.

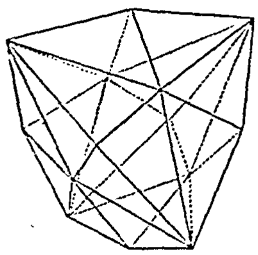

Fig. 50.

4. The hexakistetrahedrons (fig. 50), hemihedral of the hexakisoctahedron, are bounded by twenty-four scalene triangles, and most commonly have their faces grouped in four systems of six each. The edges are twelve shorter and twelve longer, lying in groups of three over each face of the inscribed tetrahedron, and twelve intermediate in pairs over its edges. The angles are six rhombic, joined in pairs by the principal axes, and four acuter and four obtuser hexagonal angles. Example: diamond.

In these forms, often named "tetrahedral," the faces are oblique to each other. Their derivation and signs are as follows. The tetrahedron arises when four alternate faces of the octahedron, two opposite above and two intermediate below, are enlarged so as to obliterate the other four; and its sign is hence $\frac{O}{2}$. But, as either four faces may be thus enlarged or obliterated, two tetrahedrons can be formed, similar in all respects except in position, and together making up the octahedron. These are distinguished by the signs + and −, added to the above symbol, but only the latter in general expressed, thus $-\frac{O}{2}$. In all hemihedric systems two forms similarly related occur, which may thus be named complementary forms. The trigonal dodecahedron is derived from the icositetrahedron by the expansion of the alternate trigonal groups of faces. Its sign is $\frac{mOm}{2}$, the most common variety being $\frac{2O2}{2}$. The deltoid dodecahedron is in like manner the result of the increase of the alternate trigonal groups of faces of the triakisoctahedron, and its sign is $\frac{mO}{2}$. Lastly, the hexakistetrahedron arises in the development of alternate hexagonal groups of faces in the hexakisoctahedron, and its sign is $\frac{mOn}{2}$.

Two semitesseral forms with parallel faces occur. (1) The pentagonal dodecahedrons (fig. 51), bounded by twelve *symmetrical* pentagons, vary in general aspect between the cube and the rhombic dodecahedron. They have six regular (and in general longer) edges, lying over the faces of the inscribed cube, and twenty-

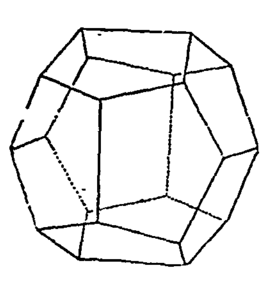

Fig. 51.

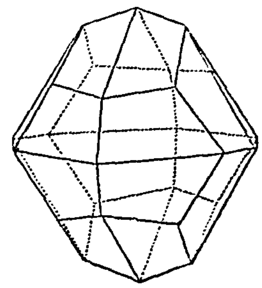

Fig. 52.

four, generally shorter (seldom longer), edges, usually lying in pairs over its edges. The solid angles are eight of three equal interfacial angles, and twelve of three interfacial angles, of which only two are equal. Each principal axis unites two opposite regular edges. This form is derived from the tetrakishexahedron, and its sign is $\frac{\infty On}{2}$. It is found frequently in iron pyrites and cobaltine.

(2) The dyakisdodecahedron (fig. 52), bounded by twenty-four trapezoids with two sides equal, has twelve short, twelve long, and twenty-four intermediate edges. The angles are six equiangular rhombic, united in pairs by the principal axes, eight trigonal, and twenty-four irregular tetragonal angles. It is derived from the hexakisoctahedron, and its sign is $\left[\frac{mOn}{2}\right]$, the brackets being used to distinguish it from the hexakistetrahedron, also derived from the same primary form. It occurs in iron pyrites and cobaltine. The two other semitesseral forms, the pentagonal

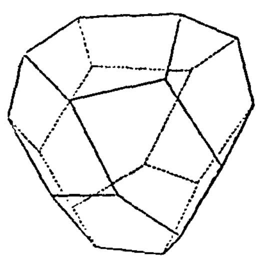

Fig. 53.

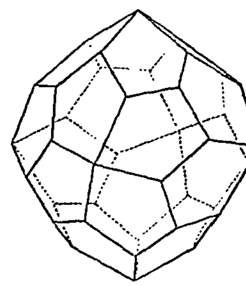

Fig. 54.

dodecahedron (fig. 53), and the pentagonal icositetrahedron (fig. 54), both bounded by *irregular* pentagons, have not yet been observed in nature.

Combinations.

Combinations.—The above-mentioned forms of the tesseral system (and this is true also of the five other systems of crystallization) not only occur singly, but often two, three, or more occur united in the same crystal, forming what are named combinations.

In this case it is evident that no one of the individual forms can be complete, because the faces of one form must interfere with, by diminishing, the faces of other forms. A combination therefore implies that the faces of one form shall appear symmetrically disposed between the faces of other forms, and consequently take the place of certain of their edges and angles. These edges and angles are thus, as it were, cut off, and a greater number of new ones produced in their place, which properly belong neither to the one form nor the other, but are angles of combination. These new faces are hence termed modifications, and the original or primary or simple form is said to be modified. Usually one form predominates more than the others, or has more influence on the general aspect of the crystal, and hence is distinguished as the predominant form, the others being considered subordinate.

The sign of the combination consists of those of its constituent forms, written in the order of their influence or importance in the combination, with a point between each pair.

It will be readily seen that such combinations may be exceedingly numerous, or rather infinite; and only a few of the more common

can be noticed. Many others more complicated will occur in the descriptive part of this article. Among holohedral combinations, the cube, octahedron, and rhombic dodecahedron are the predominant forms. In fig. 27 the cube has its angles replaced by the faces of the octahedron, which truncate the angles, and the sign of this combination is $\infty O \infty$, O. In fig. 28 this process may be regarded as having proceeded still farther, so that the faces of the octahedron nearly equal those of the cube, while in fig. 29 they now predominate; the sign, still of the same two elements, but in reverse order, is O, $\infty O \infty$. It will thus be seen that, through an increase in the amount of the abstraction of the faces of the cube, the figure gradually passes over into that of the octahedron. This may occur in all cases, and is termed the passage of the cube into the octahedron (or *vice versa*), or a "transition by decrement."

In fig. 31 the cube has its edges replaced by the faces of the rhombic dodecahedron, which truncate the edges, the sign being $\infty O \infty$, ∞O; while in fig. 32 there is the same combination, but with the faces of the cube subordinate, and hence the sign is ∞O, $\infty O \infty$. The former figure, it will be seen, has more the general aspect of the cube, the latter of the dodecahedron. Here the solid angles of the latter are truncated by the faces of the cube, and we have the passage of the cube into the dodecahedron by decrement. The same transition, through truncation or decrement, could be shown in all cases of combinations, and in both directions, the last stage of the passage into one or other form always consisting of the replacement of its solid or interfacial angles by faces of the departing figure, more or less minute. A few illustrations of this may be given, in the three most important forms.

The relationship of the tetrakishexahedron to the cube has above been stated to be, that its faces form six low quadrilateral pyramids, which rest upon or spring from the edges of the cube. (From this the form derives its trivial name of four-faced cube.) Hence these faces bevel the edges of the cube. The first stage of such bevelling (or the last stage of the truncation of the tetrakishexahedron by the faces of the cube—whichever way it may be regarded) is seen in fig. 55. As the cubic face is here dominant, the sign is $\infty O \infty$, $\infty O3$. Fig. 56 shows a somewhat similar stage

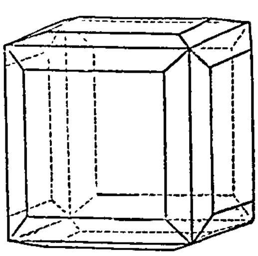

Fig. 55.

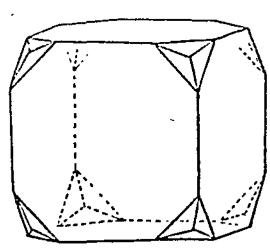

Fig. 56.

in the modification produced through the combination of the icositetrahedron with the cube. The trilateral pyramid which this form places upon the faces of the cube rests upon its solid angles, instead of, as in the last case, upon its edges; hence it is these solid angles which, in the process of decrement, it replaces by faces which form a low three-sided pyramid. The triakisoctahedron,

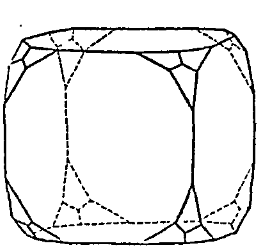

Fig. 57.

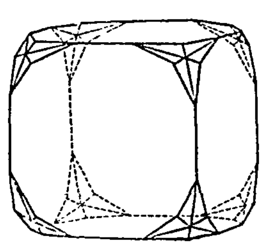

Fig. 58.

again, modifies the solid angles of the cube, as shown in fig. 57, by a low three-sided pyramid, positioned at right angles to that considered in the last combination. As the hexakisoctahedron is merely the two-faced form of that last considered, the pyramid which modifies the solid angles is, in its combination with the cube, six-sided, as in fig. 58.

As the faces of the rhombic dodecahedron truncate the edges of the octahedron, fig. 34 represents the first stage of such truncation or combination; while fig. 35 may be taken as representing the last, the faces of the octahedron being there nearly totally removed.

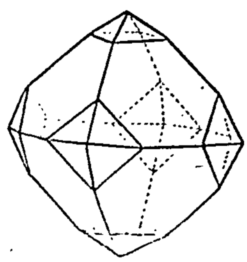

Fig. 59.

Fig. 59 shows the first stage of the passage of the octahedron into the icositetrahedron, in the truncation of the solid angles of the former form by a four-sided pyramid formed by the (6 × 4) faces of the latter. The faces of the octahedron truncate the three-faced solid angles of the rhombic dodecahedron. Fig. 35 shows the first stage of this truncation, while fig. 34 shows an advanced amount. The faces of the icosi-

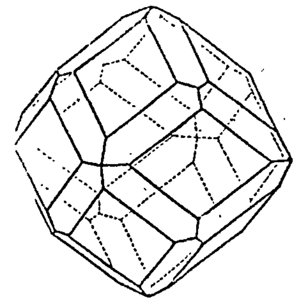

Fig. 60.

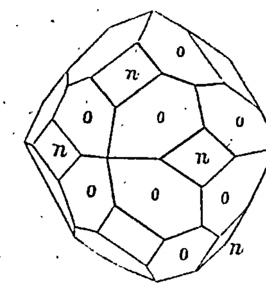

Fig. 61.

tetrahedron truncate the edges of the rhombic dodecahedron, as in fig. 60; while those of the latter truncate the unequal-angled tetragonal (or rhombic) angles of the former (fig. 61). The faces of the hexakisoctahedron bevel the edges of the rhombic dodecahedron.

While such transitions may appear indefinite, yet certain minerals have either in themselves a habit, or have at certain localities a habit, of crystallizing so markedly *in a certain stage* of these transitions as to be absolutely capable of recognition thereby.

Combinations of hemihedral or, as they have been called, semitesseral forms are of three classes:—those with holohedral forms, those in which the faces fall obliquely on one another, and those with parallel faces. Fig. 62 shows the combination of a right- Comb tions hemi- hedra forms

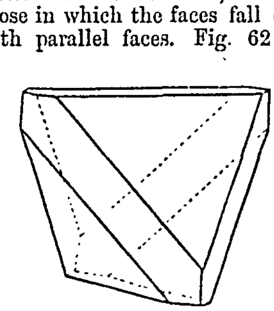

Fig. 62.

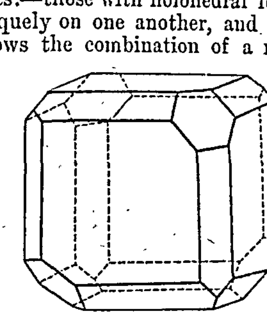

Fig. 63.

handed tetrahedron with the cube, which truncates its edges, the tetrahedron here being dominant. Fig. 63, again, shows a combination of the cubo-dodecahedron with a right-handed tetrahedron, the first or holohedral form being in this case markedly dominant.

Fig. 64 is an illustration of the second class, combinations of

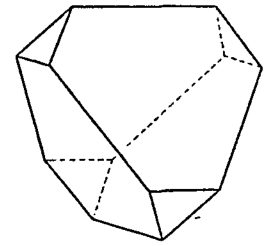

Fig. 64.

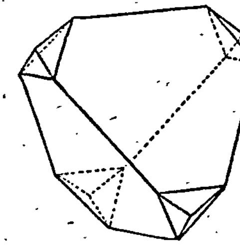

Fig. 65.

oblique-faced semitesseral forms with each other. In it a right-handed tetrahedron has its solid angles truncated by the faces of one which is left-handed; and so its sign is $\frac{O}{2}, -\frac{O}{2}$. Fig. 65 shows a combination of a right-handed tetrahedron with a left-

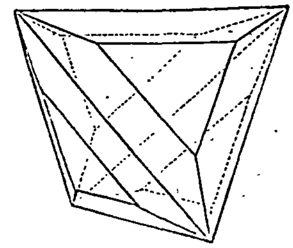

Fig. 66.

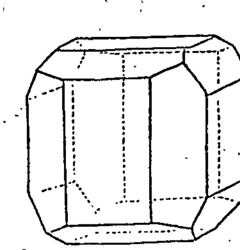

Fig. 67.

handed three-faced tetrahedron. Fig. 66 shows a combination of a right-handed hemihedron of the icositetrahedron with a right-handed tetrahedron.

Parallel-faced hemihedrons generally form combinations with holohedral forms; and the amount of relative dominance is of all degrees. Fig. 67 shows a combination, in equal amount, of the cube

with a vertical-faced pentagonal dodecahedron; while fig. 68 shows an increase in the amount of truncation effected by the latter. Fig. 69 shows the combination of the cube with the dyakidodecahedron,

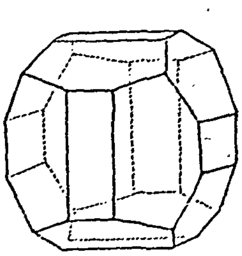

Fig. 68.

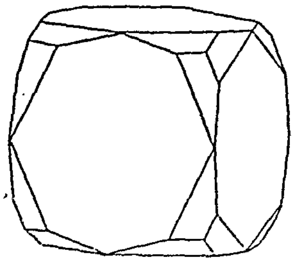

Fig. 69.

the former being dominant. In fig. 70 an octahedron, in dominance, is combined with the vertical-faced pentagonal dodecahedron; in

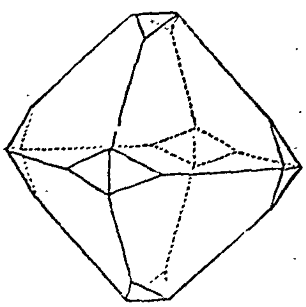

Fig. 70.

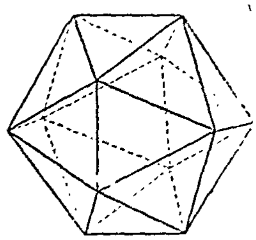

Fig. 71.

fig. 71 the faces of these forms are of nearly equal size, while in fig. 72 the octahedral faces are nearly removed. The solid angles of

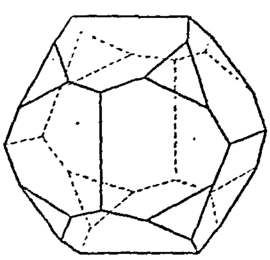

Fig. 72.

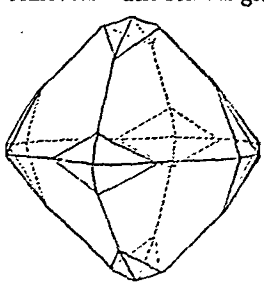

Fig. 73.

the octahedron are modified in fig. 73 by the faces of the dyakisdodecahedron. In fig. 68 a vertical-faced pentagonal dodeca-

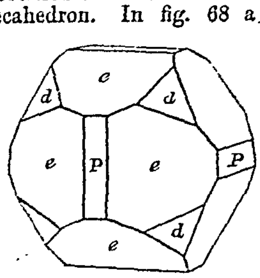

Fig. 74.

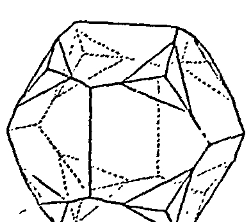

Fig. 75.

hedron is the prevailing form in combination with the cube; while in fig. 74 the faces of the octahedron are superadded. In fig. 75 its octahedral angles are modified by the faces of the icositetrahedron,

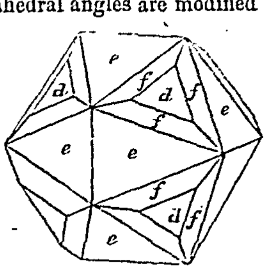

Fig. 76.

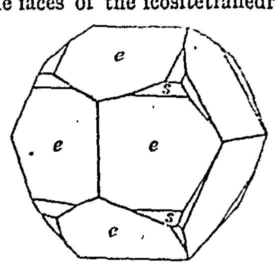

Fig. 77.

and in fig. 76 by those of the octahedron in addition. In fig. 77 they are modified by the faces of the dyakisdodecahedron.

In each of the five systems which follow there is this difference from the cubic system that one axis is always unequal to (longer or shorter than) the others. This is placed erect, and named the chief axis; its ends are poles, and the edges connected with them polar edges. The other axes are named subordinate or lateral axes, and the plane that passes through them is the base. A plane through the chief and a lateral axis is a normal chief section. In these systems also occur the three forms of "pyramids," "prisms," and "pinacoids." (1) The pyramids have their faces triangles. Pyramids in crystallography are each composed of two geometric pyramids placed base to base, and named "closed forms," as the crystals are shut in by definite faces on every side. (2) The prisms are bounded by plane faces parallel to one axis. They are thus of unlimited extent in the direction of that axis, and therefore named "open forms," but in solid crystals are shut in by faces of other forms. (3) The pinacoids, or tables, have two faces intersecting one axis and parallel to the others, and thus are also open forms, or unlimited in the direction of these axes. Forms (2) and (3), when conjoined, mutually shut in each other, or produce closed forms. Dimetric and trimetric forms.

II. *Pyramidal or Tetragonal System.*—This system has three axes at right angles, two of them equal, and the chief axis longer or shorter. The name tetragonal is derived from the form of the base, which is usually quadrangular. Pyramidal system.

There are eight tetragonal forms, of which five are closed. (1) Tetragonal pyramids (figs. 78, 79) are enclosed by eight isosceles triangles, with four middle edges all in one plane, and eight polar edges. There are three kinds of this form,

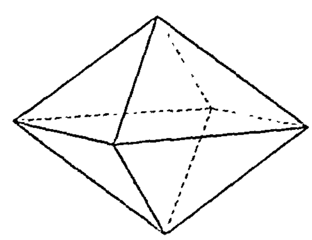

Fig. 78.

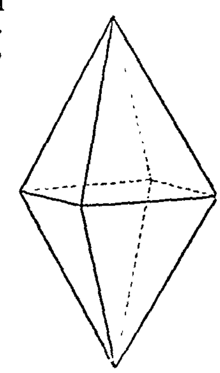

Fig. 79.

distinguished by the position of the lateral axes. In the first these axes unite the opposite angles; in the second they intersect the middle edges equally; and in the third they lie in an intermediate position, or divide these edges unequally,—the last being hemihedral forms. These pyramids are also distinguished as obtuse (fig. 78) or acute (fig. 79), according as the vertical angle is greater or less than in the regular octahedron. (2) Ditetragonal pyramids (fig. 80) are bounded by sixteen scalene triangles, whose base-lines are all in one

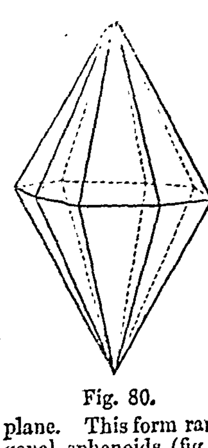

Fig. 80.

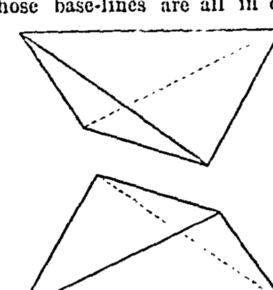

Fig. 81.

plane. This form rarely occurs except in combinations. (3) Tetragonal sphenoids (fig. 81), bounded by four isosceles triangles, are the hemihedral forms of the first variety of tetragonal pyramids. (4) The tetragonal scalenohedron (fig. 82), bounded by eight scalene triangles, whose bases rise and fall in a zigzag line, is the hemihedral form of the ditetragonal pyramid. Nos. (3) and (4) are rare. (5) The tetragonal trapezohedron is not found in minerals as a simple form. The three open forms are—(1) tetragonal prisms, bounded by four planes parallel to the principal axis, which may be either longer (fig. 83) or shorter (fig. 84) than the lateral axes; (2) ditetragonal prisms, bounded by eight similar planes; and (3) the basal pinacoid, consisting merely of two parallel faces bounding the prisms at the ends, above and below.

The various series of tetragonal crystals are distinguished from each other only by their relative dimensions. To determine these,

can be noticed. Many others more complicated will occur in the descriptive part of this article. Among holohedral combinations, the cube, octahedron, and rhombic dodecahedron are the predominant forms. In fig. 27 the cube has its angles replaced by the faces of the octahedron, which truncate the angles, and the sign of this combination is $\infty O \infty$, O. In fig. 28 this process may be regarded as having proceeded still farther, so that the faces of the octahedron nearly equal those of the cube, while in fig. 29 they now predominate; the sign, still of the same two elements, but in reverse order, is O, $\infty O \infty$. It will thus be seen that, through an increase in the amount of the abstraction of the faces of the cube, the figure gradually passes over into that of the octahedron. This may occur in all cases, and is termed the passage of the cube into the octahedron (or *vice versa*), or a "transition by decrement."

In fig. 31 the cube has its edges replaced by the faces of the rhombic dodecahedron, which truncate the edges, the sign being $\infty O \infty$, ∞O; while in fig. 32 there is the same combination, but with the faces of the cube subordinate, and hence the sign is ∞O, $\infty O \infty$. The former figure, it will be seen, has more the general aspect of the cube, the latter of the dodecahedron. Here the solid angles of the latter are truncated by the faces of the cube, and we have the passage of the cube into the dodecahedron by decrement. The same transition, through truncation or decrement, could be shown in all cases of combinations, and in both directions, the last stage of the passage into one or other form always consisting of the replacement of its solid or interfacial angles by faces of the departing figure, more or less minute. A few illustrations of this may be given, in the three most important forms.

The relationship of the tetrakishexahedron to the cube has above been stated to be, that its faces form six low quadrilateral pyramids, which rest upon or spring from the edges of the cube. (From this the form derives its trivial name of four-faced cube.) Hence these faces bevel the edges of the cube. The first stage of such bevelling (or the last stage of the truncation of the tetrakishexahedron by the faces of the cube—whichever way it may be regarded) is seen in fig. 55. As the cubic face is here dominant, the sign is $\infty O \infty$, $\infty O3$. Fig. 56 shows a somewhat similar stage

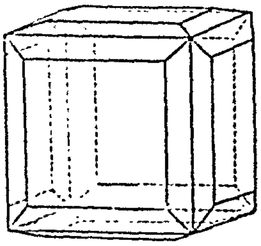

Fig. 55.

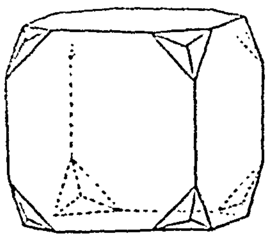

Fig. 56.

in the modification produced through the combination of the icositetrahedron with the cube. The trilateral pyramid which this form places upon the faces of the cube rests upon its solid angles, instead of, as in the last case, upon its edges; hence it is these solid angles which, in the process of decrement, it replaces by faces which form a low three-sided pyramid. The triakisoctahedron,

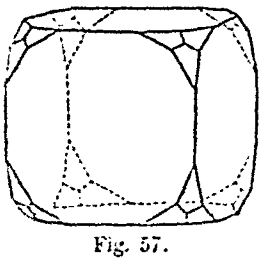

Fig. 57.

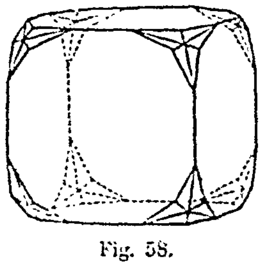

Fig. 58.

again, modifies the solid angles of the cube, as shown in fig. 57, by a low three-sided pyramid, positioned at right angles to that considered in the last combination. As the hexakisoctahedron is merely the two-faced form of that last considered, the pyramid which modifies the solid angles is, in its combination with the cube, six-sided, as in fig. 58.

As the faces of the rhombic dodecahedron truncate the edges of the octahedron, fig. 34 represents the first stage of such truncation or combination; while fig. 35 may be taken as representing the last, the faces of the octahedron being there nearly totally removed.

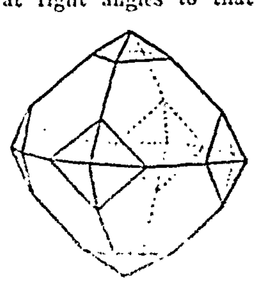

Fig. 59.

Fig. 59 shows the first stage of the passage of the octahedron into the icositetrahedron, in the truncation of the solid angles of the former form by a four-sided pyramid formed by the (6×4) faces of the latter. The faces of the octahedron truncate the three-faced solid angles of the rhombic dodecahedron. Fig. 35 shows the first stage of this truncation, while fig. 34 shows an advanced amount. The faces of the icosi-

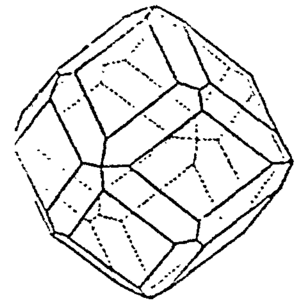

Fig. 60.

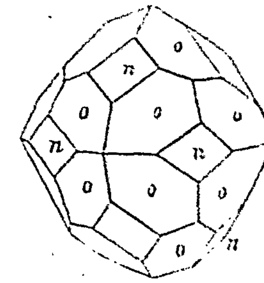

Fig. 61.

tetrahedron truncate the edges of the rhombic dodecahedron, as in fig. 60; while those of the latter truncate the unequal-angled tetragonal (or rhombic) angles of the former (fig. 61). The faces of the hexakisoctahedron bevel the edges of the rhombic dodecahedron.

While such transitions may appear indefinite, yet certain minerals have either in themselves a habit, or have at certain localities a habit, of crystallizing so markedly *in a certain stage* of these transitions as to be absolutely capable of recognition thereby.

Combinations of hemihedral or, as they have been called, semitesseral forms are of three classes:—those with holohedral forms, those in which the faces fall obliquely on one another, and those with parallel faces. Fig. 62 shows the combination of a right- Combinations of hemihedral forms.

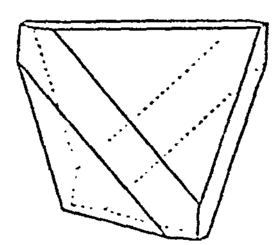

Fig. 62.

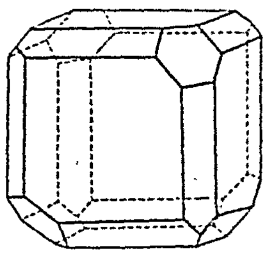

Fig. 63.

handed tetrahedron with the cube, which truncates its edges, the tetrahedron here being dominant. Fig. 63, again, shows a combination of the cubo-dodecahedron with a right-handed tetrahedron, the first or holohedral form being in this case markedly dominant.

Fig. 64 is an illustration of the second class, combinations of

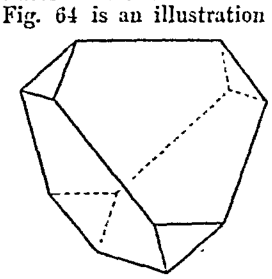

Fig. 64.

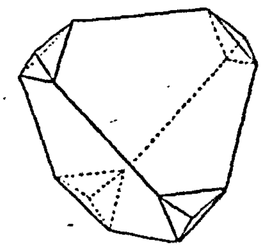

Fig. 65.

oblique-faced semitesseral forms with each other. In it a right-handed tetrahedron has its solid angles truncated by the faces of one which is left-handed; and so its sign is $\frac{O}{2}$, $-\frac{O}{2}$. Fig. 65 shows a combination of a right-handed tetrahedron with a left-

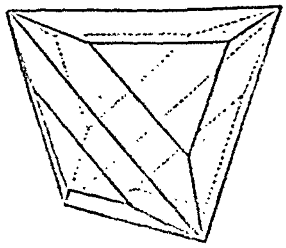

Fig. 66.

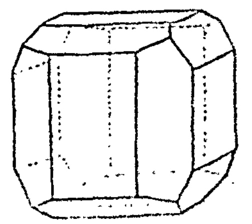

Fig. 67.

handed three-faced tetrahedron. Fig. 66 shows a combination of a right-handed hemihedron of the icositetrahedron with a right-handed tetrahedron.

Parallel-faced hemihedrons generally form combinations with holohedral forms; and the amount of relative dominance is of all degrees. Fig. 67 shows a combination, in equal amount, of the cube

with a vertical-faced pentagonal dodecahedron; while fig. 68 shows an increase in the amount of truncation effected by the latter. Fig. 69 shows the combination of the cube with the dyakidodecahedron,

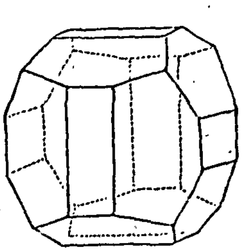

Fig. 68.

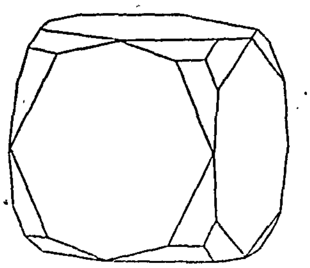

Fig. 69.

the former being dominant. In fig. 70 an octahedron, in dominance, is combined with the vertical-faced pentagonal dodecahedron; in

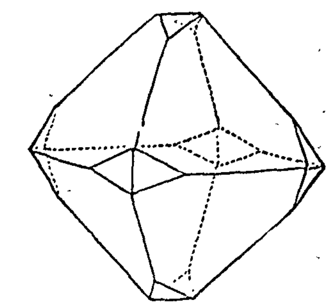

Fig. 70.

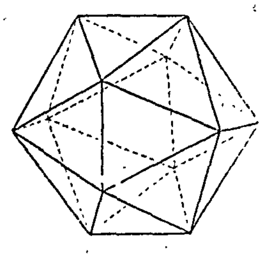

Fig. 71.

fig. 71 the faces of these forms are of nearly equal size, while in fig. 72 the octahedral faces are nearly removed. The solid angles of

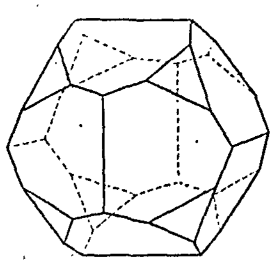

Fig. 72.

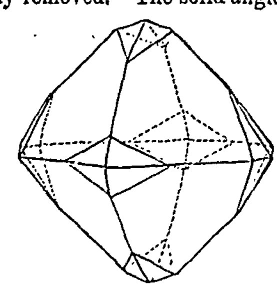

Fig. 73.

the octahedron are modified in fig. 73 by the faces of the dyakisdodecahedron. In fig. 68 a vertical-faced pentagonal dodecahedron is the prevailing form in combination with the cube; while in fig. 74 the faces of the octahedron are superadded. In fig. 75 its octahedral angles are modified by the faces of the icositetrahedron,

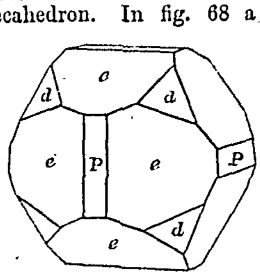

Fig. 74.

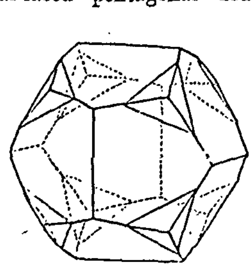

Fig. 75.

and in fig. 76 by those of the octahedron in addition. In fig. 77 they are modified by the faces of the dyakisdodecahedron.

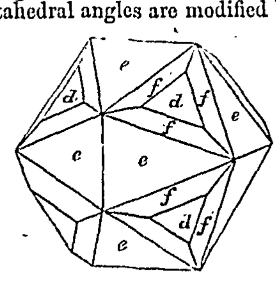

Fig. 76.

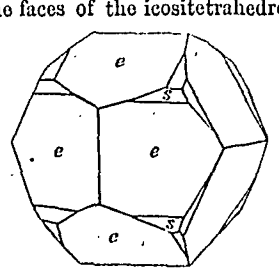

Fig. 77.

In each of the five systems which follow there is this difference from the cubic system that one axis is always unequal to (longer or shorter than) the others. This is placed erect, and named the chief axis; its ends are poles, and the edges connected with them polar edges. The other axes are named subordinate or lateral axes, and the plane that passes through them is the base. A plane through the chief and a lateral axis is a normal chief section. In these systems also occur the three forms of "*pyramids*," "*prisms*," and "*pinacoids*." (1) The pyramids have their faces triangles. Pyramids in crystallography are each composed of two geometric pyramids placed base to base, and named "closed forms," as the crystals are shut in by definite faces on every side. (2) The prisms are bounded by plane faces parallel to one axis. They are thus of unlimited extent in the direction of that axis, and therefore named "open forms," but in solid crystals are shut in by faces of other forms. (3) The pinacoids, or tables, have two faces intersecting one axis and parallel to the others, and thus are also open forms, or unlimited in the direction of these axes. Forms (2) and (3), when conjoined, mutually shut in each other, or produce closed forms.

Dimetric and trimetric forms.

II. *Pyramidal or Tetragonal System.*—This system has three axes at right angles, two of them equal, and the chief axis longer or shorter. The name tetragonal is derived from the form of the base, which is usually quadrangular.

Pyramidal system.

There are eight tetragonal forms, of which five are closed. (1) Tetragonal pyramids (figs. 78, 79) are enclosed by eight isosceles triangles, with four middle edges all in one plane, and eight polar edges. There are three kinds of this form,

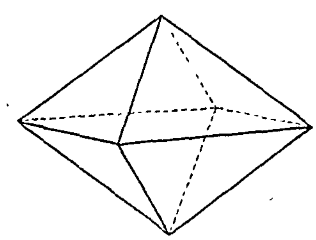

Fig. 78.

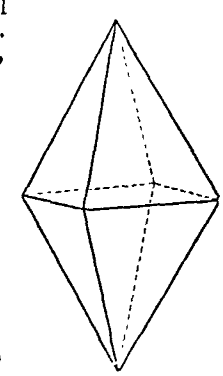

Fig. 79.

distinguished by the position of the lateral axes. In the first these axes unite the opposite angles; in the second they intersect the middle edges equally; and in the third they lie in an intermediate position, or divide these edges unequally,—the last being hemihedral forms. These pyramids are also distinguished as obtuse (fig. 78) or acute (fig. 79), according as the vertical angle is greater or less than in the regular octahedron. (2) Ditetragonal pyramids (fig. 80) are bounded by sixteen scalene triangles, whose base-lines are all in one

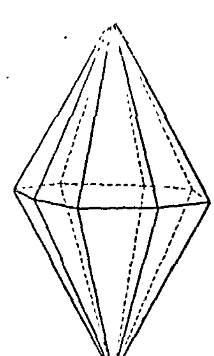

Fig. 80.

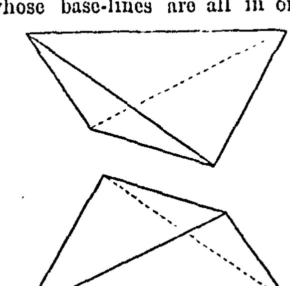

Fig. 81.

plane. This form rarely occurs except in combinations. (3) Tetragonal sphenoids (fig. 81), bounded by four isosceles triangles, are the hemihedral forms of the first variety of tetragonal pyramids. (4) The tetragonal scalenohedron (fig. 82), bounded by eight scalene triangles, whose bases rise and fall in a zigzag line, is the hemihedral form of the ditetragonal pyramid. Nos. (3) and (4) are rare. (5) The tetragonal trapezohedron is not found in minerals as a simple form. The three open forms are—(1) tetragonal prisms, bounded by four planes parallel to the principal axis, which may be either longer (fig. 83) or shorter (fig. 84) than the lateral axes; (2) ditetragonal prisms, bounded by eight similar planes; and (3) the basal pinacoid, consisting merely of two parallel faces bounding the prisms at the ends, above and below.

The various series of tetragonal crystals are distinguished from each other only by their relative dimensions. To determine these,

Primitive pyramid. one of the series must be chosen as the primary form, and for this purpose a tetragonal pyramid of the first variety, designated by P as its sign, is selected. The angle of one of its edges, especially the middle edge, found by measurement, determines its angular dimensions, whilst the proportion of the principal axis a to the

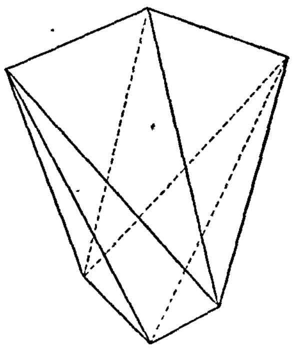

Fig. 82.

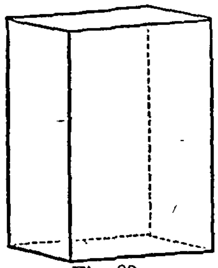

Fig. 83.

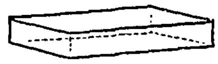

Fig. 84.

lateral axes, supposed equal to 1, gives its linear dimensions. The parameters, therefore, of each face of the fundamental form are $1 : 1 : a$.

Now if m be any (rational) number, either less or greater than unity, and if from any distance ma in the principal axis planes be drawn to the middle edge of P, then new tetragonal pyramids of the first order, but more or less acute or obtuse than P, are formed.

Derived pyramids. The general sign of these pyramids is mP, and the most common varieties $\frac{1}{2}$P, 2P, and 3P,—with the chief axis half, twice, or thrice that of P. If m becomes infinite, then the pyramid **Prism.** passes into a prism, indefinitely extended along the principal axis, and with the sign ∞P. If $m=0$, which is the case when the lateral axes are supposed infinite, then it becomes a **Pinacoid.** pinacoid, consisting properly of two basal faces open towards the lateral axes, and designated by the sign 0P. The ditetragonal pyramids are produced by taking in each lateral axis distances n greater than 1, and drawing two planes to these points from each of the intermediate polar edges. The parameters of these planes are therefore $m : 1 : n$, and the general sign of the form mPn, the most common values of n being $\frac{3}{2}$, 2, 3, and ∞. When $n=\infty$, a tetragonal pyramid of the second order arises, designated generally by mP∞, the most common in the mineral kingdom being P∞ and 2P∞. The relation of these to pyramids of the first order is shown in fig. 85, where ABBBC is the first and ACCCX the second order of pyramid. In like manner, from the prism ∞P, the ditetragonal prisms ∞Pn

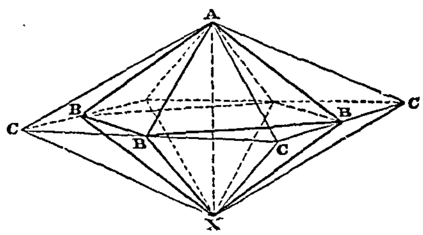

Fig. 85.

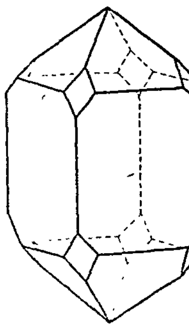

Fig. 86.

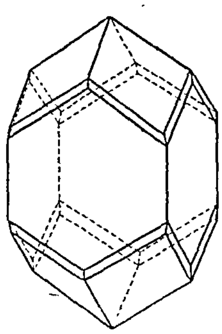

Fig. 87.

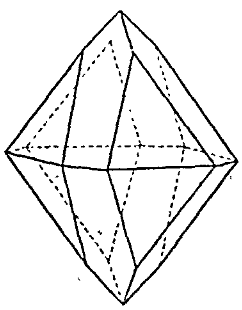

Fig. 88.

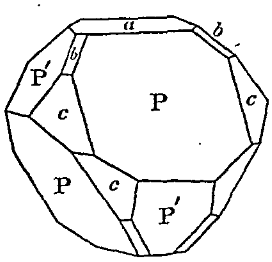

Fig. 89.

are derived, and, finally, when $n=\infty$ the tetragonal prism of the second order, whose sign is ∞P∞.

The combinations of the tetragonal system are either holohedral or hemihedral; but the latter are rare. Prisms and pinacoids must always be terminated on the open sides by other forms. Thus in fig. 86 a square prism of the first order is terminated by the primary pyramid, and has its lateral angles again replaced by another more acute pyramid of the second order, so that its sign is ∞P, P, 2P∞.

In fig. 87 a prism of the second order is first bounded by the fundamental pyramid, and then has its edges of combination replaced by a ditetragonal pyramid; its sign is ∞P∞, P, 3P3. In fig. 88 the polar edges of the pyramid are replaced by another pyramid, its sign being P, P∞. In fig. 89 a hemihedric form, very characteristic of chalcopyrite, is represented,—P and P′ being the two sphenoids, a the basal pinacoid, and b, c two ditetragonal pyramids.

Hexagonal system. III. *The Hexagonal System.*—The essential character of this system is that it has four axes,—three equal lateral axes intersecting each other in one plane at 60°, and one principal axis at right angles to these. The plane through the lateral axes, or the base, from its hexagonal form, gives the name to the system. As in the last system, its forms are either closed or open. They are divided into holohedral, hemihedral, and tetartohedral,—the last, which are rare, having only a fourth part of the faces developed. Only a few of the more common forms require to be here described.

Pyramids. The hexagonal pyramids (figs. 90, 91) are bounded by twelve isosceles triangles, and are of three kinds, according as the lateral axes fall in the angles, in the middle of the lateral edges, or in another point of these edges, the last being hemihedral forms. They are also classed as acute or obtuse, but without any precise limits. The trigonal pyramid is bounded by six triangles, and may be viewed as the hemihedral form of the hexagonal. The dihexagonal pyramid is bounded by twenty-four scalene triangles, but has never been observed alone, and rarely even in combinations. The more common prisms are the hexagonal of six sides; in these the vertical axis may be either longer than the lateral, as in fig. 92, or shorter, as in fig. 93. There are also dihexagonal, of twelve sides.

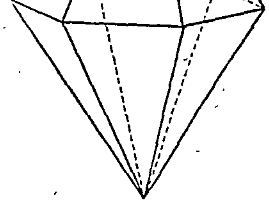

Fig. 90.

A particular pyramid P is chosen as the fundamental form of this system, and its dimensions determined either from the proportion of the lateral to the principal axis $(1 : a)$ or from the measurement of its angles. From this form (mP) others are derived exactly as in the tetragonal system. Thus dihexagonal pyramids are produced with the general sign mPn, the chief peculiarity being that, whereas in the tetragonal system n might have any rational value from 1 to ∞, in the hexagonal system it can only vary from 1 to 2, in consequence of the geometric character of the figure. When $n=2$, the dihexagonal changes into an hexagonal pyramid of the second order, whose sign is mP2. When $m=\infty$, various prisms arise from similar changes in the value of n; and when $m=0$ the basal pinacoid is formed.

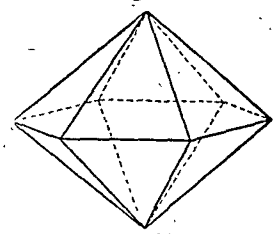

Fig. 91.

Few hexagonal mineral species form perfect holohedral combinations. Though quartz and apatite appear as such, yet properly the former is a tetartohedral, the latter a hemihedral species. In holohedral species the predominant faces are usually those of the hexagonal **Prisms.** prisms ∞P (fig. 92) and ∞P2, or of the pinacoid 0P (fig. 93); whilst the pyramids P and 2P2 are the most common subordinate forms. Fig. 94 represents the prism, bounded on the extremities by two pyramids,—one, P, forming the apex, the other, 2P2, the rhombic

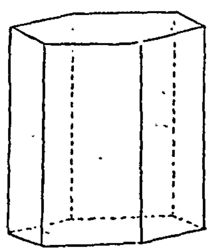

Fig. 92.

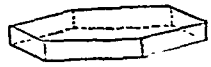

Fig. 93.

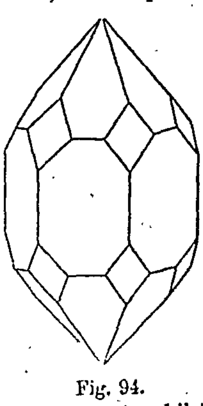

Fig. 94.

faces on the angles, or ∞P, P, 2P2. Fig. 95 is a similar form, the upper part of the pyramid being replaced by the pinacoid. In some crystals the lateral edges of the prism are replaced by the

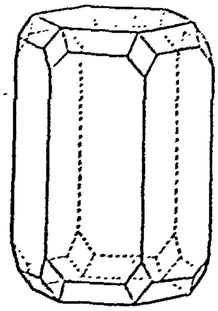

Fig. 95.

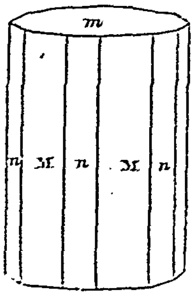

Fig. 96.

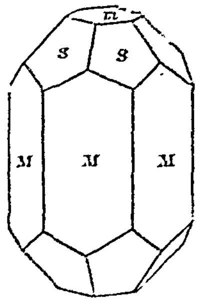

Fig. 97.

second prism ∞P2 (fig. 96), producing an equiangular twelve-sided prism, which always represents the combination ∞P, ∞P2, and cannot occur as a simple form. Figs. 97, 98 are combinations in this

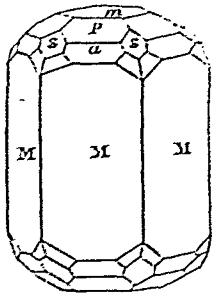

Fig. 98.

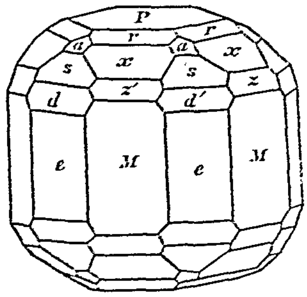

Fig. 99.

system seen in beryl. An example of a more complicated combination is seen in fig. 99, of a crystal of apatite, whose sign with the corresponding letters is ∞P(M), ∞P2(e), 0P(P), ½P(r), P(x), 2P(z), P2(a), 2P2(s), 4P2(d).

Rhombohedral forms. Hexagonal minerals frequently crystallize in those series of hemihedral forms that are named "rhombohedral," from the prevalence in them of rhombohedrons. These (figs. 100, 101) are bounded by

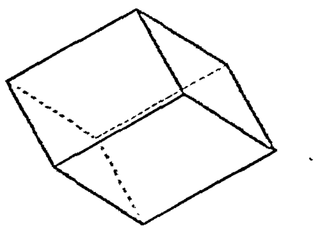

Fig. 100.

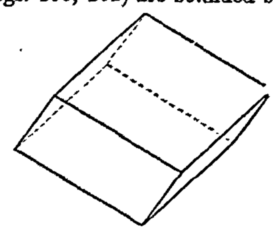

Fig. 101.

six rhombi, whose lateral edges do not lie in one plane, but rise and fall in a zigzag manner. The principal axis unites the two trigonal angles, formed by three equal plane angles; and in the most common variety the secondary axes join the middle points of two opposite edges. When the polar edges form an angle of more than 90°, the rhombohedrons are named obtuse; when of less than 90°, acute; fig. 102 represents the first, fig. 103 the second. Hexagonal scalenohedrons (fig. 104) are bounded by twelve scalene triangles, whose lateral

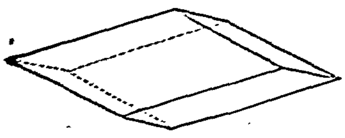

Fig. 102.

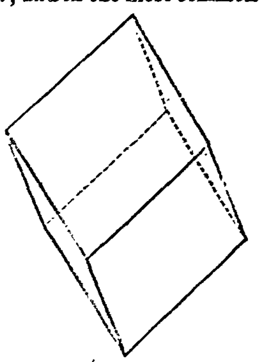

Fig. 103.

edges do not lie in one plane. The principal axis joins the two hexagonal angles, and the secondary axis the middle points of two opposite lateral edges.

The rhombohedron is derived from the first order of hexagonal pyramid by the hemihedral development of its alternate faces. Its general sign should therefore be $\frac{m\,\mathrm{P}}{2}$; but on several grounds it is found better to designate it by R or mR, and its complementary figure by $-m$R. When the prism or pinacoid arises as its limiting form, they are designated by ∞R and 0R, though in no respect changed from the limiting forms ∞P and 0P of the pyramid. The scalenohedron is properly the hemihedral form of the dihexagonal pyramid, but is more easily understood as derived from the inscribed rhombohedron mR. If the halves of the principal axis of this be multiplied by a definite number n, and then planes be drawn from the extremities of this enlarged axis to the lateral edges of the rhombohedron, as in fig. 105, the scalenohedron is constructed. It is now designated by mRn (the n on the right here referring to the chief axis), and the dihexagonal prism in this series by ∞Rn (formerly mR^n and ∞R^n).

The combinations of rhombohedral forms are very numerous, several hundreds having been described in calc-spar alone. Among the most common is the prism in combination with a rhombohedron, as seen in the twin crystal of calc-spar (fig. 106), with the sign ∞R, $-\frac{1}{2}$R, the lower half being the same form with the upper, but turned round 180°. In fig. 107 the rhombohedron mR has its polar

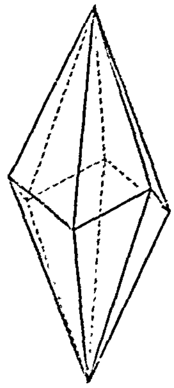

Fig. 104.

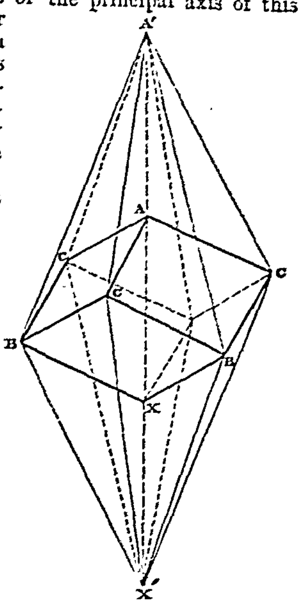

Fig. 105.

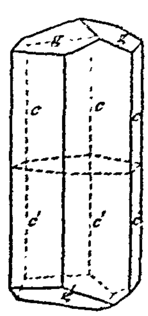

Fig. 106.

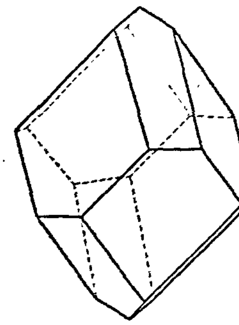

Fig. 107.

edges replaced by another rhombohedron $-\frac{1}{2}m$R, and in fig. 108 its lateral edges bevelled by the scalenohedron mRn. A more complex combination of five forms is represented in the crystal of calc-spar fig. 109, its sign, with the letters on the faces, being R^5(y), R^3(r), R(P), 4R(m), ∞R(c). Tetartohedral combinations are seen most distinctly in rock-crystal.

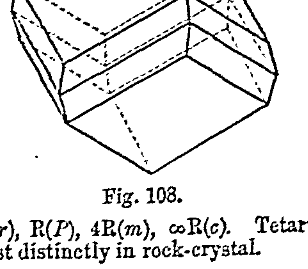

Fig. 108.

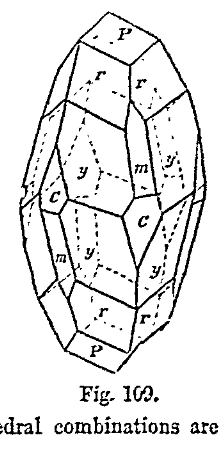

Fig. 109.

IV. *Right Prismatic or Rhombic System.*—This system is characterized by three unequal axes, all at right angles to each other. Any one of these may be assumed as the chief axis, when the others are named subordinate. The plane passing through the secondary axes, or the base, forms a rhombus, and from this one of its names is derived. As prismatic forms are most frequent (the prism standing vertically on the rhombic base), it is best defined as the right prismatic. This system comprises only a few varieties of forms that are essentially distinct, and its relations are consequently very simple.

Right prismatic system.

Pyramids. There are two closed forms. (1) The rhombic pyramids (figs. 110, 111), bounded by eight scalene triangles, whose lateral edges lie in one plane, and form a rhombus. They have eight polar edges (four acute and four more obtuse) and four lateral edges. The angles are six rhombic, the most acute at the extremities of the longest axis. (2) The rhombic sphenoids (figs. 112, 113) are bounded by four scalene

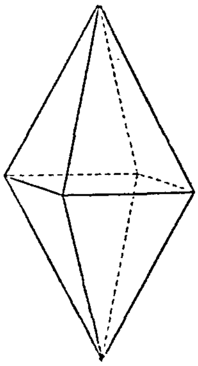

Fig. 110.

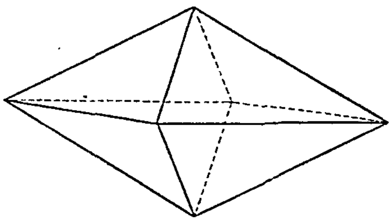

Fig. 111.

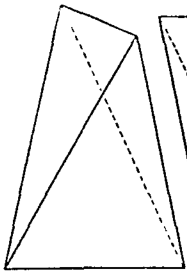

Fig. 112.

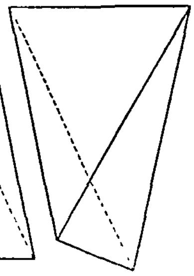

Fig. 113.

Sphenoids. triangles, with their lateral edges not in one plane, and are hemihedral forms of the rhombic pyramid. They are of very infrequent occurrence.

Prisms. The open forms, again, are rhombic prisms bounded by four planes parallel to one of the axes, which is indefinitely extended, and may be longer than the lateral, as in fig. 114, or shorter as in fig. 115. They are divided into upright (as in the above figs.) and horizontal prisms, according as either the principal or one or other of the lateral axes is supposed to become infinite. For the latter form the name doma or dome has

Domes. been used; and two kinds, the macrodome (fig. 116) and the brachydome (fig. 117), have been distinguished.

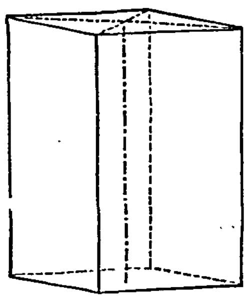

Fig. 114.

Pinacoids. Rhombic pinacoids also arise when one axis becomes $=0$ and the two others are indefinitely extended; and so we have macropinacoids (fig. 118) and brachypinacoids (fig. 119),—the qualifying term thus designating the axis to which the faces of the dome or pinacoid are parallel.

Fig. 115.

In deriving these forms from a primary, a particular rhombic pyramid P is chosen, and its dimensions determined either from the

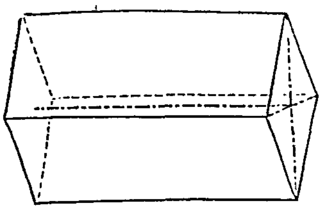

Fig. 116.

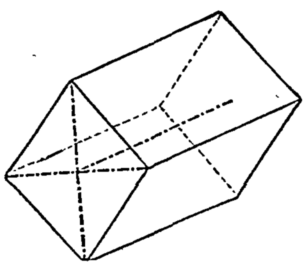

Fig. 117.

Macro- and brachy-diagonal. angular measurement of two of its edges, or by the linear proportion of its axes $a:b:c$, the greater lateral axis b being assumed equal to 1. To the greater lateral axis the name macrodiagonal is given, to the shorter that of brachydiagonal; and the two principal sections are in like manner named macrodiagonal and brachydiagonal, according to the axis they intersect. The same terms are applied throughout all the derived forms. They consequently mark only the position of the faces in respect to the axes of the fundamental crystal, and frequently of necessity without reference to the relative magnitude of the derived axes.

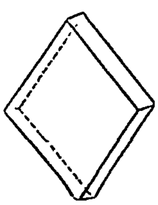

Fig. 118.

Fig. 119.

By multiplying the principal axis by any rational number m, greater or less than 1, a series of pyramids arise, whose general sign is mP, and their limits are the prism and pinacoid; the whole series being contained in this formula, $0P \ldots . mP \ldots . P \ldots . mP \ldots \ldots \infty P$,—which is the fundamental series, the lateral axes always remaining unchanged.

Derived forms. From each member a new series may, however, be developed in two directions, by increasing one or other of the lateral axes. When the macrodiagonal is thus multiplied by any number n greater than 1, and planes drawn from the distance n to the polar edges, a new pyramid is produced, named a macropyramid, with the sign $m\bar{P}n$, the mark over the P pointing out the axis enlarged. When $n=\infty$, a macrodome results, with the sign $m\bar{P}\infty$. If the shorter axis is multiplied, then brachypyramids and brachydomes are produced, with the signs $m\breve{P}n$ and $m\breve{P}\infty$. So also from the prism ∞P, on the one side, originate numerous macroprisms $\infty\bar{P}n$, with the limiting macropinacoid $\infty\bar{P}\infty$; on the other, numerous brachyprisms $\infty\breve{P}n$, with the limit form $\infty\breve{P}\infty$, or the brachypinacoid. In figs. 120, 121 the two domes are shown in their relation to the primitive pyramid.

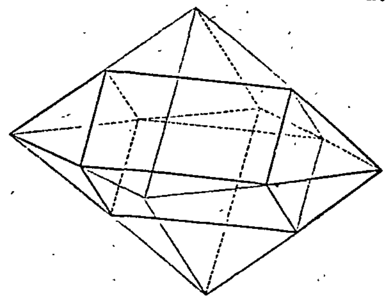

Fig. 120.

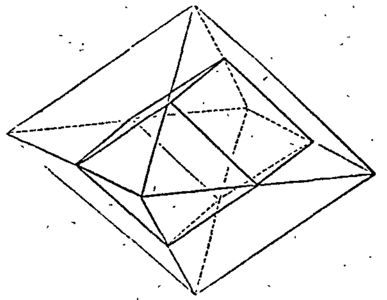

Fig. 121.

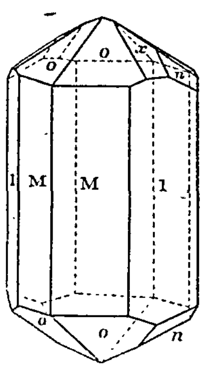

Fig 122.

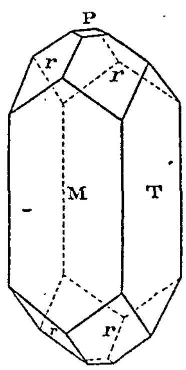

Fig. 123.

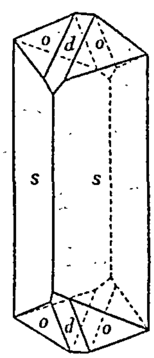

Fig. 124.

The pyramids seldom occur independent, or even as the predominant forms in a combination; sulphur, however, is an exception. Prisms or pinacoids usually give the general character to the crystal, which then appears either in a columnar or tabular or even rectangular pyramidal form. The determination of the position of these crystals, as vertical or horizontal, depends on the choice of the chief axis of the fundamental form. In the topaz crystal (fig. 122) the brachyprism and the pyramid are the predominant elements, associated with the prism, its sign and letters being $\infty\breve{P}2(l)$, $P(o)$, $\infty P(M)$. Fig. 123 of stilbite is another example, the macropinacoid $\infty\bar{P}\infty$ or M being combined with the pyramid $P(r)$, the brachypinacoid $\infty\breve{P}\infty\,(T)$, and the basal pinacoid $0P(P)$. Another instance is fig. 124 of a lievrite crystal, where the brachyprism and pyramid combine

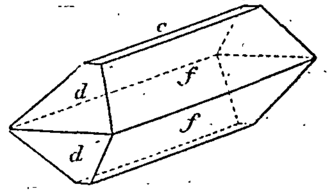

Fig. 125.

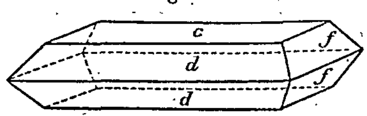

Fig. 126.

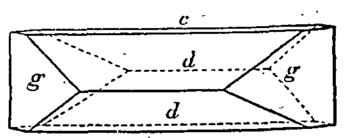

Fig. 127.

with the macrodome, or $\infty\breve{P}2$, P, $\bar{P}\infty$. The above figures are very common forms of barytes,—figs. 125 and 126 being both composed of the pinacoid 0P, a brachydome, and a macrodome, with sign 0P(*c*), $\breve{P}\infty$(*f*), $\frac{1}{2}\bar{P}\infty$(*d*). The variation in aspect arises from the predominance of different faces; and fig. 127 consists of the macrodome $\frac{1}{2}\bar{P}\infty$, the prism ∞P(*g*), and the pinacoid 0P.

Oblique prismatic system.

V. *The Oblique Prismatic System.*—This system is characterized by three unequal axes, two of which intersect each other at an oblique angle, and are cut by the third at right angles. One of the oblique axes is chosen as the chief axis, and the other axes are then distinguished as the orthodiagonal (right-angled) and clinodiagonal (oblique-angled). The same terms are applied to the chief sections, and the name of the system refers to the fact that these two planes form with the base two right angles and one oblique angle C.

Hemi-pyramidal character.

The *forms of this system approach very near to those of the right* prismatic series, but the inclination of the axis, even when almost *a right angle, gives them a* peculiar character, by which they are always readily distinguished. Each pyramid thus separates into two altogether independent forms or hemipyramids.

Prisms.

Three varieties of prism also occur—vertical, inclined, and horizontal—with faces parallel to the chief axis, the clinodiagonal, or the orthodiagonal. The horizontal prisms, like the pyramids, separate into two independent partial forms named hemiprisms or hemidomes. The inclined prisms are often designated clinodomes, the term prism being restricted to the vertical forms. Orthopinacoids and clinopinacoids are also distinguished, from their position in relation to the axes. The monoclinic pyramids (*fig.* 128) are bounded by eight scalene triangles of two kinds, four and four only being similar. Their lateral edges lie all in one plane, and the similar triangles are placed in pairs on the clinodiagonal polar edges.

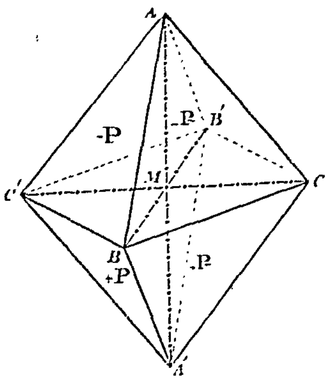

Fig. 128.

+ and − pyramids.

The two pairs in the acute angle between the orthodiagonal and basal sections are designated the positive hemipyramid, whilst the two pairs in the obtuse angles of the same sections form together the negative hemipyramid. But, as these hemipyramids are wholly independent of each other, they are rarely observed combined. More frequently each occurs alone, and then forms a prism-like figure, with faces parallel to the polar edges, and open at the extremities. Hence, like all prisms, they can only appear in combination with other forms. The vertical prisms are bounded by four equal faces parallel to the principal axis, and the cross section is a rhombus; the clinodomes have a similar form and section; whilst the horizontal prisms or domes have unequal faces, and their section is a rhomboid.

The mode of derivation of these forms closely resembles that of the rhombic series. A complete double pyramid is assumed as the fundamental form, and designated $\pm$P, in order to express the two portions of which it consists. Its dimensions are given when the proportion of its axes $a:b:c$ and the angular inclination of the oblique axes C, which is also the inclination of the orthodiagonal section to the base, are known.

The fundamental series of forms is 0P . . . . $\pm m$P . . . . $\pm$P . . . . $\pm m$P . . . . ∞P, from each of whose members, by changing the dimensions of the other axes, new forms may be again derived. Thus from $\pm m$P, by multiplying the orthodiagonal by any number n, a series of orthopyramids $\pm m\mathrm{P}^{o}n$ is produced, with the orthodomes $m\mathrm{P}^{o}\infty$ as limiting forms. The clinodiagonal produces a similar series of clinopyramids $\pm m\mathrm{P}^{c}n$, with the limiting clinodome $m\mathrm{P}^{c}\infty$ always completely formed, and therefore without the signs $\pm$ attached. From ∞P arise orthoprisms $\infty\mathrm{P}^{o}n$ and the orthopinacoid $\infty\mathrm{P}^{o}\infty$, and clinoprisms $\infty\mathrm{P}^{c}n$ and the clinopinacoid $\infty\mathrm{P}^{c}\infty$. In these signs the *o* or *c* attached to the P indicates that the orthodiagonal (*o*) or clinodiagonal (*c*) axis has been multiplied. Formerly the latter forms were enclosed in brackets, thus $(m\mathrm{P}\infty) = m\mathrm{P}\infty$.

The combinations of this system may be easily understood from their resemblance to those of the right prismatic, the chief difficulty being in the occurrence of *partial* forms, which, however, closely resemble the hemihedral forms of the previous systems. A few examples only need therefore be given.

Fig. 129 represents a very common form of gypsum crystals, $\infty\mathrm{P}^{c}\infty$, (*P*), ∞P(*f*), P(*l*). The most common form of augite is represented in fig. 130, with the sign ∞P(*M*), $\infty\mathrm{P}^{o}\infty$(*r*), $\infty\mathrm{P}^{c}\infty$(*l*), P(*s*).

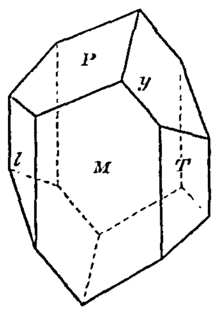

Fig. 131.

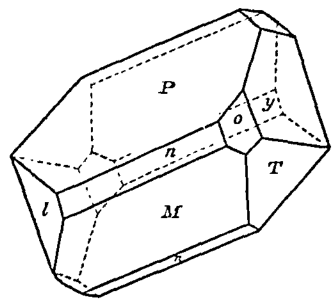

Fig. 132.

Fig. 131 is a crystal of common felspar or orthoclase, composed of the clinopinacoid $\infty\mathrm{P}^{c}\infty$(*M*), the prism ∞P(*T*), the basal pinacoid 0P(*P*), and the hemidomes $2\mathrm{P}^{o}\infty$(*y*); to which, in fig. 132 of the same mineral, the hemipyramid P(*o*) and the clinodome $2\mathrm{P}^{c}\infty$(*n*) are added.

Anorthic system.

VI. *Anorthic or Triclinic System.*—This is the least regular system, and departs the most widely, indeed almost absolutely, from symmetry of form. The axes are all unequal, and inclined at angles none of which are right angles,—so that, to determine any crystal, or series of forms, the proportion of the axes $a:b:c$, and also their angles, or those of the inclination of the chief sections, must be known. As in the previous systems, one axis is chosen as the principal axis, and the two others distinguished as the macrodiagonal and brachydiagonal axes. In consequence of the oblique position of the principal sections, this system consists entirely of partial forms wholly independent of each other, and each composed only of two parallel faces. The complete pyramid is thus broken up into four distinct quarter-pyramids, and the prism into two hemiprisms. Each of these partial forms is thus nothing more than a pair of parallel planes, and the various forms consequently mere individual faces. This circumstance renders many triclinic crystals very unsymmetrical in appearance.

Triclinic pyramids (fig. 133) are bounded by eight triangles whose lateral edges lie in one plane. They are equal and parallel two and two to each other, each pair forming, as just stated, a tetartopyramid or open form, only limited by combination with other forms, or, as we may suppose, by the chief sections. The prisms are again either vertical or inclined; the latter are named *domes*, and their section is always rhomboidal. In deriving the forms, the fundamental pyramid is placed upright with its brachydiagonal axis to the spectator, and the partial forms designated, the two upper by 'P and P', the two lower by ,P and P,, as in the figure. The further derivation now follows as in the right prismatic system, with the modifications already mentioned.

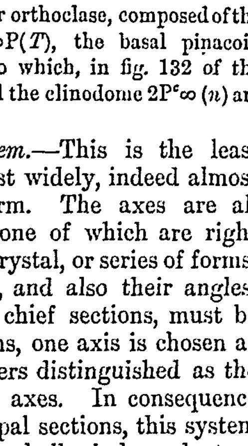

Fig. 133.

Some combinations of this system, as the series exhibited by most of the felspars, approach very near to the oblique prismatic system; whilst others, as cyanose and axinite, show great incom-

pleteness and want of symmetry. In the latter case the determination of the forms is often difficult. In the albite crystal (figs. 134, 135) P is the basal pinacoid $0P$; M the brachydiagonal pinacoid $\infty\breve{P}\infty$; s the upper right pyramid P'; l the right hemiprism $\infty P'$; T the left hemiprism $\infty' P$; and x the hemidome $'\bar{P}'\infty$. Figs. 136 and 137 are crystals of axinite, the former from Dauphiné,

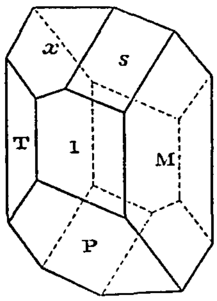

Fig. 134

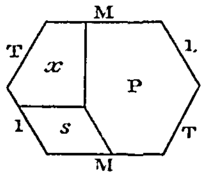

Fig. 135.

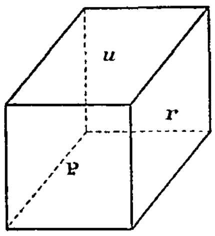

Fig. 136.

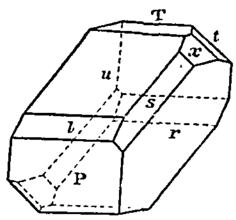

Fig. 137.

the latter from Cornwall, of whose faces the following is the development:—r the macropinacoid $\infty\bar{P}\infty$; P the left hemiprism $\infty' P$; u the left upper quarter-pyramid $'P$; l the left upper quarter-pyramid $2'P$; s the left upper partial form of the macropyramid $3'\bar{P}3$; and x the hemidome $2'P'\infty$.

The Measurement of the Angles of Crystals.

The permanence of the angular dimensions of crystals shows the importance of some accurate method of measuring their angles,—that is, the inclination of two faces to each other. Instruments for this purpose are called goniometers. Goniometers.

Two have been specially used for this purpose—the common or contact goniometer, invented by Caringeau, and the reflecting goniometer of Wollaston. The former is simply two brass rulers turning on a common centre, between which the crystal is so placed that its faces coincide with the edges of the rulers, and the angle is then measured on a graduated arc. This instrument is sufficiently accurate for many purposes and for large crystals, but for precise determination is far inferior to the reflecting goniometer. This requires smooth and even faces, but these may be very small, even the hundredth of an inch; and, as small crystals are generally the most perfect, far greater accuracy can be attained.

The reflecting goniometer is represented in fig. 138. It consists essentially of a graduated circle mm, divided on its edge into twice 180°, or more frequently into half-degrees, the minutes being read off by the vernier hh. This circle turns on an axis connected with tt, so that by turning this the circle is moved round, but it is stopped at 180°, when moving in one direction, by a spring at k. The other part of the instrument is intended to attach and adjust the crystal to be measured. The first axis of mm is hollow, and a second axis, aa, passes through it from ss, so that this and all the connected parts from b to f can be turned without moving the circle mm. The axis d passes through a hole in bc, so that it can turn the arm dc into any required position; f is a similar axis turning the arm og, and pq a fourth axis, in like manner movable in g, and with a small knob at q, to which the crystal to be measured is attached.

When about to be used, the instrument should be placed on a table, with its base horizontal (which is readily done by the screws in it), and opposite to a window at about 12 or 15 feet distance, so that its axis shall be parallel to the horizontal bars of the window. One of the upper bars of the window, and also the lower bar, or, instead of the latter, a white line on the floor or table parallel to the window, should then be chosen, in order to adjust the crystal. The observer places himself behind the instrument with the side a at his right hand. The crystal is then attached to q by a piece of wax, with the two faces to be measured upwards, and the edge of union of the faces, including the angle to be measured, as nearly as possible in the line of aa. The eye being brought near to the first face of the crystal, the axes aa and p are turned till the image of the window is seen reflected in the face with the horizontal and vertical bars in their position. The axis d is then turned through a considerable angle (say 60°), and the image of the window again sought and brought into its proper place by turning the axis f, without moving p. When this is done that face is brought into its true position, normal to d, so that no motion of d can disarrange it. Hence the image of the window may now be sought in the second face, and brought into its true position, with the horizontal bars seen horizontal, by moving the axes d and a. When this is done the crystal is properly "adjusted." The angle is measured in the following manner. First bring the zero of the circle and vernier to coincide, and then turn the inner axis a or ss, and move the eye till the image of the upper bar of the window reflected from the more distant face of the crystal coincides with the lower bar or horizontal line seen directly. Keeping the eye in its place, turn the other axis tt till the reflected image of the upper bar in the other face in like manner coincides with the lower line; the angle of the two faces is then read off on the divided circle. As the angle measured is not directly that of the faces but of the rays of light reflected from them, or the difference between the angle wanted and 180°, the circle has the degrees numbered in the reverse direction, so as to give the angle without the trouble of subtracting the one from the other.

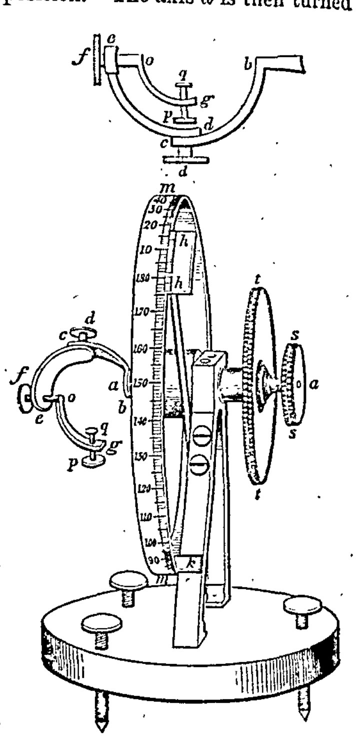

Fig. 138.

The apparatus figured is for adjusting the crystal, and is an improvement suggested by Naumann. In the original instrument the axis fo was made to push in or out in a sheath, and had a small brass plate, bent at right angles, inserted in a cleft at o, to which the crystal was attached. The crystal was adjusted as formerly by moving the plate, or the axis fo, and by slight motion of the arm dc, which should be at right angles nearly to bc when used. A very marked improvement is to have a small mirror fixed on the stand below the crystal, with its face parallel to the axis aa, and inclined at 45° to the window, when the lower line can be dispensed with, and the instrument used for various other purposes of angular measurement. Many more perfect instruments have been introduced for the purpose of insuring greater accuracy; but the simple instrument is sufficient for all purposes of determinative mineralogy, and the error from the instrument will, in most cases, be less than the actual variations in the angles of the crystals.

Departure from Geometric Simplicity and Loss of Regularity in Crystals.

Such departures may be regulated by law, or may result from an undue operation of the force of accretion in certain directions.

1. *Regular Departures from Simplicity.*—There are three varieties of this:—parallel groupings, twin forms, hemitrope forms.

Parallel Groupings.—A plurality of individuals are here arranged either so that a line which joins their centres becomes a prolongation of one or other of their crystallographic axes, or so that their axes are parallel. Crystal groups.

Fig. 20 shows the first, where cohesion sufficient for stability requires that the minute octahedra must mutually penetrate somewhat into each other. Fig. 139 shows the same in baryte. If we suppose octahedra united, the upper left-hand face of the one with the lower right-hand face of the other, there would be parallelism of their axes. Re-entering angles would, in such cases, prove a plurality of individuals, but if a number of cubes were superimposed in similar position, no such angles would occur, an elongated square prism resulting; and such arrangements, if

repeated, are linear, or, with diminishing size in the individual, acicular.

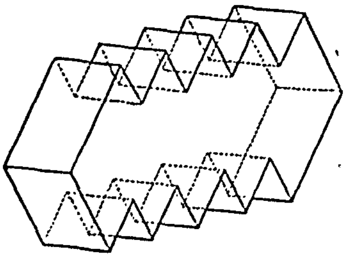

Fig. 139.

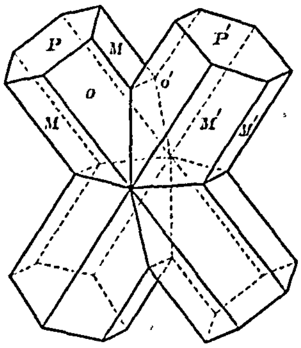

Fig. 140.

Duplex crystals.

Twins and Hemitropes.—Though closely related, formed under the operation of very similar laws, and to a certain extent passing into one another, these are not the same. In the first case a plurality of individuals must be present; in the second this is not necessary. In fig. 140 two individuals evidently intersect one another; in figs. 141, 142 one individual may be supposed to have been bisected in a certain direction, and the two halves reattached, but in a position differing in some definite manner from their relative position before the separation.

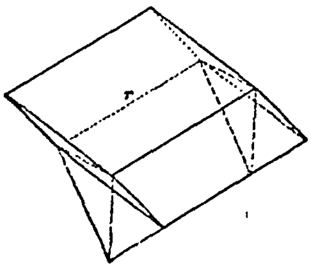

Fig. 141.

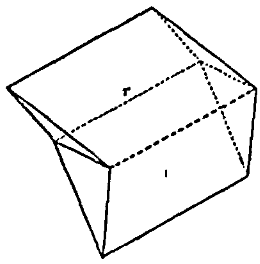

Fig. 142.

Varieties of twins.

There are four varieties of true twins: those of apposition, of intersection, of partial or completed interpenetration, and of incorporation.

The first is exemplified by spinel, as in fig. 143; the second by

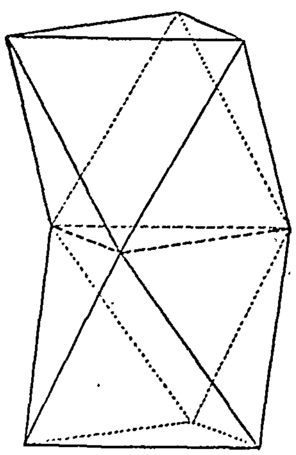

Fig. 143.

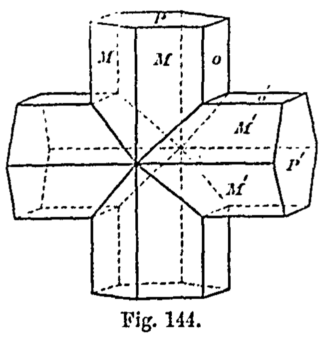

Fig. 144.

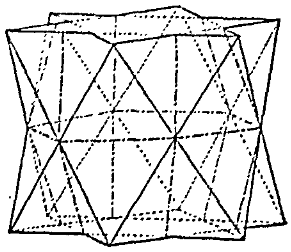

Fig. 145.

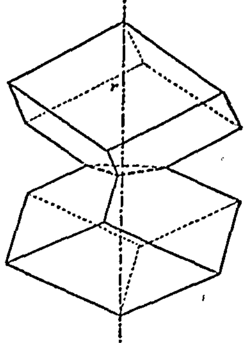

Fig. 146.

staurolite, as in fig. 144; the third by calcite, as in fig. 146, and by blende, as in fig. 145, where the two individuals of fig. 143 may be supposed to have been forced vertically into one another; and the last by quartz, as in fig. 147.

Laws of twinning.

The following are the laws of union of twins. 1. The face of union of twins, termed the "face of composition," must be either a plane which does occur in the mineral twinned, or which can occur in accordance with the fifth law of symmetry. A face of

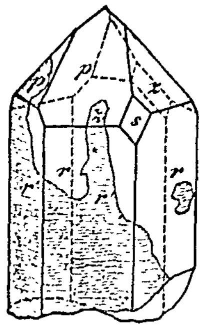

Fig. 147.

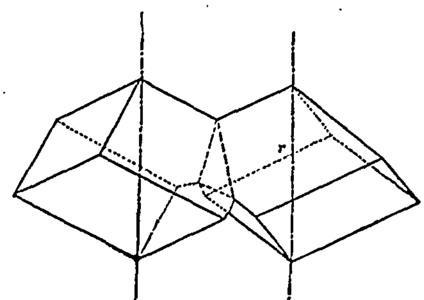

Fig. 148.

union in twins is also a face of union in hemitropes of the same mineral. 2. From the above it results that the axes of the united crystals are either parallel (fig. 148) or inclined (fig. 149). The former generally occur among hemihedric forms; and the two crystals are combined in the exact position in which they would be derived from or would reproduce the primary holohedral form. The class with oblique axes occur both in holohedric and in hemihedric forms; and the two individuals are then placed in perfect symmetry, in accordance with law 1.

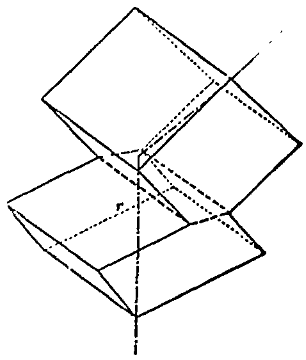

Fig. 149.

Twins are generally recognized by having *re-entering angles* (figs. 150, 151); but sometimes the crossed faces coincide in one plane, when the combination appears as a single individual (figs. 152, 153). The line of union may then be imperceptible, or it may be disclosed by the intersection of two sets of striæ (figs. 154, 155), or by some physical diversity in the characters of the two faces.

The formation of twin crystals may be again, or many times, repeated,—forming groups of three, four, twenty-four, or more. When the faces of union are parallel to each other, the crystals form

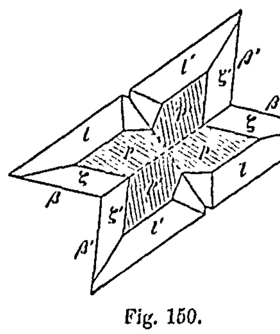

Fig. 150.

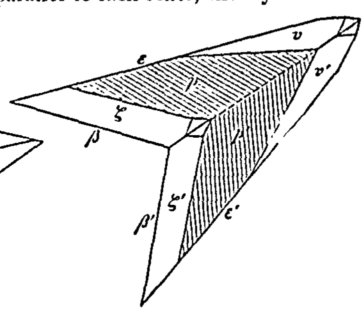

Fig. 151.

rows of indeterminate extent. When they are not parallel, they may return into each other in circles, as in rutile; or form bouquet or rosette groups, as in chrysoberyl (fig. 156); or stellate groups, as in calcite (fig. 157) and in cerussite (figs. 158, 159).

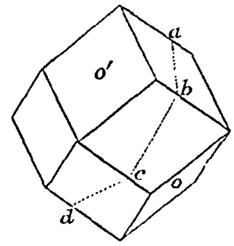

Fig. 152.

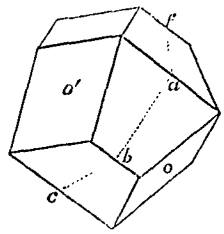

Fig. 153.

When the crystals are of different size, greater complexity results; but a number of minute crystals are frequently arranged upon a larger at those points where the angles of a single large crystal would protrude. Occasionally a simple form is twinned with a more complex one, as in chabasite (fig. 160).

Hemitropes. Hemitrope crystals we may imagine as having been formed from a single crystal, which has been cut into two halves in a particular direction, and one half turned round 180°, or 90°, or 60°. The line about which the revolution is supposed to take place is called the "axis of revolution." From the amount of turn usually being 180°, Haüy gave the name hemitrope. The position of the two

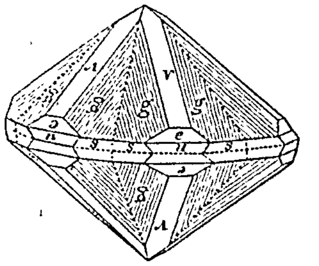

Fig. 154.

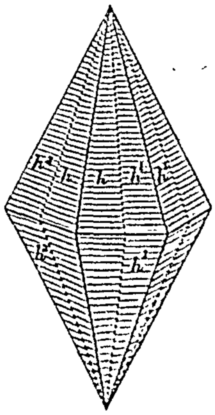

Fig. 155.

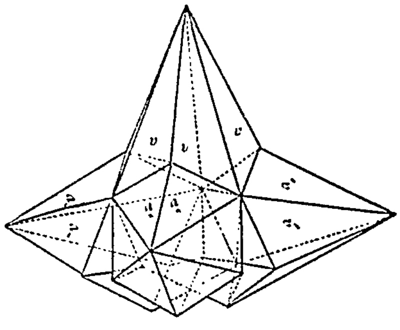

Fig. 157.

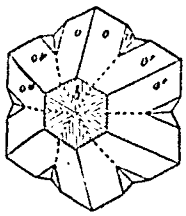

Fig. 156.

halves in this case resembles that of an object and its image in a mirror, whose surface then would represent the plane of reunion.

Laws of hemitropism. The following are the laws of hemitropes. The axis of revolution is always a possible crystallographic line,—either an axis, a line parallel to an axis, or a normal to a possible crystalline plane. The plane normal to the axis of revolution is called the twin plane; it is either an occurring or a possible plane, and usually one of the more frequently recurring planes. Both the axis and the twin plane

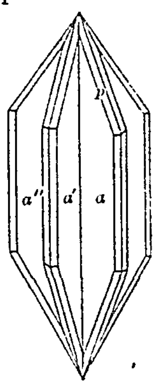

Fig. 158.

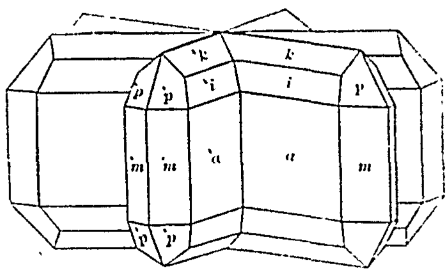

Fig. 159.

bear the same relation to both halves of the crystal in their reversed positions; consequently the parts of hemitrope crystals are symmetrical with reference to the twin plane (except in triclinic forms and some hemihedral crystals). The face of composition very frequently coincides with the twin plane; when not coinciding, the twin plane and the face of composition are generally at right angles to each other, so that the composition face is parallel to the axis of revolution. But in twins of incorporation the surfaces of composition have exercised a disturbing influence on one another, so that the surface of union is exceedingly irregular. Still in these cases the axis and the plane of twinning retain a definite position; but the face of composition, being no longer defined, is useless as a determinant.

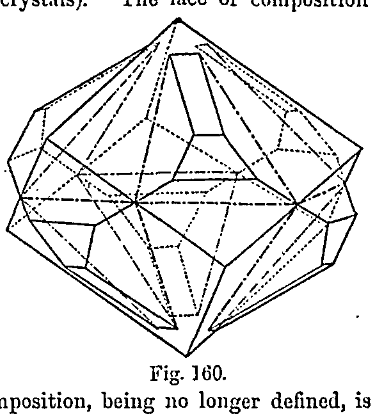

Fig. 160.

Modes of union. There are three modes in which the composition may take place in hemitropes. These may be explained by dividing a crystal into halves, with the plane of division vertical, and then turning one of the halves round.

1. One of the halves may be inverted, as if by revolution through 180° on a horizontal axis *at right angles to the plane of section*, and the two faces again united by the surfaces which were separated. Here the surfaces of union are the original ones, but the base of one of the halves has taken the place of its summit. Examples: selenite (fig. 161) and orthoclase.

2. One of the halves may be turned round through 180°, as if by revolution on *a horizontal axis, parallel to the plane of section*, and the face opposite and parallel to that of the plane of section—an originally external face—may then be applied to the other half. Here, not only has the base of one-half become a summit, but a lateral and external face of the original crystal has been thrust to its centre so as to become a face of internal union. Example: labradorite (fig. 162).

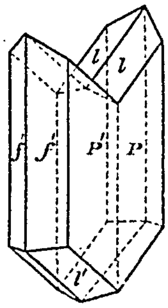

Fig. 161.

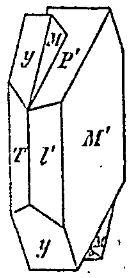

Fig. 162.

3. One of the halves may be turned round through 180°, as if by revolution *on a vertical axis*, parallel to the plane of section, the external face opposite and parallel to the plane of section becoming a face of union. Here, however, both the original summits retain their position as summits. Example: orthoclase.

The first of these modes of composition may occur in each of the systems, but it is not always apparent until disclosed by optical properties. The second is rare, and the third still more so.

In hemitrope crystals (less frequently in true twins) the halves of the crystal are frequently reduced in thickness in the direction of the ordinary twin axis; and when there is a parallel repetition of hemitropes, which frequently occurs, they are often reduced to very thin plates, not the thickness of paper, giving to the surface of the aggregate a striated structure and appearance.

Twins of cubic system. In the *cubic system* the faces of composition, both of twinning and of hemitropic revolution, are those of the cube, the dodecahedron, and the octahedron.

In the first case we have the axes of the two crystals necessarily in some cases parallel, or, more correctly, falling into one; but, as in this system all the axes are alike, or all the cubic faces similar, composition may occur along or parallel to all alike, and double or triple twins occur. We have examples in twins of the pentagonal dodecahedron (fig. 163) made up by the interpenetration of a right

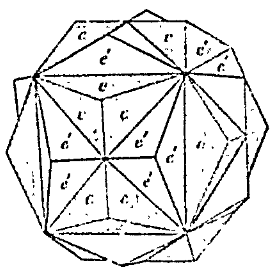

Fig. 163.

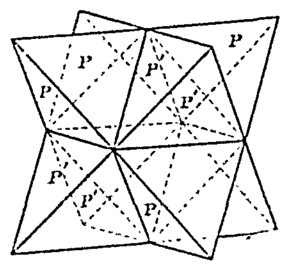

Fig. 164.

and a left (+ and −), and of the tetrahedron, as seen in pyrite and fahlerz respectively. In virtue of the position required by law 2, it will be seen that the position of the solid which is common to both intersecting crystals is in the twin of pyrite the four-faced cube, which is the holohedral form of the pentagonal dodecahedron, while in the case of the fahlerz twin (fig. 164), the common portion is an octahedron, the holohedral form of the tetrahedron.

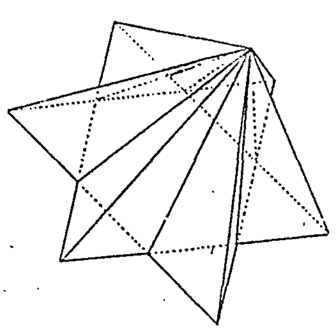

Fig. 165.

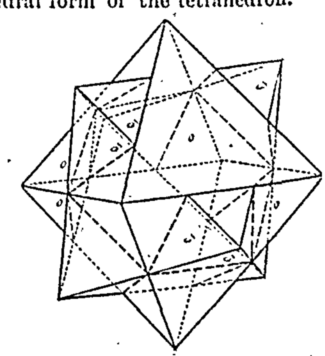

Fig. 166.

Twinning on an octahedral face is seen in the apposition twin of spinel (fig. 143), the tetrahedral twin of blende (fig. 165), the interpenetrative octahedral twin of blende seen in fig. 166, and the intersecting cubes of fluor (fig. 167).

This is also the usual twin face for hemitropes of the cubic system.

It is seen in fig. 168 of blende, where the two parts of the rhombic dodecahedron are united by it. Magnetite, spinel, and diamond

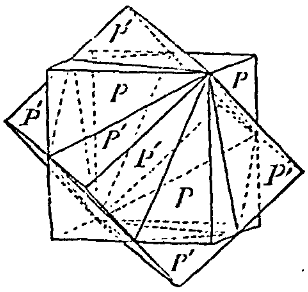

Fig. 167.

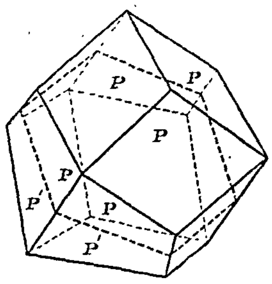

Fig. 168.

frequently occur in octahedral hemitropes of the same composition (fig. 169).

This is also the face of composition for tetartohedral hemitropes. Fig. 170 is that of the diamond. Here six of the faces of the six-

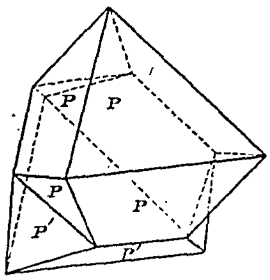

Fig. 169.

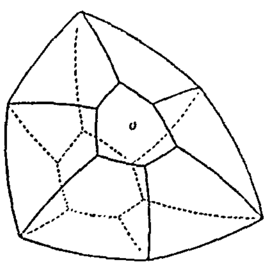

Fig. 170.

faced octahedron, with six faces diagonally opposite, form a low double six-sided pyramid (a portion of an octahedral face truncating each) through an 180° revolution of one set of these. Garnet sometimes shows both twins and hemitropes of the dodecahedron, of dodecahedral composition.

Tetragonal twins. In the *tetragonal system*, twin crystals are very uncommon, but hemitropes frequent. With parallel axes they very seldom occur, but are seen in chalcopyrite. When the axes are inclined, the plane of union is usually one of the faces of the primary pyramid; and, as these faces are all similar, composition may take place simultaneously parallel to all. Very complicated forms hence result, as seen in chalcopyrite and in cassiterite (fig. 171).

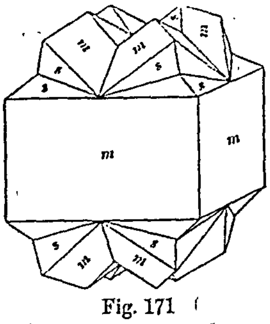

Fig. 171

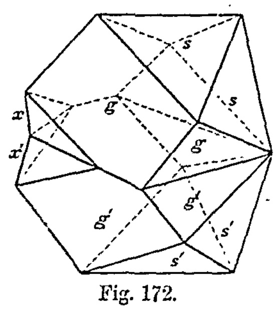

Fig. 172.

In cassiterite the plane of union is frequently one of the faces of the pyramid P∞, sometimes one of those faces that replace the polar edges of P (figs. 172 173). From the bend the latter form is termed geniculated.

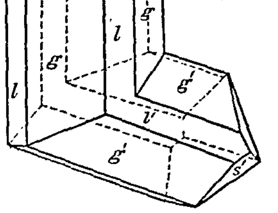

Fig. 173.

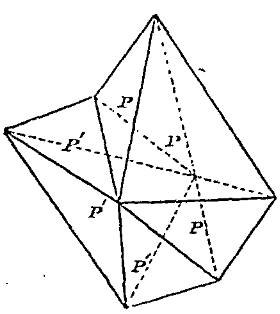

Fig. 174.

Hausmannite occurs in hemitropes of the primary P; and on the polar edges of this other twins are symmetrically repeated, a central individual appearing like a support to the others (figs. 174, 175).

Hexagonal twins. In the *hexagonal system* twins are very common among the rhombohedral (the hemihedral) and the tetartohedral forms; while hemitropes prevail among the hexagonal or holohedral forms. The twins are generally formed by the interpenetration of two rhombohedrons, a + and a −, the vertical axis being the axis of composition; as in chabasite (fig. 176), cinnabar, levyne, calcite, &c. Sometimes six or more crystals, united parallel to the prismatic planes,

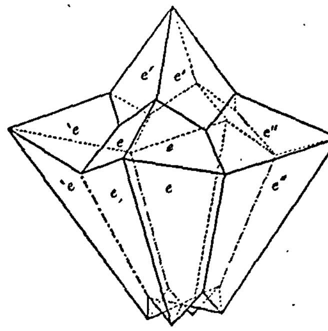

Fig. 175.

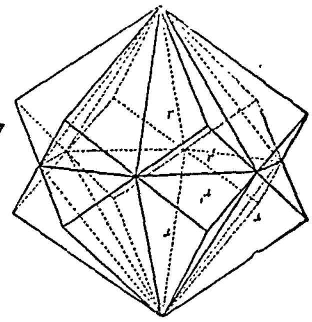

Fig. 176.

form rosettes; as in chabasite from Giant's Causeway. The almost endless stellate forms of crystals of snow are built up in this manner. Many of the most beautiful combinations to be seen among crystals result from this mode of arrangement.

Parallel groupings of hexagonal prisms also occur, as in apatite (fig. 177).

Rock crystal, in consequence of the tetartohedral character of its crystallization, exhibits twins in which the double hexagonal pyramid P may be said to be separated into two rhombohedrons *P* and *r*; these, though geometrically similar, are physi-

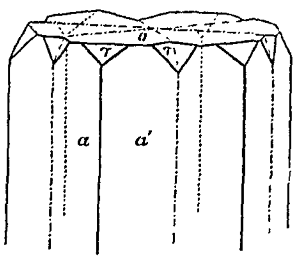

Fig. 177.

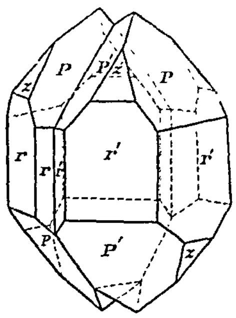

Fig. 178.

cally distinct. In fig. 178 the two individuals have not entirely interpenetrated, and might be regarded as simply grown together with parallel axes; but in fig. 147 there is so complete an interpenetration that the composite character of the crystal is only evidenced through a difference in the character of the surfaces of the two halves, which are most irregularly disposed.

The hemitropes of this system often form regular crystals, when the two halves have been united by a plane parallel to the base, so as to appear like a simple crystal, as in fig. 179. Here each end shows the forms ∞R, $-\frac{1}{2}$R, but the terminal faces appear in parallel instead of alternate position. Something of the same is seen in fig. 180, a hemitrope scalenohedron from Derbyshire. Hemitropes with the face of the primitive rhombohedron as the face of composition are also common; and they are sometimes joined by a face of $-\frac{1}{2}$R, the two axes forming an angle of 127° 34′. Occasionally a third individual is interposed in a lamellar form, as in fig. 181, where the faces of the two outer portions become parallel. This is found in some pieces of Iceland spar. When the crystals unite in a face of the primary rhombohedron, they form an angle of 89° 8′; hemitropes on this law are easily recognized by their differing so little from a right angle in the re-entering bend (figs. 182, 183).

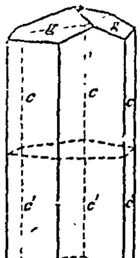

Fig. 179.

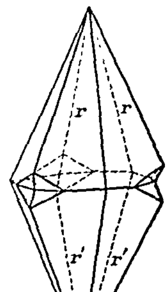

Fig. 180.

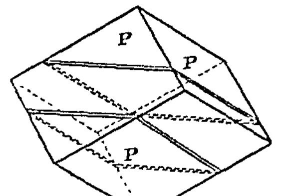

Fig. 181.

The faces which in this species act as faces of composition are exceedingly numerous; other examples are figs. 142, 146, 148, and 149.

Right prismatic twins. In the *right prismatic system* twin crystals with parallel axes are rare, but with oblique axes common, the faces of union being one of the faces of the prism ∞P. Twins of this kind occur frequently in

aragonite, cerussite, mispickel, and marcasite. In aragonite the crystals are partly interpenetrating, and partly merely in juxtaposition, as in fig. 184, where the individuals are formed by the

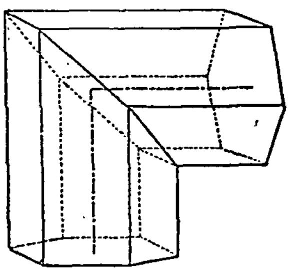

Fig. 182.

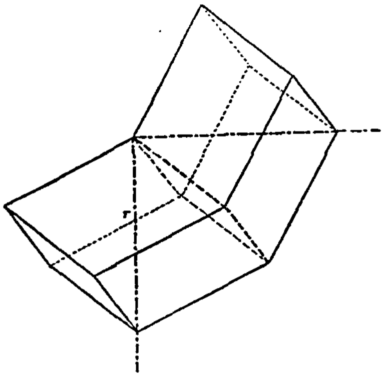

Fig. 183.

combination $\infty P(M)$, $\infty\breve{P}\infty(h)$, $\bar{P}\infty(k)$. In fig. 185 several crystals of the same combination form a series with parallel planes of union, the inner members of which are often so shortened that they form mere films, which appear as striæ on the faces $\breve{P}\infty$ and $\infty\breve{P}\infty$ of the twin.

In fig. 186 four crystals, each of the combination $\infty P, 2\breve{P}\infty$, having united in inclined planes, form a circular group, which returns into

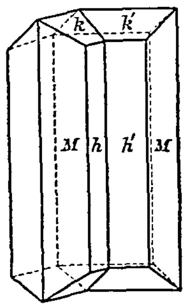

Fig. 184.

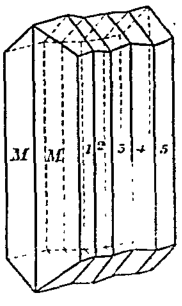

Fig. 185.

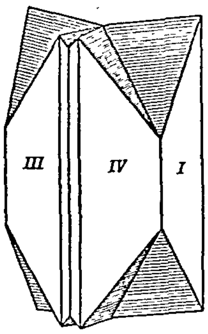

Fig. 186.

itself. Cerussite occurs in similar groups, building up a composite hexagonal crystal. It also occurs in stellate twins of two or three individuals, as in figs. 158, 159. Similar stellate combinations are also common in chrysoberyl. In staurolite, individuals of the prismatic combination ∞P, $\infty\breve{P}\infty$, $0P$ combine, either as in fig. 144 by a face of the brachydome, having their chief axes almost at right angles, or as in fig. 140 by a face of the brachypyramid $\frac{3}{2}\breve{P}\frac{3}{2}$, the chief axes and the brachypinacoids (o) of each of the crystals meeting at an angle of about 60°. This mineral, which is very frequently twinned, also forms combinations with the axes parallel (fig. 187).

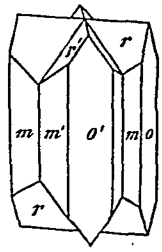

Fig. 187.

Oblique prismatic twins.

In the *oblique prismatic system*, twins are by no means so frequent as hemitropes. Twins of interpenetration with parallel axes, but the one turned as regards the other round a vertical axis, are common in orthoclase (figs. 188, 189). Such crystals are termed right-handed (fig. 188) and left-handed (fig. 189), according to the side of the crystal which has been turned. In this mineral hemitropes occur around an axis normal to M, to P, and to n (fig. 529); double twins of the last two are common (fig. 530).

Twins of hemitropes.

Harmotome and phillipsite form first hemitropes, and *then* twins of these, which are arranged sometimes as crosses and sometimes as double crosses (fig. 190). In hemitropes of gypsum the two halves are united by a face parallel to the orthodiagonal section, as in fig. 161, where the two halves have united so regularly that the faces P′, P form only one plane. In a similar manner the two halves of the augite crystal represented in fig.

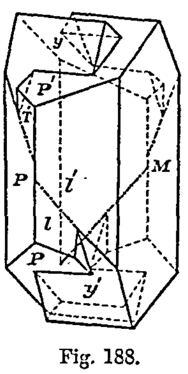

Fig. 188.

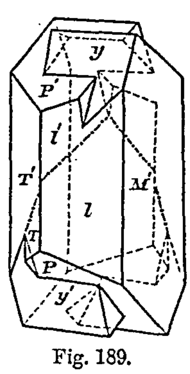

Fig. 189.

130 are in fig. 191 united so perfectly and symmetrically that the line of junction cannot be observed on the clinopinacoid. The two hemipyramids $P(s)$ (like $-P(l)$ in the gypsum crystal) form at one end of the crystal a re-entering, at the other a salient angle.

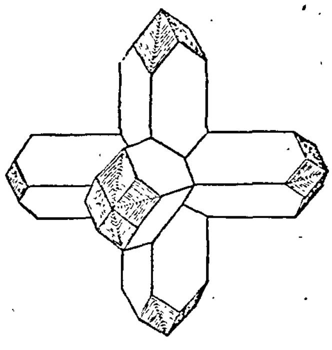

Fig. 190.

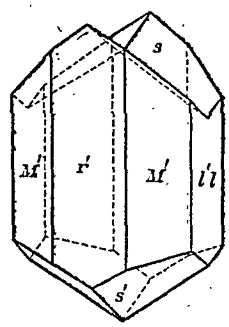

Fig. 191.

Hornblende (fig. 192) and wolfram exhibit a similar appearance. This results in the imparting a pseudo-hemimorphism to certain oblique prismatic twins, which is well seen in the twins of sphene (figs. 193 and 589), and in exalting the characteristic appearance of true hemimorphs, as seen in the twin of acmite (fig. 194). In other cases the individuals partially penetrate each other in the direction of the orthodiagonal. This mode of union is not uncommon in gypsum, and is very frequent in orthoclase. Two crystals

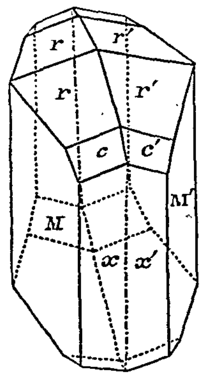

Fig. 192.

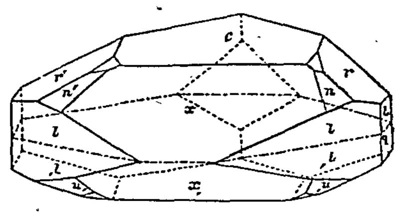

Fig. 193.

of the latter of the combination $(\infty P\infty)$, ∞P, $0P$, $2P\infty$, as in fig. 131, are often pushed into each other, as shown in fig. 195.

Anorthic twins.

In the *anorthic system* some twin formations are of great importance, *e.g.*, as a means of distinguishing the triclinic from the monoclinic species of felspar. In one variety the twin axis is the normal to the brachydiagonal chief section. But in the anorthic felspars this section is not perpendicular to the base, and consequently the two bases form on one side a re-entering, on the other a salient angle; whereas in the oblique prismatic felspars (where the brachydiagonal chief section corresponds to the clinodiagonal) no twin crystals can be produced in conformity to this law, and the two bases fall in one plane.

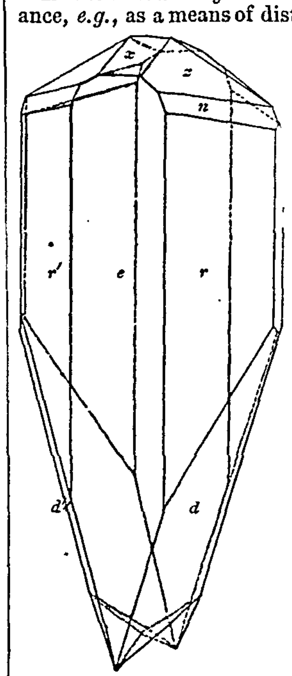

Fig. 194.

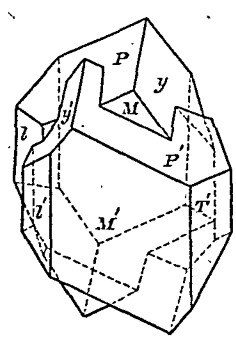

Fig. 195.

Albite and oligoclase very often exhibit such twins as in figs. 196, 197, where the very obtuse angles formed by the faces of $0P$, or P and P' (as well as those of $'\bar{P}'\infty$, or x and x'), are a very characteristic appearance, marking out this mineral at once as a triclinic species. Usually the twin formation is repeated, three or more crystals being combined, when those in the centre are reduced to mere plates. When very numerous, the surfaces P and x are covered with fine striæ, often only perceptible with a microscope. A second law observed in triclinic felspars, particularly in albite and labradorite,

is that the twin axis corresponds with that normal of the brachy-diagonal which is situated in the plane of the base. In pericline, a variety of albite, these twins appear as in fig. 198, where the two crystals are united by a face of the basal pinacoid *P*, whilst the faces of the two brachypinacoids (*M* and *M'*) form edges with very obtuse angles (173° 22'), re-entering on the one side and salient on the other. These edges, or the line of junction between *M* and *M'*, are also parallel to the edges formed by these faces and the base, or those between *M* and *P*. In this case also the twins are occasionally several times repeated, when the faces appear covered by fine striæ.

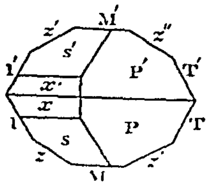

Fig. 196.

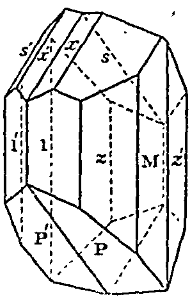

Fig. 197.

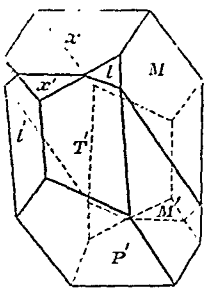

Fig. 198.

Twin growth.

Cause of the Formation of Twins and Hemitropes.—It has been shown above that the relative position of the molecules of crystals is determined by a polarity in the molecules themselves. This polarity must exist along three lines which intersect in the centre of the molecules; and unlike poles must attract each other. It has been supposed that compound crystals result from a reversion of the original polarity of the molecules of a crystal, after it has attained a certain size. Heat and electricity, resulting from movements in strata, might occasion such reversion during the formation of a crystal, and this would suffice for the explanation of hemitropes, though not directly of geniculated crystals, and still less of intersecting twins. Twins have accordingly been divided into "paragenetic" and "metagenetic." The first term is applied to the ordinarily occurring twins, in which the compound structure is supposed to have had its beginning in a nucleal compound molecule, or to have been compound in its very origin. In metagenetic twins the crystal was at first simple, but afterwards, through some change in the material furnished for its increase or possibly induced in itself, it received new layers, or an extension *in a reversed position.*

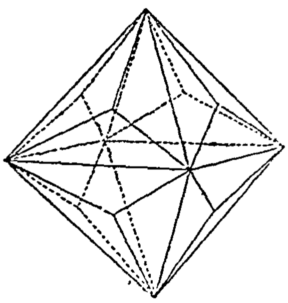

Fig. 199.

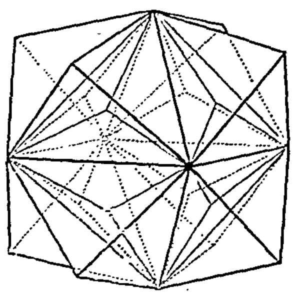

Fig. 200.

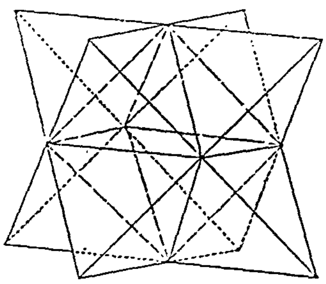

Fig. 202.

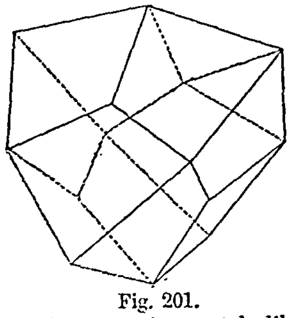

Fig. 201.

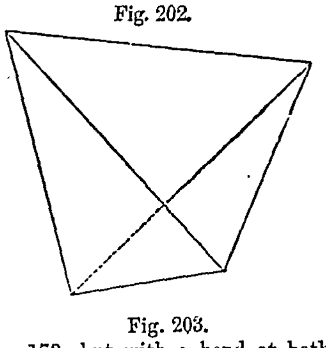

Fig. 203.

Rutile occurs in crystals like fig. 173, but with a bend at both extremities, instead of one only. Here the middle portion of the crystal is supposed to have attained a length of half an inch, and then it became geniculated simultaneously at both extremities; indeed, in this mineral such geniculations are frequently repeated until the ends are bent into one another, and produce short hexagonal prisms with central depressions or even vacuities. The repeated twinning which produces striation, as in calcite and the felspars, and the peculiar rippled structure of amethyst, are ascribed to a similar operation, acting in an oscillatory manner.

Certain intersecting twins in the cubic system may be explained simply through excessive or undue accretion of molecules along certain lines. At page 351 it was shown how the three-faced octahedron (fig. 39) was formed through an accretion of molecules upon the faces of the octahedron along axes joining the centres of its faces (those which connect the solid angles of the cube). It was also shown that when through this accretion two faces of the triakis-octahedron (fig. 199), adjacent along the edge of the octahedron, rose into one plane the rhombic dodecahedron resulted. If now accretion still goes on along the same axes, so that the trihedral pyramid rises above the level of the dodecahedral planes, fig. 200 results. This is the twin of the three-faced tetrahedron (fig. 201).

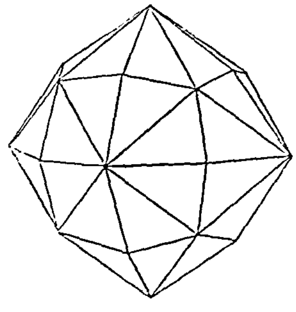

Fig. 204.

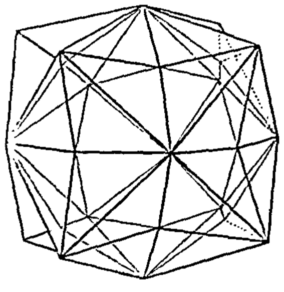

Fig. 205.

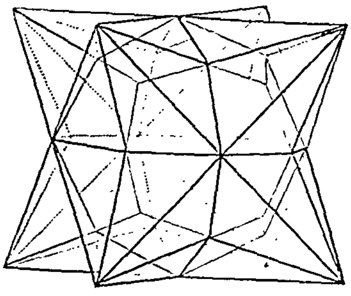

Fig. 207.

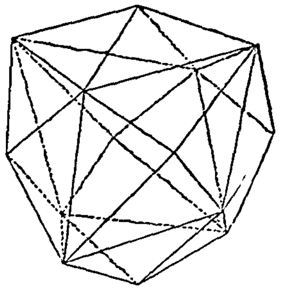

Fig. 206.

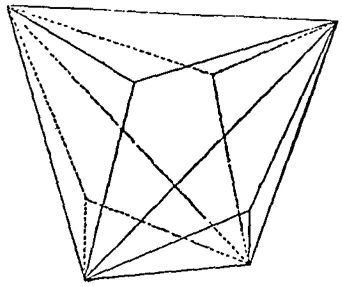

Fig. 208.

If the accretion is still along the same axes until the lateral edges of the adjacent pyramids fall into the same line, fig. 202 results; and this is the twin of the simple tetrahedron (fig. 203). Here accretion upon the faces of a complex holohedral form has produced a twin of a simple hemihedral form.

Again, starting from the six-faced octahedron (fig. 204), there is produced by the same process first fig. 205, the twin of the six-faced tetrahedron (fig. 206), and ultimately fig. 207, the twin of the three-faced tetrahedron (fig. 208).

Distortions.

2. *Departure from Regularity on Account of Undue Accretion in certain Directions.—Distortion of Crystals.*—The laws of crystallization should produce crystal forms of perfect symmetry; these laws, however, are subject, not only to the influence of other laws, but also frequently to disturbing influences which are subject to no law. Absolute symmetry, therefore, is very uncommon, crystals being generally so distorted and disguised through interference during their formation that either familiarity on the one hand or skill on the other is necessary for their recognition. As the magnitude of the angles may vary somewhat, even this guide may sometimes perplex. Hence it is necessary to be familiar with such departures from symmetry; and some of the more common are here noticed.

Of cube.

In the cubic system a cube (fig. 26), lengthened or shortened along one axis, becomes a right square prism (fig. 209), and if elongated in the direction of two axes is changed to a rectangular prism (fig. 7). Cubes of pyrites, galena, fluor-spar, &c., are generally thus distorted. It is very unusual to find a cubic crystal that is a true symmetrical cube. In some species the cube or octahedron (or other monometric form) is lengthened into a capillary

crystal or needle, as happens in red copper and pyrites. Crystals of acicular pyrites occur at the Newton-Stewart lead-mine.

An octahedron flattened parallel to two of its faces is reduced to a tabular crystal (fig. 210). If lengthened in the same direction, it takes the form in fig. 211; or if it is still further lengthened, to the obliteration of two opposite octahedral faces, it becomes an acute rhombohedron (same figure).

Of octahedron.

When an octahedron is extended in the direction of a line between two opposite edges, it has the general form of a rectangular octahedron; and still further extended, as in fig. 212, it is changed to a rhombic prism with dihedral summits. The figure represents this prism lying on its acute edge (spinel, fluor, magnetite).

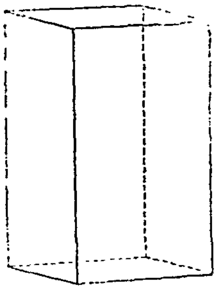

Fig. 209.

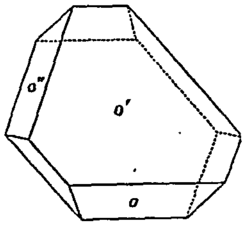

Fig. 210.

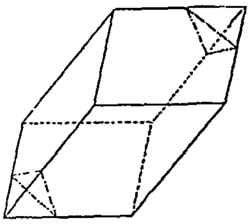

Fig. 211.

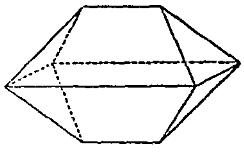

Fig. 212.

Of dodecahedron.

The dodecahedron when lengthened in the direction of the upright axis becomes a square prism with pyramidal summits (fig. 213); and when shortened along the same axis it is reduced to a square octahedron with truncated basal angles (fig. 214). Both

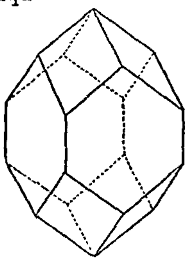

Fig. 213.

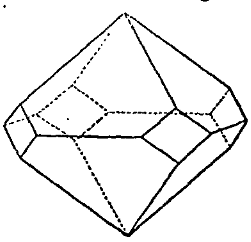

Fig. 214.

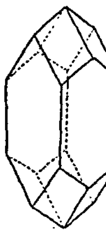

Fig. 215.

these forms are modifications of the square prism; the first mode of distortion is common in garnet, rendering it liable to be considered zircon; the second is seen in aplome, when it might be taken

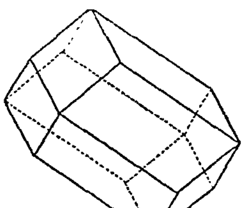

Fig. 216.

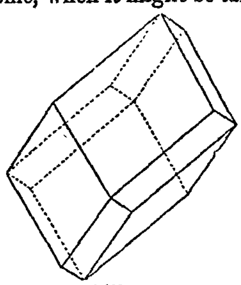

Fig. 217.

for stannite. When the first of these forms is flattened, as in fig. 215 it resembles a form of stilbite.

When a dodecahedron again is lengthened along a diagonal between the obtuse solid angles, it becomes a six-sided prism with trihedral summits, as in fig. 216; and when shortened in the same direction, it becomes a rhombohedron which has its six acute angles truncated (fig. 217). In the first case, a crystal of green garnet or uwarowite would resemble dioptase; in the latter, colourless garnet would resemble calcite.

Of trapezohedron.

The trapezohedron is exceedingly subject to distortions which frequently disguise it much. When elongated in the direction of the upright axis it becomes a double eight-sided pyramid with four-sided summits (fig. 218); a further elongation along the same axis would result in the obliteration of these summit faces, and in the production of a perfect double octagonal pyramid (fig. 219). The first of these distortions is exceedingly common in analcime and not

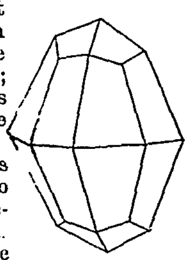

Fig. 218.

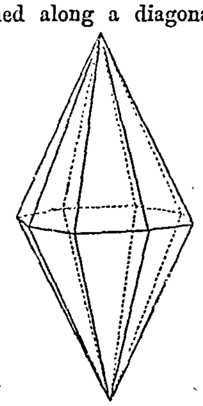

Fig. 219.

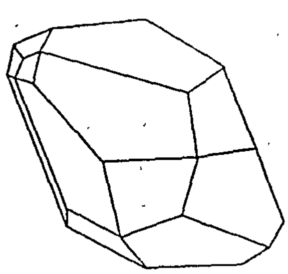

Fig. 220.

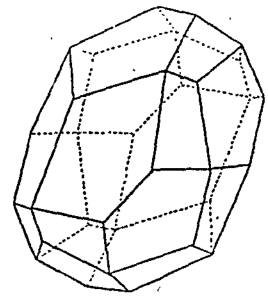

Fig. 221.

uncommon in garnet; the latter rarely occurs in analcime. Lengthened along an octahedral axis it becomes fig. 220; shortened along the same it becomes fig. 221. Both are seen in analcime.

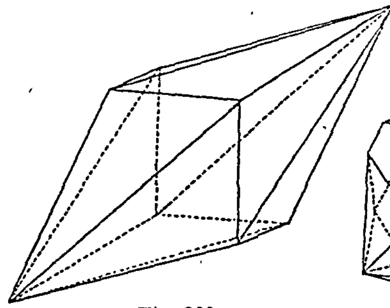

Fig. 223.

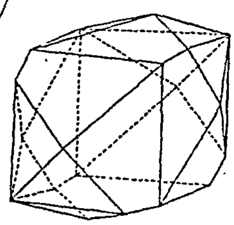

Fig. 222.

Of tetrakishexahedron.

When the tetrakishexahedron is lengthened along a single octahedral axis it assumes the form of fig. 222; still further elongated, with obliteration of one half of its planes, it becomes a scalene dodecahedron. resembling the "dog tooth" form of calcite (fig. 223). Fig. 224 is a hemihedron of this form, produced by shortening along an octahedral axis, with obliteration of all the planes which do not touch the poles of that axis.

In the case of modified crystals of this system the distortions are more complex. Fig. 225 represents a crystal of cinnamon-stone from Aberdeenshire; it is a combination of the dodecahedron and the trapezohedron. Only four dodecahedral faces remain (*d*), and those of the trapezohedron (*n*) are of unequal size. It may be best understood by regarding it as fig. 218 with the four vertical faces of fig. 213; so that it combines the distortions of both of these figures.

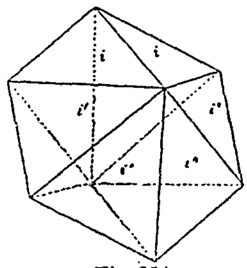

Fig. 224.

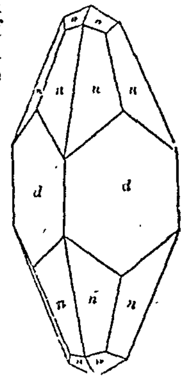

Fig. 225.

Crystals of diamond are very frequently distorted, though generally through curvatures of their faces.

Imperfections in the Surfaces of Crystals.

Of these the most important are striæ, caverns, and curvatures.

Imperfection of surfaces.

1. *Striated Surfaces.*—The parallel furrows on the surfaces of crystals are called striæ, and such surfaces are said to be striated. Each ridge on a striated surface is enclosed by two narrow planes. These planes often correspond in position to a secondary or to the primary planes of the crystal, and we may suppose these ridges to have been formed by repeated oscillation in the operation of those causes which give rise, when acting uninterruptedly, to larger planes. By this means the surfaces of a crystal are marked in parallel lines with a succession of narrow planes, meeting at angles alternately re-entering and salient, and constituting the ridges referred to. This combination of different planes in the formation of a surface has been termed an oscillation of faces.

Striation.

Cubes of pyrites are generally striated in such a way that the striæ on adjacent faces are at right angles to one another. These lines are parallel to the intersections of the primary faces with the planes of the pentagonal dodecahedron, which is the most common form of pyrites; and they have evidently resulted from an oscillation between the primary and this secondary form.

The rhombic dodecahedron is often striated parallel either with the

edges, or with the longer or the shorter diagonal of its faces. In the first case, seen in *garnet* (fig. 226), there is a passage into the six-faced octahedron; the second results from an oscillatory combination of the dodecahedron with the regular octahedron, as in magnetite; and the last with the cube, as in aplome.

Rhombohedrons of chabasite are often striated parallel to the

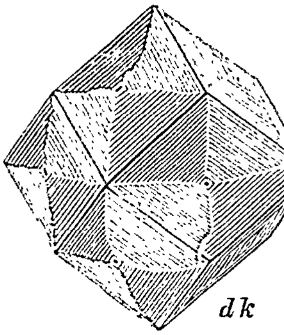

Fig. 226.

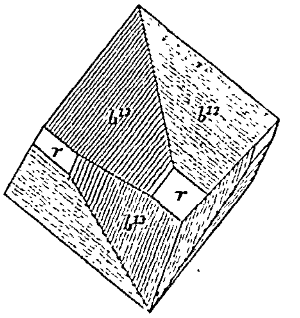

Fig. 227.

terminal edges (fig. 227), indicating an oscillatory combination between the primary faces and a secondary plane which bevels these edges.

Striation of faces is more frequent in the rhombohedral system than in any of the others. Horizontal striæ are of almost invariable occurrence in the prismatic faces of quartz, whatever be the form of the crystal. The oscillation here has taken place between the pyramidal and the prismatic faces (figs. 228, 229, 230). During its growth there seems to have been a continued effort to complete the crystal by the assumption of the terminal planes,—which effort was intermittently overcome by a preponderating one to continue the deposition of matter along its main axis. Quartz crystals, from these alternate efforts, often taper to a point, without having any regular pyramidal face.

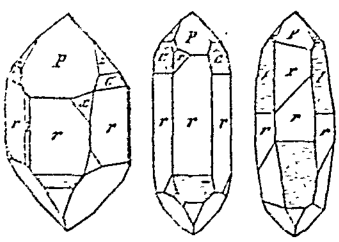

Fig. 228. Fig. 229. Fig. 230.

The lateral planes of prisms of tourmaline are very frequently convex, owing to oscillation between several lateral faces. In all such cases the interfacial angles cannot be determined, as they are lost in the rounding.

The striations on the lateral faces of foliated minerals are merely the edges of laminæ. Examples: mica and gypsum.

Cavernous faces.

2. *Cavernous Crystals.*—Crystals not unfrequently occur with a deep pyramidal depression occupying the place of each plane, as is often observed in common salt, galena (fig. 21), and sulphur. In the solution of crystals through atmospheric exposure, an approach to the same form is sometimes obtained, owing to the fact that the centres of the faces yield sooner than the edges and angles. Crystals of redruthite are often thus cavernous. Sometimes octahedrons occur with a triangular cavity, in place of each face (fig. 22). The same is met with in other forms.

Curved surfaces.

3. *Curved Surfaces.*—Curved surfaces sometimes result from the oscillatory combination already noticed. Others result from a curvature in the laminæ constituting the crystal. Crystals of diamond have convex faces, and are sometimes almost spheres. This mode of curvature, in which all the faces are equally convex, is less common than that in which a convex surface is opposite and parallel to a corresponding concave surface. Rhombohedrons of spathic iron and pearl spar are usually thus curved, as is shown in fig. 231. The saddle-shaped crystals of the same mineral (fig.

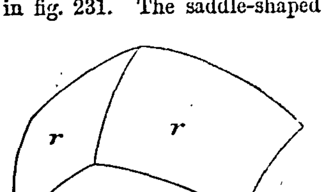

Fig. 231.

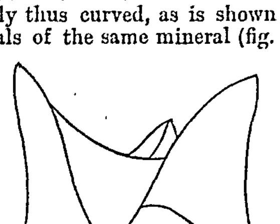

Fig. 232.

232) are remarkable instances of several reversed curvatures in the same face. A singular curvature is shown in fig. 233, of calcite. The conical crystals of brown zinc blende, and the lenticular and conical crystals of gypsum, are other examples. Crystals of quartz are sometimes curved and twisted. When this takes place in the left-handed and right-handed crystals, the twist is to the right or left according as the crystal is right- or left-handed.

The surfaces of crystals are frequently far from flat, on account of fracture, with dislocation of the several fragments, occasioned by motion in the enclosing rock, the material of which is forced, or it may be transfused, into the rents. The tourmalines and beryls (fig. 234) which occur in granitic dykes are very subject to this, the fragments being often bent as well as displaced. A more or less simultaneous effort in the crystallization of two substances may produce a structure with the external form of one, the interior of which exhibits imbedded crystals of the other, more or less perfect in their development. In *pegmatite or graphic granite*, rude crystals of felspar contain skeleton forms of quartz, of which generally only one side of the prism and two of the pyramid occur, forming a rude lettering. Similar hollow quartz forms occur imbedded in garnet, radiating from its centre (fig. 235), and roughening its surface from protrusion, without distorting its form. Totally imbedded microscopic crystals, "microliths," are, as in the latter cases, chemi-

Dislocated crystals.

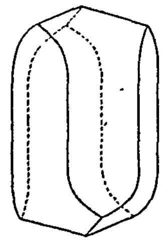

Fig. 233.

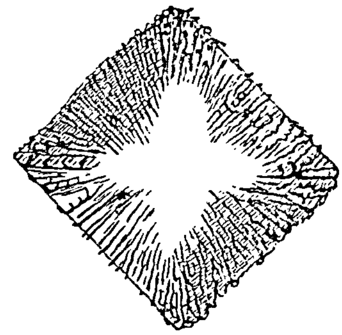

Fig. 235.

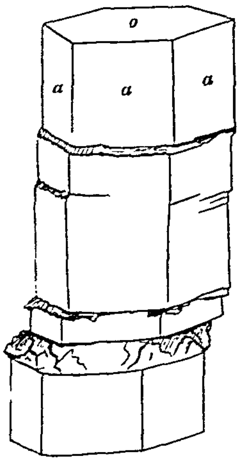

Fig. 234.

Fig. 236.

cally non-assimilable. These are frequently arranged in layers in the including crystal, as in augite and leucite. When there is a certain amount of chemical resemblance there may occur a definiteness in the arrangement; and if the enclosed substance crystallizes in a system differing from that of the mineral which includes it, the angles of the latter are more or less distorted. This is the case in "microcline," where the intrusion of a plagioclastic felspar causes some departure from the rectangularity of orthoclase. Foreign amorphous matter caught up or attaching itself to the surface of a crystal, during the process of its growth, causes lines of feeble cohesion,—as in the case of capped crystals of quartz. Here an occasional selectiveness in the sets of faces to which the foreign matter adheres seems to indicate that it has been to some extent under the influence of a polarity in its adhesion. Something of the same kind seems to have influenced the arrangement of the quartz grains caught up during the formation of the crystal of garnet shown in fig. 236. The perfect modelling of rock crystals is, however, but little interfered with by the almost numberless substances which they contain.

Aggregation of Crystals.

Crystalline aggregates which pass into amorphous masses may, in their more marked or perfect form, be assigned to an imperfect twinning.

Regular aggregates.

Crystals are often grouped in linear series, as in native copper and silver, and thus constitute long threads or reticulations. In clustered crystals those adjoining each other are generally parallel in position, and are united by a plane parallel to one of the principal sections, or to planes of common occurrence. Senarmont mentions a union in galena,

parallel to the octahedral faces, as common · and he also describes an instance where the union was parallel to the plane $3\frac{3}{2}$.

The positions of crystals on the supporting rock seem at first to be without any regularity. But by closer inspection we detect even here the same law of harmony that governs the formation of the simple and compound crystal. The various positions assumed correspond generally with the more common kinds of composition in twin crystals. This regularity is not always manifest on account of the unevenness of the surface on which they rest. In general, however, on glancing over a surface covered with crystals, a reflexion from one face will be accompanied with reflexions from the corresponding face in each of the other crystals, showing that the crystals are similarly positioned throughout.

This tendency to parallelism in the positions of associated crystals is apparent even in crystalline aggregates. In granite, for example, which is composed of felspar, quartz, and mica, the felspar crystallizations have usually a common position; that is, the corresponding extremities lie in the same direction, or nearly so. On this account granite is cleavable in one direction more easily than in others, and this direction is that of the perfect cleavage plane of the felspar; the second less perfect cleavage of the felspar permits of fracture of the rock nearly at right angles to the first; but, as there is no such third cleavage in the felspar, the workman, in fashioning the blocks of granite for paving stones, is compelled to chip or dress them off in the third direction.

Parallelism in crystal growth.

The dominant action of polarity may, moreover, give a parallel position to the main axes of different minerals belonging to the same system, when crystallizing in association, and even to those which belong to different systems. Fig. 237 is an illustration of the first of such cases, where a crystal of zircon is implanted into a crystal of xenotime, and has its main axis identically in the same line. As illustrations of the latter—a parallel position of the axes of crystals of different systems—there are records of such association in crystals of cyanite and staurolite, of muscovite and haughtonite, of albite and orthoclase. The same has been observed between crystals of rutile and specular iron,—the crystals of rutile in this case having the vertical axis in the direction of a lateral axis of the specular iron. Haidinger has observed pyroxene and hornblende crystals associated in parallel positions.

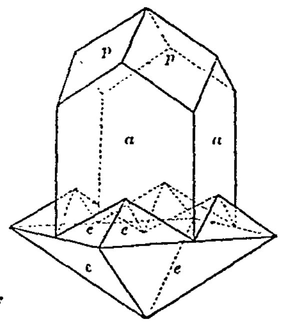

Fig. 237.

A prism of calcite terminating in the planes g (fig. 106) has been observed, in which each plane was covered with small crystals of quartz all lying symmetrically, with their pyramids pointing towards the summit of the calcite crystal. When one mineral is changed into another, a polarity of accretion is still often seen to have dominated in the arrangement. In a crystal of calcite which had been changed into a number of minute crystals of aragonite, the main axes of the latter all lay in the direction of the main axis of the original crystal of calcite.

Irregular aggregates.

Irregular Aggregation of Crystals.—Besides the regular unions now described, crystals are often aggregated in peculiar ways, to which no fixed laws can be assigned.

Thus some crystals, apparently simple, are composed of concentric crusts or shells, which may be removed one after the other, always leaving a smaller crystal like a kernel, with smooth distinct faces. Some specimens of quartz from Beeralston in Devonshire consist apparently of hollow hexagonal pyramids placed one within another. Other minerals, as fluor-spar, apatite, idocrase, heavy spar, and calc-spar, disclose a similar structure by bands of different colours. A growth rendered intermittent through the deposition of a thin layer of foreign matter is thus developed.

Many large crystals, again, appear like an aggregate of numerous small crystals, partly of the same partly of different forms. Thus some octahedrons of fluor-spar from Schlaggenwald are made up of small dark violet-blue cubes, whose projecting angles give a drusy character to the faces of the larger form. Such polysynthetic crystals, as they may be called, are very common in calc-spar.

Varieties of structure in aggregates.

Forms of Crystalline Aggregates.—Crystals have often been produced under conditions preventing the free development of their forms; and, according to the direction of the axis in which the development has been checked, they may be divided into "columnar" and "lamellar" arrangements.

The *columnar* structure is made up of a more or less fibrous arrangement; and this may be supposed to have accrued from the simultaneous growth of a multitude of crystals from a single or from closely adjacent centres of support, so that, while the crystals were free to elongate themselves in the direction of their main axis, their increase was restrained laterally, by their impact upon one another. When the surfaces of support are level, or consist of the opposing sides of a vein, the columns or fibres, frequently exceedingly delicate, are parallel, and not unfrequently they then have a silky lustre. In the latter of the above circumstances the fibres are disposed transversely to the vein. Examples: gypsum, chrysotile, satin-spar. When the surface of support is rough, or has angular projections, the fibres radiate from certain of these in all directions, producing, in a thin vein, a starlike form, whence the arrangement is called "stellular." Example: wavellite. When this takes place in an open cavity, producing brush-like forms, they are termed "radiant." Examples: antimonite, needlestone. When the points of divergent growth are so positioned that the radiating groups interlace with one another, the structure is said to be "reticulated," from its resemblance to a net. Example: tremolite. When individual members of such fibrous structure project above the general surface with acuminated extremities, they are said to be "acicular"; when the protruding columns are of uniform thickness they are termed "bacillary," or rod-like. Such terms as straight, curved, twisted-columnar, diverging, or confused-fibrous explain themselves. Such fibrous arrangements as the above may occur imbedded centrally in a rock mass, which had been the magma out of which they were formed; or they may line the inner surface of cavities, filled originally either with water or aqueous vapour. These modes of occurrence have been distinguished by Mohs as crystal groups and druses. The former includes all unions of imbedded crystals round a central nucleus; the latter those of crystals of simultaneous or regularly successive growth on a common support. In the first case, there may be spheroidal, ellipsoidal, cockscomb, or other forms, frequently seen in marcasite, pyrite, and gypsum. In the second, spheroidal forms are less rare, but are seen in the case of several of the fibrous zeolites. In such cases surfaces more or less rough are coated, and diminished in angularity, through the hemispherical forms produced by the radiation of a multitude of fibres. Certain imitative outlines thus result from the successive deposition of layers of these crystals. These forms or uniting masses are termed "globular" when nearly spherical, "botryoidal" when like bunches of grapes, "reniform" or kidney-shaped when the spheres are larger, more confluent, and less distinct, and "mammillated" when the masses are nearer to hemispheres. Mesolite occurs in globular forms; prehnite in botryoidal; hæmatite and chalcedony in reniform; and siderite and calamine in mammillated. In all the above cases the transverse fracture of such structures discloses the fibrous arrangement of the parts; but, if the growth has been intermittent, lines of deposit, concentric with the central nucleus of each sphere, are evidenced by layers of distinct colours. Fracture or separation frequently takes place, also, along such lines. In such drusy cavities—termed "geodes" when they are circular—after a certain number of such lines of deposit, grouped arrangements which have somewhat more of free crystalline development may assume other imitative forms in which there is a certain dependence on the crystallographic character of the mineral concerned. There are thus produced coralloidal or coral-like groups, fruticose or cauliflower-like groups, capillary or hair-like, and filiform or thread-like or wire-like forms. Often these groups expand in several directions, and produce arborescent, dendritic, plumose, mossy, dentiform, or other forms. Such are common among the native metals; as gold, silver, and copper. Mesolite is very frequently plumose. A "drusy crust" is the term applied to a thin rough layer of crystals, which invests either a large crystal or the surface of some other body lodged in the interior of cavities.

In the *lamellar* structure a development along the main axis would appear to have been checked, and the crystallographic force to have expended itself laterally; though this is not the invariable habit of a species under all circumstances, as exemplified by baryte. This structure consists of flat crystals, plates, or leaves. It is termed "tabular" when the plates are of uniform thickness, "lenticular" when they are thinner on the edges, "wedge-shaped" when sharp on one edge, "scaly" when the plates are thin and small, "foliaceous" when larger and easily separable; "micaceous" is also used to describe this kind of structure. It may also be curved lamellar and straight lamellar. Wollastonite, when flat lamellar, is called tabular spar; gypsum is frequently lenticular, talc scaly. Lamellar minerals when radiating from a centre often form fan-shaped, wheel-like, almond-shaped, comb-like, and other groups.

In the *granular* structure, the force of crystallization has been exerting itself along all the axes; but, from the multiplicity of crystallizing centres, there has been such mutual interference that no single individuals have been able to assume perfect or even characteristic forms. The particles in a granular structure differ much in size. When coarse, the mineral is described as coarsely granular; when fine, finely granular; if not distinguishable by the naked eye, the structure is termed impalpable. Examples of the first may be observed in granular carbonate of lime, of the

second in some varieties of specular iron, of the last in chalcedony, opal, and other species.

The above terms are indefinite, but of necessity, as there is every degree of fineness of structure in the mineral species, from perfectly impalpable, through all possible shades, to the coarsest granular. The term phanero-crystalline has been used for varieties in which the grains are distinct, and crypto-crystalline for those in which they are not discernible without the aid of a lens. Granular minerals, when easily crumbled in the fingers, are said to be friable.

The minute or crypto-crystalline minerals form aggregates somewhat similar to the above. When globular or oolitic, the minute crystals often appear to radiate from a centre, or form concentric crusts. These are often globular or nodular; as in dolomite. Somewhat similar are the stalactites and stalagmites, in which the mineral (especially rock-salt, calc-spar, malachite, hæmatite, limonite) has been deposited from a fluid dropping slowly from some overhanging body, or some rent in the roof of a cave. In this case there is generally found a long pendent cylinder or cone, the principal axis of which, generally hollow, is vertical, whilst the marginal parts are arranged at right angles to it, except where they curve round the termination of the tube, when they become hemispherical.

By far the largest masses of the mineral kingdom have, however, been produced under conditions in which a free development of their forms was excluded, and are termed amorphous. This has been the case with the greater portion of the minerals composing rocks or filling veins and dykes. The structure of these masses on the large scale belongs to geology, but some varieties of the textures, visible in hand specimens, may be noticed. The individual grains or masses have seldom any regular form, but appear round, long, or flat, according to circumstances, and as each has been more or less checked in the process of formation. Even then, however, a certain regularity in the position of the parts is often observable, as in graphic granite, where the axes of the skeleton crystals of quartz are parallel. The rock is termed massive when the grains which form it are small, or granular when they are longer and more distinct. Sometimes the rock becomes slaty, dividing into thin plates; or concretionary, forming roundish masses; at other times the interposition of some foreign substance (gas or vapour) has rendered it porous, cellular, or vesicular, giving rise to drusy cavities. These cavities are often empty, but have occasionally been more or less filled by products of change in the rock. It is named amygdaloidal when the cavities so filled have the form of an almond.

Changes of Crystalline Structure.

"Pseudomorphs" are minerals which appear under a form of crystallization which does not belong to the species. They may be recognized either by their having no cleavage, which is most usual, or by their cleavage being altogether different in direction from that of the mineral imitated. Generally they have rounded angles, rough and dull surfaces, and when broken show a granular structure. The faces of the crystal, moreover, are often covered with minute crystals of a form different from that of the mineral imitated, but which is that belonging to the substance now present. Occasionally the resemblance to real crystals is so perfect, from the perfect polish of the faces, that they are distinguished with difficulty. They may be frequently found still undergoing change.

Pseudomorphs classified. Pseudomorphs have been classed under four heads:—

1. *Pseudomorphs by Alteration.*—Formed by a gradual change of composition in a species. Of these there are two varieties: they may be pseudomorphous by loss of an ingredient, or by addition of an ingredient; change of augite to steatite is an example of the first, and of galena into anglesite is one of the second.

2. *Pseudomorphs by Substitution.*—Those formed by the replacement of a mineral which has been removed, or is gradually undergoing removal; *e.g.*, galena takes the form of pyromorphite.

3. *Pseudomorphs by Incrustation.*—Those formed through the incrustation of a crystal, which may be subsequently dissolved away. Often the cavity is afterwards filled by infiltration; *e.g.*, change of fluor to quartz.

4. *Pseudomorphs by Paramorphism.*—Those formed when a mineral passes from one dimorphous state to another; *e.g.*, change of aragonite to calcite.

These different kinds of change are not always distinguishable. In some cases a change may take place through alteration of the surface, and then, this process ceasing, the interior may be dissolved out, leaving a pseudomorph like one of incrustation; or a pseudomorph that appears to be a result of mere chemical alteration may be wholly due to substitution simply.

Again, changes of scapolite to a felspar, and of augite to uralite (hornblende), have been considered by Scheerer examples of paramorphism,—scapolite being considered dimorphous with some felspars, and augite with hornblende. But, while such paramorphic changes undoubtedly take place with aragonite, their occurrence in these silicates—which are common associates in the same rock, and must have been formed under like circumstances—is hardly probable.

Where mineral bodies have taken the form of organisms, it is more a case of molecular replacement than of true pseudomorphism.

Pseudomorphism should be understood, however, to consist, not simply in alteration of crystals, but in many instances of changes in beds of rock. Thus all serpentine, whether in mountain masses or in simple crystals, has been formed through a process of pseudomorphism—or, in more general language, of metamorphism—of olivine and augite. The same is true of other magnesian rocks, as steatitic, talcose, and chlorite slates. The crystalline rocks often offer examples of a change similar in nature. The graphite of these rocks is probably but a metamorph of some vegetable organism. Thus the subject of metamorphism, as it bears on all crystalline rocks, and that of pseudomorphism, are but branches of one system of phenomena; the chemistry of both is the same, and a knowledge of such changes is indispensable to a study of the older rock strata of the earth.

The common change of pyrites, forming the main ingredient of the upper part of metallic lodes, to earthy red or brown iron ore, thus producing the "gossan" of miners, is one of many examples of these processes now in progress. Often the gossan contains disseminated silver or gold, derived from the decomposed ores. This is a case of pseudomorphism, as truly as when a simple crystal of pyrites becomes limonite; the mode of change and its laws are the same. Again, phosphates, vanadiates, and arseniates of lead, &c., as well as carbonates and sulphates, are among the surface species, or those that occupy the upper part of metallic lodes; they are the results of alteration within those depths to which atmospheric agencies penetrate.

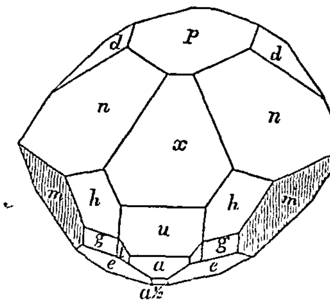

Fig. 238.

Pseudomorphs are always records of past existences, in some cases they may be the only evidence we possess of such prior existence. Figs. 238, 239 are pseudomorphs of quartz or hornstone after datholite; the measured angles of these crystals show that the imitated crystal was datholite; but that mineral does not now occur in crystals of either of these forms.

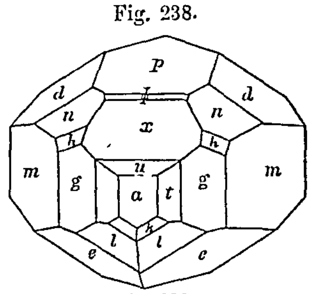

Fig. 239.

The process of petrification of organic bodies is in reality a species of pseudomorphic formation, and has been produced in all the above modes. External and internal casts of organic bodies are not uncommon. In other cases the original substance has been replaced by some mineral which has preserved, not merely the external form, but even the minutest detail of internal structure,—so that the different kinds of wood have been distinguished in their silicified trunks. The most common petrifying substances are silica and carbonate of lime. In encrinites, echinites, belemnites, and other fossils, the crystals of calc-spar often occur in very regular positions. In some varieties of petrified wood both the ligneous structure and the cleavage of the calc-spar are observable.

Different from the above are mineralized bodies, in which the original structure is still retained, but their chemical nature partially changed. In these a complete series may be often traced, as from wood or peat, through the varieties of brown coal, common coal, anthracite, and graphite.

Causes of Change.—The causes of change are the simplest and most universal operations about us:—(1) the process of gradual alteration to which some substances are liable on account of the presence of oxygen and carbonic acid in the atmosphere, and the reaction of substances thus formed on adjacent ingredients, aided or promoted by electrical currents or by heat; (2) the solvent power of ordinary waters, cold or hot, or of steam; (3) reactions, in accordance with chemical principles, of the ingredients Origin of pseudomorphs.

dissolved in these waters, or in mineral or sea waters, heated or at the ordinary temperature; (4) the action of gases exhaling from the earth; (5) changes referable to volcanic action.

Ordinary waters hold in solution, as is well known, more or less of mineral matter. When water containing carbonic acid is passed through a large number of ordinarily occurring minerals, it gives evidence of the presence of an alkali, or lime, or magnesia; and some of these minerals give the tests even with the first drops. Pure water gives with many of them a similar result, but more slowly. Limestone in forty-eight hours yields soluble ingredients to the extent of 0·4 to 1 per cent. of the whole mass. The lime, magnesia, and alkalies appear in the condition of carbonates; and the iron passes from the state of carbonate to that of peroxide during evaporation. The silicates of magnesia, lime, and manganese are especially ready in yielding to this action. Silica, however, is more soluble in ordinary than in carbonated water.

These facts illustrate two important points:—(1) that ordinary waters lying upon and filtering through the earth's crust are constantly active in dissolving and decomposing minerals and rocks, and that even species reputed indestructible are thus acted upon; and (2) that the waters are thus furnishing themselves with agents capable of effecting other chemical changes. These waters penetrate all rocks, as well as percolate through soils. Hence the action is a universal one, everywhere going on; and the results are universal. Bones, shells, corals, and animal remains generally are also sources of carbonate of lime, phosphates, and fluorides; and plants may contribute also potash and soda, and sometimes silica.

Carbonic acid is a constant ingredient of the atmosphere, and is dissolved by the rains as they descend; hence this active decomposing agent is present in all ordinary waters; but it is also a result of different mineral changes. Sulphate of iron along with vegetable matters gives oxygen to the carbon of the vegetable matter, and thus produces carbonic acid and pyrites or sulphuret of iron; and the large quantities of pyrites in coal-beds show on how grand a scale this process has taken place. Sulphate of zinc in a similar manner produces carbonic acid and blende or sulphuret of zinc. Bischof observes that the carbonic acid which has thus been eliminated must have been sufficient in quantity to make an atmosphere of carbonic acid equal in height to our present atmosphere. Again, decomposition of sulphurets produces sulphuretted hydrogen; this by the oxidating action of the atmosphere forms sulphuric acid, and the sulphuric acid acting on limestone produces gypsum, and liberates carbonic acid. Sulphurous acid is also generated in the neighbourhood of volcanoes, and rapidly becomes sulphuric acid, with the same result. Moreover, silica in waters, if aided by heat, will decompose limestone and liberate carbonic acid. Hence it is that this gas is exceedingly common in exhalations from mineral springs; indeed it occurs more or less in all waters.

The dissolving and decomposing action of carbonated waters is therefore general. The sea also partakes of this character, and, in virtue of the numerous salts which it holds dissolved, is a powerful agent in carrying on the changes to which the process leads. Such changes and the various pseudomorphs to which they give rise have to be regarded as types and evidences of vast metamorphic transformations,—processes either of decay or of reformation which have modified widespread rock-masses, and which are at the present time altering the structure of the crust of the earth. It is through a study of pseudomorphs, and of the processes which have gone to form them, that mineralogy is to become the germ from which alone the petrological department of geology can have its true development, and become a living instead of a merely speculative science.

Physical Properties of Minerals.

Characters Depending on Light.

There are few more interesting departments of science than the relations of mineral bodies to light, and the modifications which it undergoes either when passing through them or when reflected from their surface. In this place, however, we only notice these phenomena so far as they point out distinctions in the internal constitution of minerals, or furnish characters for distinguishing one species from another.

of *Lustre.*—Though the varieties of lustre admit of no precise or mathematical determination, they are of considerable value in mineralogy. One highly important distinction founded on them is that between minerals of metallic and non-metallic aspect or character. Transparency and opacity nearly coincide with this division,—the metallic minerals being almost constantly opaque, the non-metallic more or less transparent. Minerals which are perfectly opaque, and show the peculiar brilliancy and opacity of surface of polished metals, are named metallic; those which possess these properties in an inferior degree are semi-metallic; and those without these properties are non-metallic.

Lustre has reference to either the intensity or the quality of the reflected light, considered as distinct from colour. Several degrees in intensity have been named:—(1) splendent, when a mineral reflects light so perfectly as to be visible at a great distance, and lively and well-defined images are formed in its faces, as galena, specular iron, or cassiterite; (2) shining, when the reflected light is weak, and only forms indistinct and cloudy images, as heavy spar or calcite; (3) glistening, when the reflected light is so feeble as not to be observable at a greater distance than arm's length, and no longer forms an image, as talc; (4) glimmering, when the mineral held near the eye in full clear daylight presents only a number of small shining points, as red hæmatite and granular limestone. When, as in chalk or kaolin, the lustre is so feeble as to be indiscernible, the mineral is said to be dull.

In regard to the kind or quality of the lustre, the following varieties are distinguished:—(1) the metallic, seen in much perfection in native metals and their compounds with sulphur, and imperfectly in glance coal; (2) adamantine, found in beautiful perfection in the diamond, and in some varieties of blende and cerussite; a modification is metallic adamantine, as seen in wolfram and black cerussite; (3) vitreous or glassy, seen in rock crystal, or common glass, or, inclining to adamantine, in flint glass; subvitreous is seen in broken calcite; (4) resinous, when the body appears as if smeared with oil, as in pitchstone, blende, and garnet; (5) waxy, like beeswax, as seen in wax-opal and ozocerite; (6) pearly, like mother-of-pearl, seen in gyrolite, talc, heulandite; (7) silky, the glimmering lustre seen on fine fibrous aggregates like amianthus, tremolite, chrysotile, krokidolite.

These degrees and kinds of lustre are generally exhibited differently by unlike faces of the same crystal, but always similarly by like faces. The lateral faces of a right square prism may thus differ in lustre from that of a terminal face. Thus the lustre of the lateral faces of apophyllite is vitreous, while that of the terminal, at right angles thereto, is pearly; chrysotile is silky when split along the fibres, dull when at right angles to them.

The surface of a cleavage plane, in foliated minerals, generally differs in lustre from the sides; and here again in some cases the latter are vitreous, while the former is pearly, as in heulandite.

As shown by Haidinger, only the vitreous, adamantine, and metallic lustres belong to faces perfectly smooth and pure. In the first, the index of refraction of the mineral is 1·3 to 1·8; in the second, 1·9 to 2·5; in the third, above 2·5. The pearly lustre is a result of reflexion from numberless lamellæ, or cleavage planes, within a translucent mineral; and in hydrated minerals, as in the zeolites, it is the result of incipient change,—namely, a loss of water which ensues upon exposure to the atmosphere.

Colour.—This is a property which is of very inferior value. Minerals are so seldom, if ever, absolutely pure that very minute quantities of an intensely coloured impurity may impart colour to a substance inherently colourless, or overpower a feebler colour which may be its own. Colour.

Some few minerals have colour so strong or have a constitution so little susceptible of intermixture, that they retain almost unimpaired the colour special to them. Such a substance is pyrite; its brass-yellow colour may be heightened to gold-yellow by intermixture with copper sulphide, or it may be slightly bleached by arsenic; but the nature of its composition does not admit of the intrusion of ordinary colouring ingredients. The yellow of native gold, again, may be paled by impoverishment with the white of silver, down to the dull tint of electrum; but no foreign colouring matter can intrude itself into a metallic mass. Such substances as these,—native metals, sulphides, and oxides,—have colours essential to them, dependent on their constitution, and to a great extent characteristic of the species.

A second class of minerals are colourless of themselves, and thus very subject to the influence of minute quantities of foreign tinctorial impurity. These are absolutely transparent and devoid of colour when in crystals, but white and opaque when reduced to powder; as ice and snow, calcite and chalk, rock-crystal and sand. But such substances are generally coloured; "muddied" it would be called in the first case, though it is equally so with the others. Such false colour may be imparted in several ways. It may be (1) from their holding dissolved some colouring matter; (2) from mechanical mixture of colouring substances such as metallic oxides, or minute crystals ("endomorphs") of another mineral; or

(3) from chemical replacement,—the substitution of a smaller or larger quantity of a coloured isomorphous ingredient.

As illustration of the first, silica, colourless in rock-crystal, has been found of almost every tint, due frequently to volatile hydrocarbons which are dissipated by heat. Fluorite also, found of almost every shade of every colour, may possibly be to a certain extent referred here.

Quartz, felspar, and calcite are often coloured accidentally by imbedded layers of foreign "inclusions," or by "spangling endomorphs." These are mechanically mixed, so far as regards their presence in a structure of different and non-assimilable chemical composition, but crystallographically arranged. They either mark the lines of interrupted or intermittent growth; or, in the case of endomorphs, the axial positions of the minute intruding foreign crystals lie in one plane, or in the same sets of planes.

As an instance of colours introduced through definite chemical replacement, calcite may be cited. Carbonate of lime is colourless; if a portion of this be replaced by carbonate of magnesia there is a certain amount of pearly opacity; if by carbonate of manganese, of a pink tinge; if by carbonate of iron, of yellow, which may be increased through oxygen absorption and "weathering" to an ochre tint, and ultimately to a dark brown.

Sulphuret of zinc, chemically white, and mineralogically transparent, may, through metallic substitution, be found of almost all tints of yellow, orange, brown, and black. Again, hornblende, augite, and garnet,—silicates, which in their purest states of tremolite, malacolite, and water garnet are colourless,—acquire green, brown, red, and black tints from the assimilation of other metallic silicates.

Hence it would appear that a very advanced practical knowledge of the subject is necessary to enable us to avail ourselves of the information which is to be derived from this external feature.

The accidentally coloured minerals sometimes present two or more colours or tints, even in a single crystal,—very remarkable examples occurring in fluor-spar, apatite, sapphire, amethyst, tourmaline, and cyanite. This is still more common in compound minerals, on which the colours are variously arranged in points, streaks, clouds, veins, stripes, bands, or in brecciated and ruin-like forms. Some minerals again change their colour from exposure to light, the air, or damp. Then either the surface alone is affected or "tarnished," and appears covered as with a thin film, producing in some minerals, as silver and arsenic, only one colour; in others, as chalcopyrite, hæmatite, bismuth, stibine, and anthracite, various or iridescent hues, when they are said to have a pavonine lustre. Or occasionally the change pervades the whole mineral, the colour either becoming paler, or disappearing, as in chrysoprase and rose-quartz, or becoming darker, as in brown spar, siderite, and rhodonite. In a few minerals a complete change of colour takes place, as in heterosite, and in the chlorophæite of the Western Isles of Scotland, which, on exposure for a few hours, passes from a transparent yellow-green to black. These mutations are generally connected with some chemical or physical change. The tarnished colours sometimes only appear on certain faces of a crystal belonging to a peculiar form. Thus a crystal of copper pyrites (like fig. 89) has one face P′ free from tarnish; the faces *b* and *c*, close to P′, dark blue; the remainder of *c*, first violet, and then, close to P, gold-yellow.

Some crystalline minerals exhibit in certain directions a very lively play or change of colours from reflected light. It is well seen in many various hues on the cleavage-planes of labradorite, and seems produced by a multitude of very thin quadrangular pores, interposed in the mineral, like minute parallel laminæ. On the cleavage-planes of hypersthene it appears copper-red, and is occasioned by similar pores, or by numerous small brown or black laminæ of some foreign substance interposed in a parallel position between the planes of the hypersthene. The chatoyant or changing colours of the sun-stone arise from scales of hæmatite similarly interposed, and that of avanturine from scales of mica. The play of colour in the noble opal seems to be produced very nearly in the same manner as that in the labradorite. A similar opalescence is seen in certain minerals when cut in particular forms. In the sapphire, cut hemispherically over the chief axis, it appears like a star with six rays; in garnet it shows four rays; in certain varieties of chrysoberyl and of adularia it has a bluish tint; and it is also very remarkable in the cat's-eye variety of quartz. Iridescence often arises from very fine fissures, producing semicircular arches of prismatic tints, which, like the colours of thin plates in general, are referred to the interference of light.

Streak. *Streak.*—This name is applied to the appearance and the colour of the line or furrow produced in minerals by drawing the edge of a hard-tempered knife or file along their surface, or to the stain obtained by rubbing a soft mineral on such a substance as paper or porcelain. Taken along with the hardness, which may to a certain extent be determined by the same operation, it is one of the most valuable tests which we possess.

The furrow may be lustrous or it may be dull. Powder or splinters may lie along its course, or a still adherent ridge may have been merely rolled over. The furrow and the powder may each be possessed of colour, though such may not be distinguishable in the mineral, or may have a colour quite different from that of the mineral. Three illustrations of the usefulness of this test may suffice. Argentiferous gold, chalcopyrite, and pyrite, differing immensely in value, may readily be mistaken for each other. The knife, when drawn along the surface of the first, sticks in it, ruts up an adhering ridge, and leaves a shining streak of the same colour as the specimen. When drawn along the second it ruts up a trench covered with a dusty powder, which when rubbed on paper or in the hand is greenish yellow. When drawn along the third it has no effect, as pyrite is harder than the knife. Psilomelane, hæmatite, and limonite all occur in black, glossy, stalactitic forms, and have all been termed "black hæmatite." There is here also great difference in the value. The knife makes little impression on psilomelane, but leaves a blue lustrous line; it makes a blood-red line in hæmatite, and a rich ochre-yellow in limonite. Graphite and molybdenite both crystallize in hexagonal plates, both occur in the same rocks, both have a grey-black colour and a brilliant metallic lustre, both stain the hands or paper; the streak of the first—best seen on paper—is black, tending to blue; that of the last is greenish. Rough porcelain is the best material for determining the streak of soft minerals.

Diaphaneity.—Minerals, and even different specimens of the same species, vary much in this quality. Some transmit so much light that small objects can be clearly seen, or letters read, when placed behind them; such are named transparent. They are semitransparent when the object is seen only dimly, as through a cloud, and translucent when the light that passes through is so broken that the form of the object can be no longer discerned; some minerals are only thus translucent on the thinnest edges. Others transmit no light, and are named opaque. Transmission of light.

Refraction.—It has already been mentioned that most crystals—all, in fact, except those of the cubical system—exhibit the phenomena of double refraction. For a general explanation of these phenomena the reader is referred to LIGHT, vol. xv. p. 609 *sq*. Double refraction.

The direction in which there is no double refraction is named the optic axis of the crystal,—sometimes, less happily, the axis of double refraction. Now in certain minerals it is found that there is only one direction with this property, whereas in others there are two such directions; and they have in consequence been divided into uniaxal and binaxal. To the former belong all crystals of the tetragonal and hexagonal systems, to the latter all those of the other three systems. In the former the optic axis coincides with or is parallel to the crystallographic chief axis. In some uniaxal crystals the index of refraction for the extraordinary ray is greater than for the ordinary ray; and in others it is smaller. According as it is greater or less they are said to have positive (attractive) or negative (repulsive) double refraction. Optic axis.

Quartz is an example of the former, the index of refraction, according to Malus, being for $O=1\cdot5484$, for $E=1\cdot5582$; calc-spar of the latter, the index of O being $=1\cdot6543$, that of E $1\cdot4833$. The index of E is in both cases taken at its maximum.

It should be observed that the optic axes are not single lines, but directions parallel to a line, passing through every part of the crystal. It is also important to remark that this property divides crystals into three precise groups:—the cubic, with single refraction; the tetragonal and hexagonal, with double refraction, and uniaxal; those of the other three systems, also double, but binaxal. These properties are therefore of the greatest use in determining the system to which a mineral belongs.

Polarization.—Intimately connected with this property is that of the polarization of light, which affords an easier means of determining mineralogical characteristics than the direct study of double refraction. For the elements of this subject see LIGHT, vol. xv. p. 611 *sq*. Polarization.

While a consideration of the optic axes enabled us merely to arrange the systems of crystallization in three groups, the phenomena of polarization not only bear out a further subdivision of the whole into the above six systems, but disclose, in many cases, phenomena markedly special to individual species. The optical consideration of these phenomena enables us to fix three directions at

Axes of optical elasticity.

right angles to one another—called the axes of optical elasticity—such that the effect of the crystal on the luminous vibrations of the elastic ether is a maximum in one of these directions, a minimum in a second, and a maximum-minimum in the third. The length of these axes is chosen in terms of this action. In certain cases the direction of the axes of optical elasticity is different for light of different colours.

The position of these axes in relation to the crystallographic axes, and the ratios of their lengths, enable us to class all crystals as follows:—

1. Crystals of the cubic system. Here the three axes of elasticity are all equal. The refraction is simple.

2. Crystals of the tetragonal and of the rhombohedral systems. Two of the axes of optical elasticity are equal in these systems; the third is greater or less according as the crystals are negative or positive. The two equal axes lie in a plane perpendicular to the principal crystallographic axes; the third axis coincides with the principal axis.

3. Crystals of the right prismatic system. The direction of the three axes of optical elasticity coincides with the crystallographic axes, taken parallel to the diagonals of the base of the rhombohedron, and to the vertical edge of the prism (the primitive parallelepiped of Levy).

4. Crystals of the oblique prismatic system. Only one of the axes of optical elasticity coincides necessarily with the crystallographical horizontal axis, or the diagonally horizontal axis of the rhombic base, the direction of the two others not having any evident relation, *a priori*, with the inclined or diagonally inclined axis of the base, and with the vertical axis (or vertical edge of the primitive parallelepiped).

5. Crystals of the anorthic system. The three axes of optical elasticity have no relation that can be assigned *a priori* to the crystallographic axes, whatever position may be assigned to these in relation to the primitive solid.

In crystals belonging to the last three systems the three axes of elasticity are unequal.

The axes of elasticity are in general such that a ray passing through the crystal in the direction of any one of them is divided into two, which follow that direction with different velocities depending on the lengths of the other two axes. To any other direction there will in general also correspond two different velocities; but their ratio will now depend in a more complex manner on all three axes. In two directions (and only in two, if the axes are all unequal) the ratio becomes unity, or the ray is not divided. These directions are the optic axes.

The displacement of the axes of elasticity for light of different colours, already mentioned, takes place for two axes in crystals of the oblique prismatic system and for all three axes in the anorthic (*i.e.*, doubly oblique) system. In the other systems it does not occur.

Colour phenomena.

In order to follow the distinctive features of the different systems farther, it is necessary to consider the colour phenomena which they display, when examined in a beam of polarized light. Various instruments have been devised for this purpose, as, *e.g.*, the polarizing apparatus of Norrenberg, fitted with a condensing lens below and above the crystal slice, or with a low-power (3-inch) eye-piece. The polariscope of Hoffman of Paris is more efficient, but the apparatus of Descloizeaux (fig. 240), who has made this mode of investigation a special study, has the widest scope of usefulness. In this apparatus a blackened mirror is employed for polarizing the light, taking the place of a tourmaline plate, a Nicol's prism, or a bundle of thin glass. The mirror is inferior to the other two in completeness of polarizing power, and in not admitting of rotation; while it shares this defect with the last. It is, however, superior to all in extent of field, while it does not, like the first, affect white light. A Nicol's prism is used for examining or analysing the light which passes.

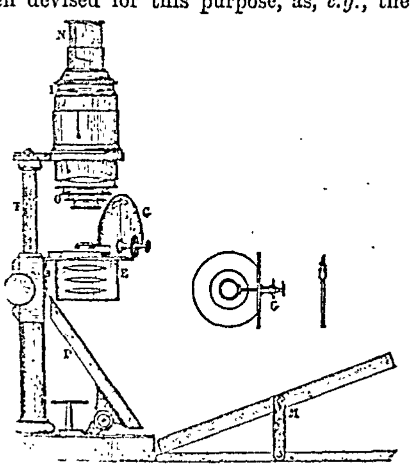

Fig. 240.—Apparatus of Descloizeaux.

The description of the many beautiful phenomena that may be observed with polarizing apparatus when applied to sections of crystals belongs to the subject of OPTICS (PHYSICAL), to which heading also we must refer for the phenomena of circular polarization.

Optic properties of composite crystals.

Double Refraction and Polarization of Composite Crystals.—In all the crystallized bodies whose action upon light we have been considering, the phenomena are identical in all parallel directions, the smallest fragment having the same property as the largest, from whatever part of the crystal it is taken. In the mineral world, however (and among the products of artificial crystallization), there occur crystals which are composed of several individual crystals whose axes are not parallel. These crystals sometimes occur in such regular symmetrical forms that mineralogists have long regarded them as simple forms; and it is probable that they would have still been so viewed if they had not been exposed to the scrutiny of polarized light.

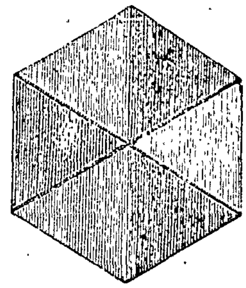

Fig. 241.

A composite structure has been observed in the case of Brazilian topaz, sulphate of potash, and apophyllite. Bipyramidal sulphate of potash, which Count Bournon supposed to be a simple crystal, was found to be a tesselated crystal, composed of three pairs of crystals of the prismatic sulphate of potash combined so that each pair had their principal axes parallel. When exposed to polarized light, each pair gave the system of binaxal rings, and when held at a distance from the eye had the tesselated appearance shown in fig. 241; each opposite pair of the triangles having the same tint.

The most remarkable of this class of minerals is the tesselated apophyllite. The examination of this body by polarized light is due to Brewster. For his results the reader is referred to his paper in the *Edinburgh Transactions*, vol. ix. p. 323.

Figs. 242, 243 are representations of the figure produced in polarized light by an internal slice of the barrel or cylindrical

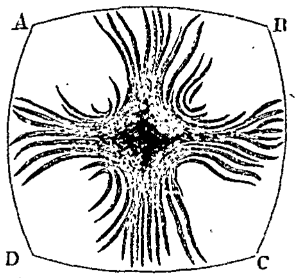

Fig. 242.

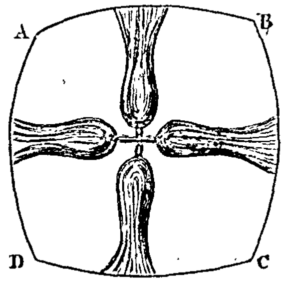

Fig. 243.

apophyllite from Kudlisaet, in Disco Island. The figures are from different specimens. The shaded part of them has only one axis of double refraction, while the four sectors have two axes. The mechanical structure of the cleavage planes resembles the optical figure even after the planes are ground.

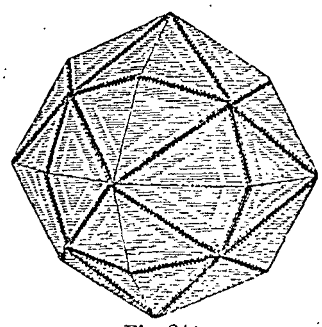

Fig. 244.

The minerals stilbite, heulandite, chabasite, and many others, are similarly complex in structure.

Crystals with Planes of Double Refraction.—Analcime, a mineral ranked among the cubical crystals, was found by Brewster to be singular in its action upon light, and to exhibit the extraordinary property of many planes of double refraction, or planes to which the double-refracting structure was related in the same manner as it is to one or two axes in other minerals. It crystallizes most commonly in the form of the icositetrahedron. If we suppose a complete crystal of it to be exposed to polarized light, it will give the remarkable figure shown in fig. 244, where the dark shaded lines represent planes in which there is neither double refraction nor polarization,—the double refraction and the tints commencing at these planes, and reaching their maximum in the centre of the space enclosed by three of the dark lines. When light is transmitted through any pair of the four planes which are adjacent to any of the three axes of the solid, it is doubly refracted, the least refracted image being the extraordinary one, and consequently the double refraction negative in relation to the axes to which the doubly-refracted ray is perpendicular. If we suppose the crystal to have the form of a

Fig. 245.

cube, the planes of double refraction will be, as in *fig.* 245, a plane passing through the two diagonals of each face of the cube.

The tints vary as the square of the distance from the nearest plane of double refraction.

Pleochroism.

Pleochroism.—Closely connected with double refraction is that property of transparent minerals named pleochroism (of many colours), in consequence of which they exhibit distinct colours when viewed by transmitted light in different directions. Crystals of the cubic system do not show this property, whilst in those of the other systems it appears in more or less perfection,—in tetragonal and hexagonal minerals as dichroism (two colours), in the rhombic and clinic systems as trichroism (three colours). In most cases these changes of colour are not very decided, and appear rather as different tints or shades than as distinct colours. The most remarkable of dichromatic minerals are the magnesian mica from Vesuvius, the tourmaline, and ripidolite; of trichromatic, iolite, andalusite from Brazil, diaspore from Schemnitz, and axinite.

In a specimen of yellow Iceland spar the extraordinary image is of an orange-yellow colour, while the ordinary image is yellowish white. Along the axis of double refraction the colour of the two pencils is exactly the same, and the difference of colour increases with the inclination of the refracted ray to the axis. This is the invariable law of the phenomena in uniaxal crystals. Sir John Herschel found several tourmalines to have a blood-red colour along the axis, and at right angles to it to be yellow-green. There can be little doubt that this property will be found in every crystal of sufficient refraction. Even if the crystal is colourless, a slight inequality in the intensity of the two images may be observed; and when it is distinctly coloured the difference of intensity is very easily seen, even when the two colours are not of a different kind.

The phenomena of dichroism are best seen in crystals with two axes of double refraction, and are well exemplified in iolite, a mineral which crystallizes in six- or twelve-sided prisms. These prisms are of a deep blue colour when seen along the axis, and of a yellowish brown colour when viewed in a direction perpendicular to it.

If *abcd* (fig. 246) is a section of the prism of iolite in a plane parallel to the axis of the prism, the transmitted light will be blue through the faces *ab* and *dc*, and yellowish brown through *ad*, *bc*, and in every direction perpendicular to the axis of the prism. If we grind down the angles *a*, *c*, *b*, *d*, so as to replace them with faces *mn*, *m'n'* and *op*, *o'p'*, inclined 31° 41' to *ad*, or to the axis of the prism, then, if the plane *abcd* passes through the optic axes, we shall observe, by transmitting polarized light through the crystal in the directions *ac*, *bd*, and subsequently analysing it, a system of rings round each of these axes. The system will exhibit the individual rings very plainly if the crystal is thin; but if it is thick, we shall observe, when the plane *abcd* is perpendicular to the plane of primitive polarization, some branches of blue and white light diverging in the form of a cross from the centre of the system of rings, or the poles of no polarization, as shown at *p* and *p'* (fig. 247), where the shaded branches represent the blue ones. The summits of the blue masses are tipped with purple, and are separated by whitish light in some specimens and yellowish light in others. The white light becomes more blue from *p* and *p'* to *o*, where it is quite blue, and more yellow from *p* and *p'* to *c* and *d*, where it is completely yellow. When the plane *abcd* is in the plane of primitive polarization, the poles *p*, *p'* are marked by spots of white light, but everywhere else the light is a deep blue.

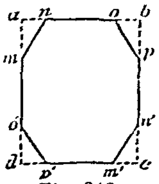

Fig. 246.

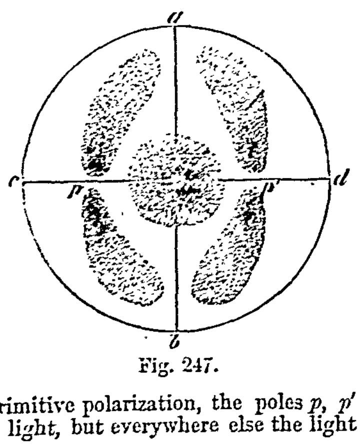

Fig. 247.

In the plane *cadb* (fig. 247) the mineral, when we look through it by common light, exhibits no other colour but yellow, mixed with a small quantity of blue, polarized in an opposite plane. The ordinary image at *c* and *d* is yellowish brown, and the extraordinary image faint blue, the former receiving some blue rays and the latter some yellow ones from *c* and *d* to *a* and *b*, where the difference of colour is still well-marked. The yellow image becomes fainter from *a* and *b* to *p* and *p'*, till it changes into blue, and the faint blue image is strengthened by other blue rays, till the intensity of the two blue images is nearly equal. As the incident ray advances from *c* and *d* to *p* and *p'*, the faint blue image becomes more intense, and the yellow one, receiving an accession of blue rays, becomes of a bluish white colour. The ordinary image is whitish from *p* and *p'* to *o*, and the extraordinary is deep blue; but the whiteness gradually diminishes towards *o*, when they are both almost equally blue.

The principal axis of double refraction in iolite is negative. The most refracted image is purplish blue, and the least refracted one yellowish brown.

Brewster found that the dichroism of several crystals is changed by heat, and that in some cases this property may be communicated to them. Babinet found that all negative crystals, such as calcareous spar, corundum (including ruby and sapphire), tourmaline, and emerald, absorb in a greater degree the ordinary ray, with the exception of beryl, apatite, and some apophyllites; while positive crystals, such as zircon, smoky quartz, sulphate of lime, and common apophyllite, absorb in a greater degree the extraordinary ray. Babinet found also that certain crystals, such as red tourmaline and ruby, transmit rays of their peculiar colour without being polarized,—in which cases the black cross of their system of rings is coloured, and this unpolarized light exists both in the ordinary and extraordinary ray.

Haidinger devised an instrument for showing and for testing the pleochroism of minerals. In *fig.* 248, *p* is an oblong cleavage-rhombohedron of Iceland spar which has two glass prisms *w*,*w* of

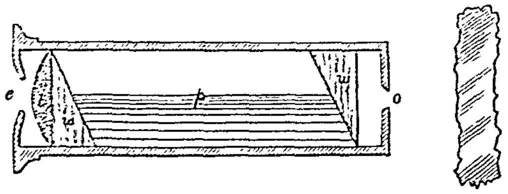

FIG. 248.—Section of Dichroiscope.

18° cemented to its ends with Canada balsam. This combination is placed in a metallic case, which has a convex lens *l* at one end and a square hole *o* about the fifteenth of an inch in width at the other. The lens is of a focal distance which shows an object held about half an inch from the square hole.

On looking through the lens and prisms two images of the square hole are seen just touching each other. The light of the one image is polarized in the plane which intersects the short diagonal of the prism; that of the other is polarized in the plane of the longer diagonal. When a pleochroic crystal or fragment is held at focal distance and examined by transmitted light, then, on the turning of the instrument bringing the polarization of its planes into coincidence with those of the crystal, the two images of the square opening will show the colours of the oppositely polarized pencils of which the light transmitted by the crystal is composed; this constitutes its pleochroism. The dichroism is then seen by looking through the crystal in one direction only, and the contrast of the two colours is made more obvious.

Phosphorescence.

Phosphorescence.—This is the property possessed by particular minerals of emitting light in certain circumstances, without combustion or ignition.

Thus some minerals appear luminous when taken into the dark, after being for a time exposed to the sun's rays or even to the ordinary daylight. Many diamonds, and also calcined barytes, exhibit this property in a remarkable degree; less so aragonite, calc-spar, and chalk. Many minerals, including the greater part of those thus rendered phosphorescent by the influence of the sun, also become so through heat. Thus some topazes, diamonds, and varieties of fluor-spar become luminous by the heat of the hand; other varieties of fluor-spar, and phosphorite, require a temperature near that of boiling water; whilst calc-spar and many silicates are only phosphorescent at from 400° to 700° Fahr.

Electricity produces phosphorescence in some minerals, as in green fluor-spar and calcined barytes. In others it is excited when they are struck, rubbed, split, or broken; as in many varieties of zinc-blende and dolomite when scratched with a quill, pieces of quartz when rubbed on each other, and plates of mica or needles of pectolite when suddenly separated.

The light emitted by phosphorescent minerals is of various tints. The variety of fluor called chlorophane emits, as its name expresses, a green light. The same particle may emit varying tints, as in the fluor from Aberdeenshire, which, as the heat falls, or the energy of the phosphorescence wanes, emits tints which pass from violet, through blue, green, and yellow, to dull purplish red. The yellow blende from the same place is vividly phosphorescent when heated. Fluor generally phosphoresces with a tint of its own colour.

Too high a heat destroys the phosphorescence, which may, however, be restored by either exposure to sun's light or to electricity.

The mineral phosphoresces vividly when the discharge passes through it; it generally phosphoresces with a different colour after it has been thus recharged.

Fluorescence. *Fluorescence* is the property whereby rays of light of a refrangibility higher than those ordinarily seen by the human eye are rendered visible. The substance when placed in the violet end of the spectrum, and carried beyond it into the invisible rays, becomes luminous, through "degrading" the rays of extreme refrangibility. This property is well marked in those varieties of fluorite which are pale green by transmitted light, and deep purple by reflected light. Ozocerite and some petroleums also exhibit the property.

Electric, Magnetic, and Thermic Properties.

Electric properties of minerals. *Electricity.*—Friction, pressure, and heat may all excite electricity in minerals. To observe this property delicate electroscopes are required, formed of a light needle terminating at both ends in small balls, and suspended horizontally on a steel pivot by an agate cup. Such an instrument can be electrified negatively by touching it with a stick of sealing-wax excited by rubbing, or positively by merely bringing the wax so near as to attract the needle. When the instrument is in this state, the mineral, if also rendered electric by heat or friction, will attract or repel the needle according as it has acquired electricity of an opposite or of a similar kind; but if the mineral is not electric it will attract the needle in both conditions alike.

Most precious stones become electric from friction, and are either positive or negative according as their surface is smooth or rough. All gems become positive when polished; the diamond even when unpolished is positive. Pressure between the fingers will excite distinct positive electricity in pieces of transparent double-refracting calc-spar. Topaz, aragonite, fluor-spar, carbonate of lead, quartz, and other minerals show this property, but in a much smaller degree. Some bodies remain excited much longer than others, topaz for a very long time. Heat or change of temperature excites electricity in many crystals; as in tourmaline, calamine, topaz, calc-spar, beryl, barytes, fluor-spar, diamond, garnet, and others; these are hence said to be thermo- or pyro-electric. Some acquire polar pyro-electricity, or the two electricities appear in opposite parts of the crystal, which are named its electric poles. Each pole is alternately positive and negative, the one when the mineral is heating, the other when it is cooling. Hankel's investigations of these phenomena are specially noteworthy.

As already noticed, many polar electric minerals are also remarkable for their hemimorphic crystal forms. Tourmaline, calamine, and boracite are among the species thus affected. The polarity continues so long as the temperature is increasing, and becomes reversed when it commences to decline; and when the heat is stationary it disappears.

Pyro-electricity. Rose and Reiss name one of the poles the analogue electric pole, and the other the antilogue electric pole. The former becomes positive while the crystal is heating, and negative while cooling; the latter negative while heating, and positive while cooling. Becquerel found that in tourmaline at 30° C. electrical polarity was sensible; it continued unchanged to 150°, as long as the temperature continued to rise; if the temperature remained

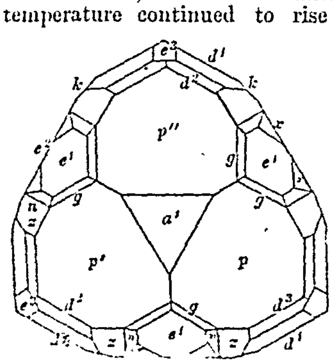

Fig. 249.

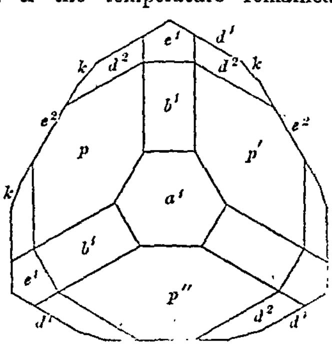

Fig. 250.

stationary an instant, the polarity disappeared, but shortly manifested itself reversed, when the temperature commenced to decline. If but one end of the crystal was heated the crystal was unpolarized, and when two sides were unequally heated each acquired an electrical state independent of the other. In tourmaline the extremities of the prism are dissimilarly modified, and that end which presents the greater number of planes is the antilogue pole; or, if the number of planes is the same, the secondary rhombohedrons of the antilogue pole have (one or more of them) longer vertical axes than those of the analogue pole. Fig. 249 (tourmaline) is the antilogue pole (negative under increasing heat), and fig. 250 the analogue pole. The pyramid of the analogue end is more flattened by its facets than that of the antilogue end; thus e^3 and $d^{\frac{2}{3}}$ of the antilogue end are more acuminating than e^1 and d^2 of the analogue end. The same is the case with the other two crystals (figs. 251, 252).

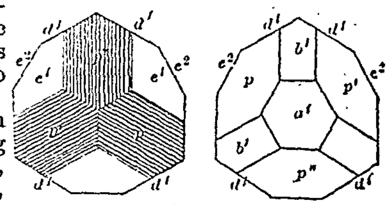

Fig. 251.

Pyro-electricity has been observed in the following substances: — tourmaline, topaz, axinite, boracite, scolezite, prehnite, electric calamine, sphene, rhodizite, heavy spar, rock-crystal.

Pyro-electricity is of two kinds,—either terminally polar or centrally polar. In the former the extremities are opposite poles. In the latter two sides of a prism are of the same name, and the opposite pole to each is intermediate between the two.

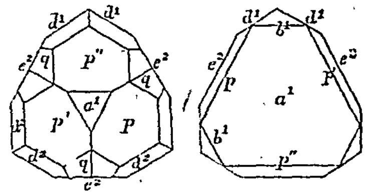

Fig. 252.

The examples of the first kind are tourmaline, calamine, and scolezite, which are uniaxal; axinite, binaxal; boracite and rhodizite, with four axes. Calamine, like tourmaline, has the sharper extremity the antilogue end, and the more flattened the analogue. Compound crystals from Altenberg have both ends analogue, and the portion which lies between the twins antilogue electric; the pyro-electric axis corresponds with the vertical axis of the prism, as in tourmaline. Boracite, which crystallizes in cubic forms, with the opposite solid angles differently modified, has four pyro-electric axes, corresponding to the four octahedral axes. In fig. 253 of this species, the plane which has its angles modified by v is the antilogue pole, and that with the unmodified angles the analogue pole; and, generally, the antilogue pole has either more numerous or larger facets. Rhodizite resembles boracite in its pyro-electricity.

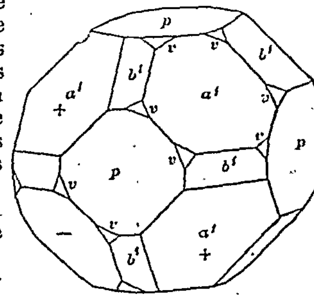

Fig. 253.

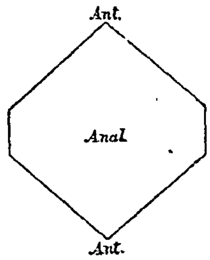

Fig. 254.

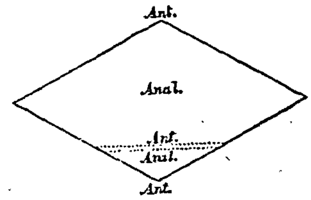

Fig. 255.

The species in which pyro-electricity of the second kind has been observed are prehnite and topaz. If fig. 254 represent a tabular crystal of prehnite, the poles will be situated as marked, the analogue being central, and the antilogue at either extremity of the shorter diagonal of the rhombic prism. Topaz has in a similar manner a central analogue pole, and an antilogue at either extremity of the shorter diagonal. In some instances there is a separate set of similar poles near one or the other angle, as in fig. 255; this must be due to the crystals being of a composite nature.

Magnetism. *Magnetism.*—This property is very characteristic of the few minerals in which it occurs,—chiefly ores of iron or nickel. Some magnetic iron ores possess polar magnetism, or are natural magnets; while the common varieties of magnetite, meteoric iron, magnetic pyrites, precious garnet, and other minerals, are simply magnetic. Most minerals are only attracted by the magnet, but do not themselves attract iron.

Minerals, as other substances, have also been divided into magnetic and diamagnetic. See MAGNETISM.

The ordinary mode of testing whether a mineral is magnetic or not is to bring it near a pole of a delicately suspended magnetic

needle, and observe whether it causes it to vibrate. Another mode is to apply a strong magnet to the mineral in powder. These are sufficient for the mineralogist. Delesse has experimented extensively upon the magnetic force of minerals, and has determined the relative amount for numerous species. Calling this force for Styrian steel 100, the following are some of his results:—

Native platinum	2·173 to 3·047
Magnetic iron ore	15·00 to 65·00
Franklinite, from the United States	1·033
Chromic iron	0·136 to 0·065
Spinel (pleonaste), from Monzoni, Tyrol	0·078
Titanic iron (rhombohedral), often magnetipolar	5·764
Specular iron, sometimes magnetipolar	0·14 to 2·35
Graphite	0·015 to 0·040
Spathic iron (spherosiderite, the highest)	0·092 to 0·287
Iron pyrites	0·039 to 0·057
Vivianite	0·027 to 0·075
Columbite of Bodenmais and Haddam	0·151
Pyrochlore	0·010
Chrysoprase (quartz is diamagnetic, but many varieties are magnetic)	0·004
Felspar, sometimes feebly magnetic.	
Labradorite of an antique green porphyry	0·077
Hornblende	0·012 to 0·057

Magnetic polarity.

Crystallomagnetic Action.—The magnetic polarity thus far alluded to belongs to the mass, and has no relation to crystalline form. There is also a kind of polarity directly related to the crystalline or optic axes of minerals. A crystal of cyanite, suspended horizontally, points to the north, by the magnetic power of the earth only, and is a true compass needle, from which even the declination may be obtained; and the line of direction is the line of the optic axes. Other crystals, which are called negative, take a transverse or equatorial position. The latter are diamagnetic crystals.

Heat conductivity.

Conductivity for Heat.—Senarmont found that the conducting power of colloids and of crystals of the cubic system is equal in all directions, but that it varies in different directions in crystals belonging to all the other systems, exhibiting characters analogous to those deduced from their double refraction, conformable with the optic axes of the crystal, and referable, as in the latter case, to axes of elasticity, or unequal compression of the molecules.

The fundamental fact is easily shown by taking two slices of rock-crystal, one cut transverse to the axis and one parallel to it. Through the centre of each plate a small hole is drilled for the reception of a bent wire, which by insertion into the hole sustains the plate. The other end of the wire is to be heated, and the rate of the conduction of the heat is rendered visible by the amount of a thin coating of beeswax, with which the plate has been previously coated, which is melted round the central hole. It will be seen that in the transverse slice the wax is melted in a circular form, while in the longitudinal slice the form is elliptical (fig. 256). The conduction is equal in all directions, as regards the transverse axes of the hexagonal prism, but more rapid in one direction in the longitudinal slice, and that direction is the line of its optic axis. In the case of quartz the two diameters of the ellipse are as 1000 to 1312.

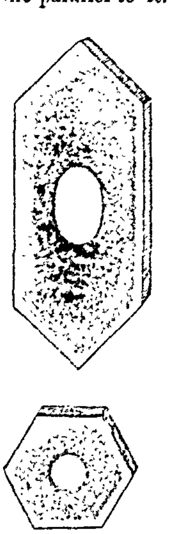

Fig. 256.

If the regular disposition of the molecules of amorphous bodies be interfered with by unequal tension or compression, the regularity of their power of conducting heat is destroyed, and they also show elliptical forms of melted wax; and the shorter axis of the ellipse is in the line of pressure or undue packing of the molecules. The heat thus does not travel so fast in this direction,—partly because it is spent in the heating up of the greater number of molecules. Hence we might conclude that along the main axis of quartz a smaller number of molecules are packed in an equal space than along the transverse. The following are the more important of Senarmont's results.

Senarmont's investigations.

1. Crystals of the tetragonal and rhombohedral systems have one axis of conductivity which is either greater or smaller than the others, and this axis coincides with the main crystallographic axis. The isothermal surfaces are ellipses which lie in the line of this axis, and these ellipses may be either elongated or flattened in the direction of this line.

2. In crystals of the right prismatic system the isothermal surfaces have three unequal axes, which coincide with crystallographic axes drawn parallel to the edges of the rectangular prism.

3. In crystals of the oblique rhombic system the isothermal surfaces have three unequal axes, one of which coincides with the horizontal diagonal of the base, while the other two have directions which are not referable to any law.

4. In crystals of the anorthic system the isothermal surfaces have three unequal axes, all with indeterminable positions.

In crystals of a single axis there appears to exist no constant relation between the axis of optic elasticity, whether maximum or minimum, and the axis of the greatest or of the least calorific conductibility. Thus, of the minerals examined by Senarmont, quartz (+), calcite (−), cassiterite (+), rutile (+), and calomel (+) have all their greatest axis of conductibility parallel to the principal axis; idocrase, beryl, tourmaline, and corundum, all optically negative, have on the contrary their smallest axis of conductibility parallel to the axis.

In crystals belonging to the oblique rhombic system there is rarely coincidence between the thermic axes and the axes of optic elasticity. In gypsum and in felspar these lie apart to a marked extent.

Dilatation.

Dilatation by Heat.—In crystals of those systems in which the molecules are arranged unequally as regards their axes, the amount of their dilatation when heated is unequal in the direction of their axes. Our knowledge of this subject is chiefly due to Mitscherlich.

In crystals of cubic symmetry the expansion is equal in all directions. The dimetric systems—the pyramidal and hexagonal—are brought together as regards this quality, inasmuch as the axes of volumetric change are in these the same; for, while these in the pyramidal correspond with the crystallographic axes, in the hexagonal the three axes are the vertical, one lateral axis, and an axis lying intermediate to the other two and at right angles to the first lateral axis. The expansion along the principal axis may be either greater or less than along the others; and in some minerals there is even contraction along one axis.

In the right prismatic system the axes of dilatation correspond to those of form. In the oblique prismatic one axis corresponds with the orthodiagonal, but the others make angles not only with the other crystallographic axes but, strange to say, with the axes both of thermic conductivity and of optic elasticity. We are as yet ignorant of the properties of anorthic crystals in this respect.

As a consequence of this unequal expansion along different axes, the angles of crystals, other than those of the cubic system, are altered under the influence of heat. The alteration is extreme in the case of calcite, where, through elongation along the vertical axis, with some concomitant contraction of the transverse, the angle of the rhombohedric faces is, when the crystal is heated from 32° to 212° F., diminished from 105° 5′ to 104° 56′ 23″,—the form thus approaching that of a cube, as the temperature is raised.

Dolomite, in the same range of temperature, diminishes 4′ 46″. In some rhombohedrons, as of calc-spar, the vertical axis is lengthened (and the lateral shortened), while in others, like quartz, the reverse is true. The variation is such, either way, that the double refraction is diminished with the increase of heat; for calc-spar possesses negative double refraction, and quartz positive. According to Fresnel the same is true of gypsum. The dilatation for calc-spar, according to experiment, is 0·001961.

Kopp has shown that in the carbonates of lime, magnesia, iron, manganese, and zinc, which are nearly the same in the angle of their crystals, the vertical axis is shorter the greater the atomic volume And since heat diminishes the density, and therefore necessarily increases the volume, the axis a should be lengthened by an increase of temperature, as is actually the case. He has determined by calculation that the change of angle from 32° to 212° should be 7′ 37″.

Although in the greater number of cases the variations are so small as to be scarcely measurable, yet they may be sufficient for establishing a difference between substances which have identical geometric form while belonging to different systems of crystallization. The angle of a rhombohedron might at a certain temperature be 90°, and so coincide with a cube; but that angle would in a rhombohedron change whenever the temperature altered, while the angle of a true monometric cube is constant at all temperatures. The increase in volume and diminution in density which generally result from heating are always accompanied by a change in optical properties. In trimetric crystals, where the principal indices alter unequally, the change affects the amount of divergence of the optic axes. The amount of alteration in gypsum, when the divergence is diminished, is extreme. At the ordinary temperature the angle of the divergence of the optic axes which lie in the plane of symmetry is about 90° for red light; when heated to 177° it is diminished to 0°, and for the moment the crystal appears to be uniaxal. When more highly heated, the axes again diverge, but in a plane at right angles to the original one, and in cooling these changes take place in reverse order. In barytes and celestine again, the alteration in the angle of the optic axes is a divergence when heated.

Characters depending on Cohesion.

These characters are of five kinds:—(1) hardness, (2) tenacity, (3) elasticity, (4) cleavage, (5) fracture. All may be considered as related to the power of resisting attempts to separate one part from another.

Hardness.

1. *Hardness.*—A harder body is distinguished from a softer, either by attempting to scratch the one with the other, or by trying each with a file. Each of these methods is used by the mineralogist in determining the hardness of the species, though the latter is in most cases to be preferred. Both methods should be employed when practicable.

Certain varieties of some minerals give a low hardness under the file, owing either to impurities or imperfect aggregation of the particles, while they scratch another mineral upon which a file would have no effect, showing that the particles of the first are hard, though loosely aggregated. Chiastolite, spinel, and sapphire are common examples of this. When the mineral is too hard to be impressed by a file, the peculiarity of the grating sound will suffice for the practised ear.

Mohs introduced a scale of hardness, consisting of ten minerals, which gradually increase in hardness from 1 to 10. The intervals between 2 and 3 and 5 and 6 are larger than the others. Breithaupt has therefore introduced another degree of hardness between each of the above, and thus his scale consists of twelve minerals.

The scale is as follows:—

1. Talc, common laminated light green variety.
2. Gypsum, a crystallized variety.

2·5. Mica (muscovite).

3. Calcite, transparent variety.
4. Fluor-spar, crystalline variety.
5. Apatite, transparent variety.

5·5. Scapolite, crystalline variety.

6. Felspar (orthoclase), white cleavable variety.
7. Quartz, transparent.
8. Topaz, transparent.
9. Sapphire, cleavable varieties.
10. Diamond.

If the file abrades the mineral under trial with the same ease as No. 4, and produces an equal depth of abrasion with the same force, its hardness is said to be 4; if with more facility than 4 but less than 5, the hardness may be $4\frac{1}{4}$ or $4\frac{1}{2}$, written in decimals 4·25, 4·5. Several successive trials should be made to obtain certain results.

The use of the file is acquired with very little experience; usually a single trial is sufficient. Care must be taken to apply the file to edges of equal obtuseness. That part also of the specimen should be selected which has not been altered by exposure, and has the highest degree of transparency and compactness of structure. The pressure for determination should be rather heavy, and the file should be passed three or four times over the specimen.

Where the scale of hardness is wanting, or a first rough determination is sought, the following experiments may serve:—

Every mineral that is scratched by the finger-nail has H. = 2·5 or less. Minerals that scratch copper have H. = 3 or more. Polished white iron has H. = 4·5. Window-glass has H. = 5 to 5·5. Steel point or file has H. = 6 to 7; hence every mineral that will cut or scratch with a good penknife has H. less than 6. Flint has H. = 7, and only about a dozen minerals, including the precious stones or gems, are harder.

Many specimens present different degrees of hardness on dissimilar faces; as an example of which we mention cyanite and mica. This is confined to the inequilateral primary forms, and like the similar difference of colour, lustre, &c., finds a ready explanation in the theory of their formation; unlike faces are the result of the action of a polar force acting along unlike axes.

This difference in faces parallel to unlike axes may be perceived in nearly all cases, when the methods of trial are sufficiently delicate. Huygens observed long ago that the cleavage face of a crystal of calc-spar differed in hardness from the other faces; and even in a monometric crystal it has been found that the faces of the cube and octahedron are not exactly alike in this respect.

Tenacity.

2. *Tenacity.*—Solid minerals are said to be brittle, sectile, malleable, flexible, or elastic:—

1. *Brittle,* when parts of a mineral separate in powder or grains on attempting to cut it; as baryte, calc-spar.
2. *Sectile,* when pieces may be cut off with a knife without falling to powder, but still the mineral pulverizes under a hammer; as brucite, gypsum.
3. *Malleable,* when slices may be cut off, and these slices flatten out under a hammer; as native gold, native copper.
4. *Flexible,* when the mineral will bend and remain bent after the bending force is removed; as gypsum, graphite, talc.
5. *Elastic,* when after being bent it will spring back to its original position; as mica.

A liquid is said to be *viscous* when, on pouring it, the drops lengthen and appear ropy; as petroleum.

Elasticity.

3. *Elasticity.*—Investigations on this property have not to any extent been entered upon. The unequal elasticity of unlike faces of crystals has been shown by Savart in his acoustic investigations, and he was able to distinguish the rhombohedral from the other faces in the pyramid of quartz crystals; he also showed that the figures formed upon vibrating plates of crystals were directly connected with their optic axes. Milne, by measuring the amount of recoil of a sphere of calcite when struck at different points by another of rock-crystal, found that the elasticity, as thus measured, was greatest along the line of the optic axis, and least in directions at right angles to it. He also found that points which lay intermediate between the main and the transverse axes were most indented by the blows. This goes to show that, although there may be fewest molecules arranged along the lines of the transverse axes, yet cohesion operates with greater intensity along these than in intermediate directions.

When the tenacity of a mineral is overcome by an overwhelming amount of traction, or its elasticity by a sudden shock, its parts are separated, either in flat and continuous surfaces, or in surfaces which are irregular in the extreme. The first of these modes is termed cleavage, the second fracture. In those substances in which cleavage exists it is found that the planes or directions along which it takes place lie in certain strictly definite positions to one another and to the axes of the crystal. They show not the smallest tendency to a transition or gradual passage into the other directions of greater coherence.

Cleavage.

4. *Cleavage.*—The number of these parallel cleavage-planes is altogether indefinite, so that the only limit that can be assigned to the divisibility of some minerals, as gypsum and mica, arises from the coarseness of our instruments. These minima of coherence, or cleavage-planes, are always parallel to some face of the crystal; and similar equal minima occur parallel to every other face of the same form. Hence they are always equal in number to the faces of the form, and the figures produced by cleavage agree in every point with true crystals, except that they are artificial. They are thus most simply and conveniently described by the same terms and signs as the faces of crystals.

Some minerals cleave in several directions parallel to the faces of different forms, but the cleavage is generally more easily obtained and more perfect in one direction than in the others. This complex cleavage is well seen in calc-spar and fluor-spar, and very remarkably in zinc blende, where it takes place in no less than six directions. As in each of these the division may be indefinitely continued, it is clear that no lamellar structure in any proper sense can be assigned to the mineral. All that can be affirmed is that contiguous atoms have less coherence along a direction normal to these planes than in other directions. When cleavage takes place in three directions, it of course produces a perfect crystal form, from which the system of crystallization and angular dimensions of the species may be determined; it is thus often of very great importance.

The common cleavage in the different systems is as follows, those of most frequent occurrence being in italics:—(1) In the cubic system, *Octahedral,* O, along the faces of the octahedron; *Hexahedral,* $\infty O \infty$, along those of the cube; and Dodecahedral, ∞O. (2) In the tetragonal system, Pyramidal, P, or $2P\infty$; *Prismatic,* ∞P, or $\infty P \infty$; or *Basal,* 0P. (3) In the hexagonal system with holohedral forms, Pyramidal, P, or P2; *Prismatic,* ∞P, or $\infty P \infty$; or *Basal,* 0P; with rhombohedral forms, *Rhombohedral,* R; Prismatic, ∞R; or *Basal,* 0R. (4) In the right prismatic system, Pyramidal, P; *Prismatic,* ∞P; Macrodomatic or Brachydomatic, $\bar{P}\infty$ or $\breve{P}\infty$; *Basal,* 0P; Macrodiagonal, $\infty \bar{P} \infty$; or *Brachydiagonal,* $\infty \breve{P} \infty$. (5) In the oblique prismatic system, Hemipyramidal, P, or $-P$; *Prismatic,* ∞P; Clinodomatic, $P^{c}\infty$; Hemidomatic, $P^{o}\infty$ or $-P^{o}\infty$; *Basal,* 0P; Orthodiagonal, $\infty P^{o} \infty$; or *Clinodiagonal,* $\infty P^{c} \infty$. (6) In the

anorthic system, Hemiprismatic, $\infty P'$, or ∞P; Hemidomatic either along the macrodome or the brachydome: *Basal*, $0P$; Macrodiagonal, $\infty \bar{P} \infty$; or *Brachydiagonal*, $\infty \breve{P} \infty$.

In some minerals, as mica and gypsum, the cleavage is readily procured; these may be held in the hand and divided by a knife. Others only cleave with more or less difficulty; these must be placed on a firm support resting on lead, folded paper, or cloth, and a sharp blow struck on a chisel applied in a proper direction. This may often be ascertained by examining the specimen in a strong light. Sometimes it is necessary to subject them to extreme compression in a vice. Some of the hardest substances have not only a perfect but a facile cleavage,—as euclase, topaz, and diamond; many of the softest species have none. The planes produced also vary much in their degree of perfection, being highly perfect in some, as mica and calc-spar, and imperfect in others, as garnet and quartz. In a very few crystalline minerals cleavage-planes can hardly be said to exist. Cleavage must be carefully distinguished from the planes of union in twin crystals, and the division-planes of laminar minerals.

racture. 5. *Fracture.*—This is the irregular manner in which substances may be broken. Even minerals possessed of cleavage may be fractured in other directions; but in amorphous bodies fracture alone occurs. The following varieties of fracture occur, and are highly characteristic:—

1. *Conchoidal*, almost typical of amorphous bodies, but occassionally seen in crystals,—rounded cavities, more or less deep. The name is taken from the resemblance to the successive lines of interrupted growth in a bivalve shell. Seen in flint, obsidian, asphalt. In calcite the direction of this fracture is intermediate to the planes of the mineral's cleavage.
2. *Even*, when the surface of fracture is smooth and free from inequalities.
3. *Rough*, when the surface of fracture is rugged, with numerous small elevations and depressions.
4. *Splintery*, when covered with small wedge-shaped splinters.
5. *Hackly*, when the elevations are sharp, slightly bent, or jagged, as broken iron.
6. *Earthy*, when it shows only fine dust.

Taste, Odour, Touch.

aste. *Taste* belongs only to soluble minerals. The different kinds adopted for reference are as follows:—

1. *Astringent*, the taste of blue vitriol.
2. *Sweetish astringent*, taste of alum.
3. *Saline*, taste of common salt.
4. *Alkaline*, taste of soda.
5. *Cooling*, taste of saltpetre.
6. *Bitter*, taste of epsom salts.
7. *Sour*, taste of sulphuric acid.
8. *Pungent*, taste of sal-ammoniac.
9. *Metallic*, taste of zinc sulphate.

dour. *Odour.*—Excepting a few gaseous and soluble species, minerals in the dry unchanged state do not give off odour. By friction, moistening with the breath, and the elimination of some volatile ingredient by heat or acids, odours are sometimes obtained which are thus designated:—

1. *Alliaceous*, the odour of garlic. Friction of arsenical iron elicits this odour; it may also be obtained from any of the arsenical ores or salts by means of heat.
2. *Horse-radish odour*, the odour of decaying horse-radish. This odour is strongly perceived when the ores of selenium are heated.
3. *Sulphurous*. Friction will elicit this odour from pyrites, and heat from many sulphurets.
4. *Bituminous*, the odour of bitumen.
5. *Fetid*, the odour of sulphuretted hydrogen or rotten eggs. It is elicited by friction from some varieties of quartz and limestone.
6. *Argillaceous*, the odour of moistened clay. It is obtained from serpentine and some allied minerals after moistening them with the breath; others, as pyrargillite, afford it when heated.
7. *Empyreumatic* or *ozonic*. Quartz, when two portions strike one another.

ich. *Touch.*—Some minerals are distinguished by a greasy feeling, as talc; others feel smooth, as celedonite; others meagre, like clay; others cold. This last character distinguishes true gems from their imitations in glass. Some, in virtue of their hygroscopic nature, adhere to the tongue.

Chemical Properties of Minerals.

Influence of Chemical Composition on the External Characters of Minerals.—That the characters of a compound must to a certain extent depend on those of its component elements seems, as a general proposition, to admit of no doubt. Hence it might be supposed possible from a knowledge of the composition of a mineral to draw conclusions in reference to its form and its other properties; but practically this has not yet been effected. Relation of composition to physical properties.

The distinction between the mineralizing and mineralizable or the forming and formed elements lies at the foundation of all such inquiries. Certain elements in a compound apparently exert more than an equal share of influence in determining its physical properties. Thus the more important non-metallic elements, as oxygen, sulphur, chlorine, fluorine, are remarkable for the influence they exert on the character of the compound. The sulphurets, for example, have more similarity among themselves than the various compounds of one and the same metal with the non-metallic bodies. Still more generally it would appear that the electro-negative element in the compound is the most influential, or exerts the greatest degree of active forming power. After the non-metallic elements the brittle, easily fusible metals rank next in power; then the ductile ignoble metals; then the noble metals; then the brittle, difficultly fusible; and, last of all, the metals of the earths and alkalies.

Generally each chemical substance crystallizes only in one form or series of forms. Some substances, however, show dimorphism, or crystallize in two forms, and thus may compose two or more minerals. Thus sulphur, which in nature usually crystallizes in the right prismatic system, when melted forms oblique prismatic crystals. Carbon in one form is the diamond, in another graphite; carbonate of lime appears as calc-spar and as aragonite; the bisulphuret of iron as pyrite and as marcasite. An example of trimorphism occurs in titanic acid, forming the three distinct species anatase, rutile, and brookite. It is remarkable that of dimorphic minerals one form is almost always right prismatic; thus:—

	Rhombic Form.
Cyanite, anorthic	Sillimanite, Andalusite.
Calc-spar, hexagonal	Aragonite.
Susannite, *do.*	Leadhillite.
Rutile, Anatase } pyramidal	Brookite.
Pyrolusite, right prismatic	Polianite.
Cuprite, cubic	Chalcotrichite (?)
Senarmontite, cubic	Valentinite.
Pyrite, do.	Marcasite.
Rammelsbergite, do	Chloanthite.
Argentite, do	Acanthite.
Freieslebenite, oblique prismatic	Diaphorite.
Sulphur, do.	Sulphur.

Even the temperature at which a substance crystallizes influences its forms, and so far its composition, as seen in aragonite, Glauber salt, natron, and borax.

Isomorphism.—Still more important is the doctrine of isomorphism, designating the fact that two or more simple or compound substances crystallize in one and the same form, or often in forms which, though not identical, yet approximate very closely. This similarity of form is generally combined with a similarity in other physical and in chemical properties. Among minerals that crystallize in the tesseral system, isomorphism is of course common and perfect, there being no diversity in the dimensions of the primary form; but for this very reason it is generally of less interest. It is of more importance among crystals of the other systems, the various series of which are separated from each other by differences in the proportions of the primary form. In these perfect identity is seldom observed, but only very great similarity. Isomorphism.

The more important isomorphic substances are either simple substances, as (1) fluorine and chlorine; (2) sulphur and selenium; (3) arsenic, antimony; (4) cobalt, iron, nickel; (5) copper, silver, mercury, gold (?); or combinations with oxygen, as (6) lime, magnesia, and the protoxides of iron, manganese, zinc; (7) sesquioxides, as of iron, manganese, chromium, and alumina; (8) phosphoric acid, vanadic acid, arsenic acid; (9) sulphuric, selenic, chromic acids; or combinations with sulphur, as (10) sulphuret of iron and of zinc; (11) sulphuret of antimony and of arsenic; (12) sulphuret of lead, of copper, and of silver. These substances are named vicarious from the singular property that in chemical compounds they can mutually replace each other in definite proportions, and very often without producing any important change in the form or other physical properties. But there are numerous instances among the silicates where the mutual replacement of the isomorphic

bodies, especially when the oxides of the heavy metals come in the room of the earths and alkalies, exerts a most essential influence on the external aspect of the species, particularly in regard to colour, specific gravity, and transparency. The varieties of hornblende, augite, garnet, epidote, and many other minerals are remarkable proofs of this influence. This intermixture of isomorphic elements confers many valuable properties on minerals, and to it this department of nature owes much of its variety and beauty. Without the occasional presence of the colouring substances, especially the oxides of iron and manganese, the non-metallic combinations would have exhibited a very monotonous aspect. It is also remarkable that in some silicates the substitution of a certain portion of the metallic oxides for the earthy bases seems to be almost a regular occurrence; whilst in others, as the felspars and zeolites, this rarely happens. This fact is also of great economic interest, as drawing attention to important elements often combined with others of less value. Thus iron oxide and chrome oxide, sulphuret of copper and sulphuret of silver, nickel and cobalt, may be looked for in connexion. The general chemical formulæ for such compounds is formed by writing R (=radical or basis) for the whole isomorphic elements; and in special instances their signs are placed one below the other, connected by a bracket, or, as is more convenient, are enclosed in brackets one after the other separated by a comma. Thus the general sign for the garnet is $\dot{R}_3\ddot{Si}_2+\dddot{R}\ddot{Si}$, which, when fully expressed, becomes $(\dot{Ca}_3, \dot{Fe}_3, \dot{Mg}_3, \dot{Mn}_3)\ddot{Si}_2+(\dddot{Al}, \dddot{Fe}, \dddot{Cr})\ddot{Si}$; and this mineral forms many varieties as the one or other element preponderates.

Of the forms special to similar groups of atoms the more notable are—the cubic system, special to metals proper, and binary compounds as protoxides and haloid salts; the tetragonal to binoxides; the rhombohedral to carbonates; the hexagonal to sesquioxides and phosphates and their isomorphs; the prismatic to sulphates and their isomorphs.

The isomorphism of minerals goes as a whole to show that form depends on the number of molecules present, and is comparatively little influenced by the nature of the molecules themselves.

DESCRIPTION OF MINERAL SPECIES.

The arrangement adopted in the following description of mineral species is chemical. Simple substances are considered first, in the order of their quantivalence, then binary compounds, and lastly those of more complex structure. Our limits permit of the briefest notice of the less important, in order that more space may be available for the delineation of the characteristic and transition forms of such as go to constitute the more important rock masses.

The following abbreviations are used:—H., hardness; G., specific gravity (distilled water at 60° Fahr. and barometer 30 inches=1); cl., cleavage; sol., soluble; s. [h. or n.] acid, sulphuric [hydrochloric or nitric] acid; B.B., before blowpipe; ox., oxidizing; red., reducing; c.c., chemical composition; com., combination.

In the chemical formulæ, barred letters express two equivalents, and the dots over the symbols indicate the combination with them of as many equivalents of oxygen as there are dots.

In the symbolic notation the several faces of crystals are separated by semicolons, and the constituent members of combinations by commas. The lettering on the faces of the figures is for the most part that adopted by Miller. In the enumeration of crystal forms, that which is typical of the mineral is placed first.

SIMPLE SUBSTANCES.

Bi-valent elements.

1. SULPHUR, S.

(*a*) Right prismatic. P (*p*) polar edges 106° 38′, 84° 58′, middle edge 143° 17′; ∞P 101° 58′; 0P (*c*); $\frac{1}{3}$P (*s*); P̆∞ (*n*). Crystals pyramidal, single or in druses; also stalactitic, disseminated, and pulverulent. Cl. basal and ∞P. H.=1·5 to 2·5; G.=1·9 to 2·1. Fracture conchoidal or splintery; brittle, sectile. Lustre resinous, streak and colour sulphur-yellow, passing into red, brown, or green. Sublimes in the closed tube. Fuses a little above the temperature of boiling water. Takes fire at 518° F., and burns with a pale blue flame with odour of sulphurous acid. C.c.: pure sulphur, occasionally mixed with traces of selenium, and when amorphous with clay or bitumen. Found chiefly in Tertiary strata. Localities: Girgenti in Sicily, with celestine; Conil in Spain; Bex in Switzerland; Cracow in Poland; deposited from hot springs in Solfatara near Naples; from hot springs in Iceland; from sulphur springs in New York; and in cavities of decomposing galena, cinnabar, and pyrites at several localities.

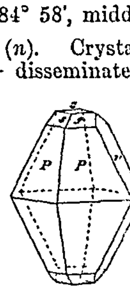

Fig. 257.

(*b*) Oblique prismatic. The crystals of volcanic sulphur are of this form; they occur in the neighbourhood both of extinct and of recent volcanoes. They are slender, needle-shaped, and interlacing, and have generally more or less of a red-brown tinge. Oxhaveer and Cape Reykjanes in Iceland, Sicily, and the volcanoes of the Pacific, the Chilian Andes, and California yield this variety.

2. SELENSULPHUR, S.Se.

Like sulphur, but reddish brown to orange-yellow. B.B. burns with fumes of selenious acid mixed with the sulphurous. Found in the crater of Volcano in the Lipari Islands, and Kilauea in Hawaii.

3. SELENIUM, Se.

H.=2; G.=4·3. Brownish black to lead-grey; thin splinters translucent and red. From Culebras in Mexico.

4. TELLURIUM, Te.

Rhombohedral; R 86° 50′. In minute hexagonal prisms, with basal edges replaced; usually massive and granular. Cl. lateral perfect, basal imperfect. H.=2 to 2·5; G.=6·1 to 6·3. Tin-white; sectile. C.c.: tellurium with a little gold and iron. Occurs at Facsebaya near Zalathna (Transylvania), and in several mines in Boulder county, Colorado; masses 25 lb in weight have been obtained there.

5. ARSENIC, As.

Tri-valent elements.

Rhombohedral; R 85° 36′ (fig. 258). Usually in botryoidal investing masses composed of numberless layers. The structure is fine granular, rarely columnar. H.=3·5; G.=5·7 to 5·93. Cl. basal. Colour black and dull, but when fresh broken very splendent and silver-white; fracture uneven. When rubbed or heated gives out a garlic-like odour. B.B. volatile, with formation of white fumes. C.c.: arsenic, with some antimony, and traces of iron, silver, and gold. Andreasberg in the Harz, Annaberg, Schneeberg, Freiberg, Joachimsthal, Allemont (Dauphiné), Kongsberg (Norway), the Altai, Chili, Pebble mine (Dumfriesshire), Tyndrum (Perthshire).

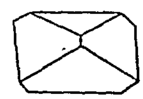

Fig. 258.

6. ANTIMONY, Sb.

Rhombohedral; R 87° 35′; but rarely crystallized, generally in foliated or granular masses. Cl. basal. H.=3; G.=6·6 to 6·8. Tin-white, with slight yellow tarnish. Brittle and sectile. B.B. easily fusible; volatilizes, and on charcoal leaves a white deposit, burning with a pale flame. Found at Andreasberg, Przibram (Bohemia), Sala (Sweden), Allemont, Southham in East Canada, and Borneo.

7. ALLEMONTITE, $SbAs_3$.

Hexagonal, spherical, reniform, and investing. H.=3·5; G.=6·1 to 6·2. Lustre, when fresh, metallic. Tin-white to lead-grey, but with a blue or brown tarnish. B.B. strong odour of garlic, with residuum of oxide of antimony. C.c.: antimony 37·85, arsenic 62·15. Almost always in curved foliated laminæ. Occurs at Allemont, Przibram, Schladming in Styria, Andreasberg.

8. BISMUTH, Bi.

Rhombohedral; R 87° 40′. Crystals, -R, 0R, generally distorted; also reticulated, spear-head twins, or arborescent; also disseminated and granular. Cl. basal, perfect. H.=2·5; G.=9·6 to 9·8. Brittle and sectile. Reddish white, often tarnished grey, brown, or blue. B.B. easily fusible, even in candle flame. Volatilizes on charcoal, leaving a citron-yellow crust. Sol. in n. acid; solution precipitated when thrown into water. Occurs in gneiss and clay slate in veins and disseminated, along with ores of cobalt, silver, lead, and zinc. Alva in Stirlingshire, Cumberland, Devonshire and Cornwall, Schneeberg, Marienberg, Joachimsthal, Bieber, Modum (Norway), Falun (Sweden), Bolivia.

9. TELLURIC BISMUTH, Bi_2Te_3.

Bismuth 52, tellurium 48. Virginia, Dahlonega in Georgia, Montana. A variety with 7 per cent. of selenium and H.=2 also occurs.

10. TETRADYMITE, Bi_2Te_2S.

Rhombohedral; 3R 68° 10′. Almost always twins of 3R and 0R, with the faces of 0R at 93°. Cl. basal, perfect. Sectile, and thin laminæ flexible. H.=1 to 2; G.=7·2 to 7·5. Steel-grey. B.B. fuses, yielding a grain of metal which ultimately volatilizes. Sol. in n. acid. C.c.: 59·6 bismuth, 35·9 tellurium, and 4·5 sulphur. Schemnitz.

11. Wehrlite, $Bi(Te_3S)$.

Hexagonal. Cl. basal. H. = 1 to 2; G. = 8·44. High lustre. Steel-grey. C.c.: bismuth 61·15, tellurium 29·74, sulphur 2·33, silver 2·07. Deutsch-Pilsen in Hungary.

12. Joseite, $Bi_3Te_2(SSe)_2$.

Hexagonal. Cl. basal. G. = 7·93. Colour grey-black to steel-grey. Brittle. C.c.: tellurium 15·93, sulphur 3·15, selenium 1·48, bismuth 79·15. San José (Brazil). A Cumberland variety yielded tellurium 6·73, sulphur 6·43, bismuth 84·33, corresponding to $Bi_4(TeS_4)$.

13. Diamond, C.

Quadrivalent elements.

Var. 1. *Crystallized.*—Cubic; very frequently hemihedral. Crystals most generally with curved faces. Twins common on the octahedral face; hemitropes also common (see figs. 170, 204, 205, 207). Crystals vary remarkably in appearance (see figs. 259 to 262). Cl. octahedral. H. = 10; G. = 3·5 to 3·6. Transparent, or translucent when of dark colour. Refracts light strongly. The back planes of diamonds reflect all the light which strikes them at an angle exceeding 24° 13′, and thence comes their peculiar brilliancy. High adamantine lustre. Colourless, but often tinged white, grey, and brown,—more rarely yellow, pink, blue, green, and black, those last named being the rarest. Disperses light highly, and hence emits brilliant flashes of all the colours of the spectrum. Becomes positively electric by friction. B.B. infusible, but burns into carbonic

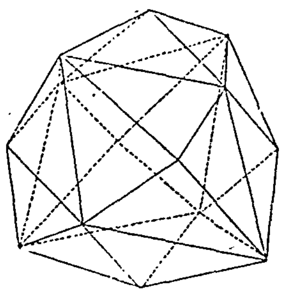

Fig. 259.

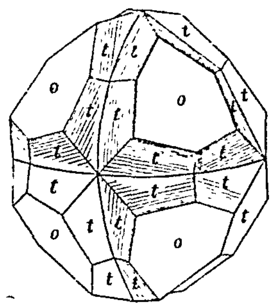

Fig. 260.

acid in oxygen gas. When air is excluded is unchanged at the temperature of melting cast iron, but at that of melting malleable iron is changed into a black coke, or, it is said, into graphite. Insoluble in all acids and alkalies. C.c.: carbon, with traces of silica and earths. Geologic formation apparently a laminated flexible quartz rock called itacolumite, which occurs in Brazil, the Urals, Georgia, and North Carolina, in the vicinity of places where diamonds have been found. Minute crystals have been found in xanthophyllite, and in talc slate and serpentine, in the Schischimskian hills, near Zlatoust (Russia). They have also been obtained in Brazil imbedded in a conglomerate composed of much-worn pebbles of quartz, chalcedony, and gold, cemented by limonite or

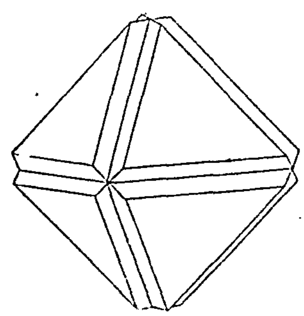

Fig. 261.

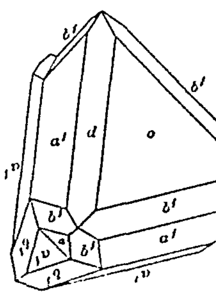

Fig. 262.

ferruginous clay. In South Africa they are imbedded in a steatitic clay. Diamonds were formerly obtained in India, at Panna, Raolconda, and Golconda. So few are now obtained here that the mines are let for £1 a year. From these mines were obtained not only the Kohinoor, which was possibly the same as the great diamond mentioned by Tavernier as having been seen by him in the possession of the Great Mogul, which weighed 280 carats, but the Regent, of 136 carats (which, not only from its size, but from the perfection of its form, is very much the finest diamond known), the Nizam, an uncut diamond of 340 carats, and the Carlow, rose-cut, 193 carats. More lately diamonds were found in great quantity in the neighbourhood of Rio Janeiro in Brazil; they occur in two different deposits: the one called "gurgulho" consists of broken quartz covered by a bed of sand; the other, "cascalho," consists of rolled quartz pebbles united by ferruginous clay; both rest on talcose clays, which are the debris from talcose rocks. The first deposit affords the finest diamonds, and both contain gold, platinum, magnetite, and rutile. A dodecahedral diamond of 257 carats was lately found at Bogagem in this district; this was reduced by cutting to an oblong brilliant of 125 carats, and is the second most valuable diamond,—the Kohinoor, now reduced to an imperfectly circular brilliant of 102 carats, occupying the third place. The two coloured diamonds most worthy of note are a green diamond in the Dresden collection weighing 31 carats, which is a little deeper in tint than a beryl, and a blue diamond in the Hope collection, of 44 carats, as highly coloured as a sapphire, which it is by some considered to be. Diamonds have lately been found in very large quantities, and some of great size, north of the Cape of Good Hope; these for the most part are of yellow colour and of very inferior value. While a Brazilian cut brilliant of one carat is worth from £20 to £25, the value of the finest brilliants from the Cape is only from £3 to £4, and that of the yellow diamonds is from £2 to £2, 10s. Apart from its employment as an ornamental stone, the diamond has an intrinsic value from its being utilized for cutting glass and for grinding and polishing other gems. Of late years its usefulness has had a new application, it being employed for the drilling of rocks in tunnelling operations and in the boring of artesian wells. A singular observation has resulted from these last methods of utilizing it, namely, that the hardness of the African diamonds, as tested by the amount of their endurance, is markedly inferior to that of the Brazilian and Indian. So much is this recognized that, while the bort, or minute crystals, of the latter command a price of 15s. per carat, the African can be got for about 5s. The cleavage of certain of the African diamonds is so eminent that even the heat of the hand causes some of them to fall in pieces. Such diamonds, generally octahedra, may be recognized by a peculiar watery lustre; they are called plate diamonds. The above facts give some ground for the supposition that there may be a slight difference in their composition, possibly that both may contain small, but different, quantities of hydrogen. The circumstances under which diamonds have been formed are altogether unknown. The fact of their being changed into a kind of coke at a very high temperature is an argument against their having been produced through the operation of heat, and it has long been known that an excess of carbon dissolved by molten cast iron crystallizes on cooling in the form of graphite; yet the only attempts to form diamonds deserving of being mentioned as having been attended with any measure of success are those in which sugar charcoal was dissolved in molten silver at the temperature only of melting steel. There were thus obtained a few minute black and also colourless octahedral and cubo-octahedral crystals with curved faces, mingled with a much larger amount of graphitoidal carbon.

Var. 2. *Massive.*—In black pebbles or masses called *carbonado*, sometimes 1000 carats in weight. H. = 10; G. = 3·012 to 3·42. C.c.: carbon except ·27 to 2·07 per cent. of ash. Found in the mines of Baranco, &c., in Bahia.

Var. 3. *Anthracitic.*—Like anthracite, but scratches the diamond. In mammillar masses, partly in concentric layers, and globular. Brittle. G. = 1·66. C.c.: carbon 97, hydrogen ·5, oxygen 1·5. When cut and polished, refracts and disperses light, like the diamond. Supposed from Brazil.

14. Graphite, C.

Hexagonal in flat crystals; $p{:}p$ 85° 29′. Usually foliated, scaly, or compact. Cl. basal. H. = 0·5 to 1; G. = 1·9 to 2·2. Lustre metallic. Colour and streak black to dark steel-grey; flexible in thin laminæ; very sectile; feels greasy; leaves a mark on paper of its own colour; conducts electricity. B.B. burns with difficulty; heated with nitre, deflagrates. C.c.: carbon, with small quantities of volatile matter, and ash from 5 to 40 per cent. Strathfarrer (Inverness-shire), Mull, Craigman (Ayrshire), Borrowdale in Cumberland, Ural Mountains, Ceylon, Greenland. Used for making pencils.

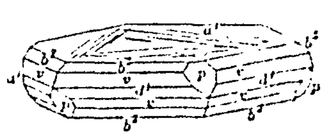

Fig. 263.

15. Tin, Sn.

Tetragonal in greyish white metallic grains. Reported as occurring with Siberian gold; with bismuthite from Guanajuato in Mexico.

16. Iron, Fe.

Cubic; in grains and plates or disseminated. H. = 4·5; G. = 7 to 7·8. Steel-grey or iron-black. Fracture hackly, very magnetic. B.B. infusible. Sol. in h. acid. Two varieties are to be distinguished. (*a*) *Telluric Iron*, in grains and plates. Almost pure iron, or contains graphite, carbon, lead, or copper, but no nickel. At Chotzen in Bohemia in limestone; in an argillaceous sandstone in the keuper at Mühlhausen; in Thuringia along with fossils; in an ironstone conglomerate in Brazil, and in lava in Auvergne; in the mine of Hackenburg; at Bexley, in Liberia, Africa, along with quartz, a zeolite, and magnetite; enclosed in magnetite in Unst (Shetland) and in Sutherlandshire; in basalt in Antrim, Ireland; in the gold sands of Brazil, the Urals, and Olahpian (Transylvania). (*b*) *Meteoric iron*, steel-grey to silver-white. Native metals.

Almost always contains nickel, with cobalt, copper, and several minerals which are non-terrestrial. When polished and etched with nitric acid the surface is marked by lines of unaffected interlacing crystals called Widmannstätten's figures; most of the nickel is contained in these. Occurs in masses which vary in size from the smallest microscopic dust as dredged from the depths of the ocean to upwards of 32,000 lb. Many of these masses have been seen to fall. Several (suspected, however, to be terrestrial) have been found imbedded in a basaltic rock near Disco Bay in Greenland, one of which is 44,000 lb in weight. Several contain hydrogen in their pores, condensed to the extent of eight times the volume of the mass; and the pitted depressions frequently observable upon their surface give countenance to the view that, if not discharged from a volcanic throat, they were set at liberty by some sudden disrupting gaseous explosion.

17. Zinc, Zn.

Rhombohedral. Said to be found in large hexagonal pyramids. Cl. basal, perfect. H. = 2; G. = 7. Lustre metallic. Colour and streak bluish white. Found in a geode in basalt near Melbourne, Australia, coated with smithsonite, erythrine, and aragonite. Also in the gold sands of the Mittamitta river.

18. Copper, Cu.

Cubic (figs. 28, 30, 26, 33, 37, 264). Twins, on an octahedral face. Crystals generally distorted. Often filiform and arborescent, or in plates and laminæ. H. = 2·5 to 3; G. = 8·5 to 8·9. Lustre dull metallic. Colour and streak copper-red, with yellow or brown tarnish. B.B. easily fusible, colouring the outer flame green. Sol. in n. acid. Occurs in many rocks (generally igneous), and frequently associated with zeolites. In the Faroes, Unst (Shetland), Cornwall, Chessy near Lyons, the Banat (Hungary), Siberia, China, Mexico, Brazil, Chili, and Australia. Masses of great size are found, much the largest being from the Ontanagon river, on the south of Lake Superior. One mass found in February 1857 was 45 feet in length, 22 feet in width, and 8 feet in thickness; its weight was 420 tons. Another was found in 1869, 65 feet in length, 32 in width, and from 4 to 7 feet in thickness; this weighed upwards of 1000 tons, and had a value of 400,000 dollars.

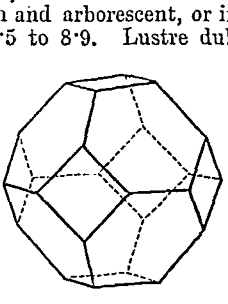

Fig. 264.

19. Lead, Pb.

Cubic, but only in thin plates, capillary or filiform. Cl. none. H. = 1·5; G. = 11·36 to 11·4. Ductile, malleable, and sectile. Bluish grey, but with a blackish tarnish. Found in lava in Madeira, and at the mines near Cartagena in Spain; in amygdaloid near Weissig; in basaltic tufa at Rautenberg in Moravia; with gold near Mount Alatau in the Altai, at Velika in Slavonia, and at Olahpian in Transylvania; near Ekaterinburg in the Urals; in the district of Zomelahuacan in Vera Cruz, in foliated galena, in granular limestone; in the iron and manganese bed of Paisberg in Wermland (Sweden), with hæmatite, magnetite, and hausmannite; in white quartz, north-west, near the Dog Lake of the Kaministiquia, an affluent of Lake Superior; imbedded in hornstone in plates and grains, in the mine of Bogoslovskoi in the Kirghiz steppes; in greenstone porphyry at Stützerbach in Thuringia; with hæmatite in the islands of Nias on the west coast of Sumatra.

20. Mercury, Hg.

Cubic. Occurs in small liquid globules in its gangue, but may be solidified at −39°, when it forms octahedral crystals. G. = 13·596 when liquid, 15·612 when solid. Lustre brilliant metallic; tin-white. B.B. volatile, sometimes leaving a little silver. Readily sol. in n. acid. Occurs generally in clay shales or schists of different ages. The globules of mercury are usually found in rents in cinnabar, or accompanying calomel, at most of the localities for these minerals. Found at Idria in Carniola and Almaden in Spain. At Idria it is obtained by washing a soft clay slate. In Transylvania and Galicia springs issuing from the Carpathian sandstone bear along globules of mercury. At the Pioneer mine in California some of the quartz geodes contain several pounds of mercury. At Cividale in Lombardy it is found in an Eocene marl. It has also been observed occasionally in drift, and has even been stated to have been found in a peat bog.

21. Silver, Ag.

Cubic (figs. 26, 30, 33, 40, 37). Crystals generally small, also and most frequently filiform, arborescent, and in plates or crusts. These either project into cavities, coat their surfaces, or ramify in a reticulated manner throughout the mass of the rock. Twins of octahedral and trapezohedral composition. No cl. H. = 2·5 to 3; G. = 10·1 to 11·1. Lustre metallic. Colour and streak silver-white, but generally tarnished yellow, brown, or black. Malleable, ductile, and sectile, but less so than gold. B.B. easily fusible. Sol. in n. acid; the solution colours the skin black. C.c.: silver, with varying proportions of gold, platinum, mercury, copper, antimony, and bismuth. The auriferous from Norway contains silver 72, gold 28; from quartz reefs in Sutherland, silver 71·4, gold 28·6. The cupriferous from Courcy near Caen contains 10 per cent. of copper. The antimonial from Bohemia contains 1 per cent. of antimony. The mercurial from Kongsberg in Norway has ·4 of mercury, found chiefly in veins in gneiss, clay slate, and limestone. Localities: Alva and elsewhere in Scotland, Ballycorus in Ireland, and Cornwall in England; at Freiberg, Andreasberg, and Kongsberg; along with native copper at Lake Superior; in Mexico, in Peru, and in the United States. The finest crystallized silver occurs at Lake Superior, and at Kongsberg. At the last locality the crystals are an inch in diameter, and are disposed on large filiform brushes. Silver occurs in large masses; three of 436, 560, 812 lb have been recorded from Kongsberg. A block which smelted 44,000 lb was for some years used as a table by Duke Albert on his annual visits of inspection to the Schneeberg mine in Saxony. A Mexican specimen was found of 400 lb; the mines of Huantaya in Peru have yielded masses of 444 and 960 lb. Britain produces annually about 760,000 oz. of silver, chiefly, however, from lead ores. The value of annual produce for the whole world from all sources is from 8 to 10 millions of pounds sterling.

22. Schneiderite (*Gold Amalgam*), Au_2Hg_3.

Tetragonal four-sided prisms, easily crumbling, yellowish white to white; sometimes in grains the size of a pea. C.c.: gold 41·63, mercury 58·37. Found at Mariposa in California. A variety $(Au, Ag)_2 Hg_5$ is found along with platinum in Columbia; this contains gold 38·39, silver 5, mercury 57·40.

23. Arquerite, Ag_6Hg.

Cubic. In octahedra, also in grains and dendrites. G. = 10·8. Like native silver, but softer. C.c.: silver 86·5, mercury 13·5. From Arqueros in Coquimbo, Chili. *Kongsbergite*, $Ag_{18}Hg$, occurs at Kongsberg, with 95·1 of silver and 4·9 of mercury.

24. Amalgam, $Ag.Hg_2$, and $AgHg_3$.

Cubic (fig. 33, in combination with 40, 30, 41, 38). Cl. dodecahedral. H. = 3 to 3·5; G. = 10·5 to 14. Colour and streak silver-white. Fracture conchoidal, brittle, grates when cut. In closed tube yields mercury and leaves silver. Sol. in n. acid. The first variety (silver 34·8, mercury 65·2) occurs at Moschellandsberg in the Palatinate, where the veins of mercury and silver intersect one another; the second (silver 26·25, mercury 73·75) there, and also at Allemont in Dauphiné, Almaden in Spain, in Hungary, and in Sweden. From Rosilla in Atacama (Chili) Domeyko reports the following other compounds: Ag_3Hg_4, silver 46·8, mercury 53·2, white and silvery; $AgHg$, silver 55·1, mercury 44·9, granular and dull; Ag_5Hg_3, silver 64·2, mercury 35·8; of the last there is a mass weighing 22 lb in the museum of Santiago.

25. Gold, Au.

Cubic (figs. 30, 26, 33, 40, 36) and more complex forms. Crystals generally small and indistinct through elongation, assuming capillary and arborescent shapes. Also in thin plates. Twins rare; twin face octahedral. Frequently in rounded and apparently colloidal masses impacted in clay, or loose in small grains (pipettes) rolling in the bed of streams. Fig. 265 is of such a mass found in Sutherland. No cl. H. = 2·5 to 3; G. = 17 to 19·4. Lustre metallic, but frequently dull and partly coated with a brown crust. Colour and streak yellowish white to bright gold-yellow. Malleable, ductile, and sectile; the purer varieties the more so and the softer. B.B. easily fusible. Sol. in aqua regia, generally with precipitation of chloride of silver. Solution yellow, stains skin purple-red, with corrosion. C.c.: gold, with silver from ·72 to 26 per cent.; sometimes iron and copper under 1 per cent. Found in beds and veins generally of quartz in metamorphic rocks of a schistose nature, rarely in diorite and porphyry, and very rarely in granite. Its general associate is limonite, formed from decomposition of pyrite; sometimes also hæmatite and magnetite. Occurs also in microscopic grains in quartz, from which it is extracted by crushing and amalgamation. The geologic range is from the Azoic to the Tertiary and Cretaceous, as in California; but even in these more recent rocks the original source must have been at least Palæozoic. Of localities which yield gold the following may be noticed:—the Leadhills in Scotland, Wicklow in Ireland, Dolgelly in North Wales, Cornwall in England; Transylvania, Hungary, and Piedmont; the Urals, Ekaterinburg, and India; Kordofan, the coast opposite Madagascar, and the Gold Coast (the fame of which has been recently revived); Minas Geraes in Brazil, Bolivia, North Carolina, and

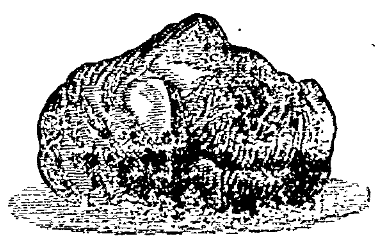

Fig. 265.

California; and more recently New South Wales and Queensland in Australia, Tasmania, and New Zealand.

Some of the largest single masses of gold found in recent times are the following:—one of 22 oz. in Transylvania, of 28 lb in North Carolina, of 20 lb in California, one of 96 lb troy near Miask in the Urals, and one of 184 lb 8 oz., which yielded £8376, 10s. 6d., at Ballarat, Australia.

The annual produce of gold from Australia is about 5 millions of pounds sterling, of the United States about 15 millions, and the whole earth about 23 millions.

The following sub-species may be noticed:—

1. *Electrum.* This name for the alloys of gold and silver was applied by Pliny, whenever the proportion of the latter metal was one-fifth. An alloy of 2 gold and 1 silver contains 21 per cent. of silver; this is found in Sutherland. One of 1 to 1 contains 36 per cent. of silver, this last being the most usual proportion. It occurs in Transylvania, in the Altai, and in Colombia. Its colour is brass-yellow to yellowish white. G. = 12·5 to 15·5.

2. *Porpezite*, or *Palladium Gold* (*ouro-poudré*), from Porpez in Brazil, contains 9·85 per cent. of palladium and 4·17 of silver.

3. *Rhodium Gold*, from Mexico (G. = 15·5 to 16·8), contains from 34 to 43 per cent. of rhodium.

26. Platinum, Pt.

Cubic; rarely in small cubes or octahedrons, usually in minute scaly grains, sometimes cohering, and also in rounded lumps. No cl. H. = 4 to 4·5; G. = 17 to 19. Lustre metallic. Colour and streak pale steel-grey. Malleable and ductile with difficulty, having a hackly fracture. When containing much iron, magnetipolar. B.B. infusible. Sol. in aqua regia, but only when heated; solution red; corrodes the skin. C.c.: platinum, but never to a greater extent than 86·5 per cent. The remainder consists of iron, iridium, rhodium, palladium, osmium, gold, copper, and a mechanical mixture of iridosmine. The iron exists in quantities varying from 4·3 per cent. to double that amount. Occurs in Brazil in syenite; near Popayan (Colombia) in alluvium, associated with chromite, iridium, palladium, gold, and copper; in the Urals in alluvium derived from crystalline rocks; and at Nijni-Tagilsk in serpentine along with chromite. It is also found in Borneo, California, and Carolina, and is said to have been found in the county of Wicklow in Ireland. The sands of many rivers yield it in small amount. Platinum does not occur in large masses. A mass in the Madrid Museum from Condoto weighs 26½ oz.; masses have been found in the Urals from 11 to 21 lb.

Iron Platina is a sub-species. This, which has a composition $FePt_2$, and contains from 11 to 13 per cent. of iron, is found at Nijni-Tagilsk. G. = 14·6 to 15·8; H. = 6. It is magnetipolar, and attracts iron much more strongly than an ordinary magnet.

27. Platiniridium.

In minute silver-white grains. H. = 6 to 7; G. = 16·94 to 22·8. Contains 55·44 platinum, 27·79 iridium, 6·86 rhodium, 4·14 iron, 3·3 copper, ·49 palladium. Is found in Brazil.

28. Iridium, Ir.

Cubic (fig. 27). H. = 6 to 7; G. = 21·57 to 23·46. Cl. cubic, traces. Very slightly malleable. Silver-white to steel-grey. B.B. unchanged. Insoluble in all acids. C.c.: 76·8 iridium, 19·64 platinum, 0·89 palladium, 1·78 copper. Found at Nijni-Tagilsk, generally in minute grains. Is the heaviest known substance.

Avaite, sub-species. From Ava in India. C.c.: 60 iridium, 20 platinum (according to Prinsep).

29. Palladium, Pd.

Cubic; in minute octahedrons, and in grains. H. = 4·5 to 5; G. = 11·3 to 11·8. Malleable. Light steel-grey. B.B. infusible. Slowly dissolves in n. acid, forming a brown-red solution. C.c.: palladium, with a little platinum and iridium. From the gold sands of Brazil, often in small plumose crystalline lumps. Also from St Domingo, and the Urals. Does not tarnish with sulphurous fumes.

30. Allopalladium, Pd_3.

Hexagonal; in small flat hexagons. Cl. basal, perfect. Lustre bright silvery. Colour pale steel-grey. From Tilkerode in the Harz, with gold.

31. Newjanskite (*Osmiridium*), IrOs (iridium 49·78, osmium 50·22) and Ir_3Os.

Hexagonal; P 124°. 0P, P, ∞P. Generally in flat scales. Cl. basal perfect. H. = 7; G. = 18·8 to 19·47. Lustre metallic. Colour tin-white. B.B. unchanged. Insoluble in all acids. The analyses of this mineral give quantities of iridium varying from 44 to 77 per cent., and of osmium from 21 to 49. Ruthenium, rhodium, and platinum make up the 100 parts. The largest quantity of ruthenium is 8·49, and one variety from New Granada was found to contain no ruthenium, but 12·3 of rhodium, which is more than double its usual amount. Occurs with platinum in Choco (Colombia); at Newjansk and several localities in the Urals, in Australia, in northern California (somewhat abundantly in gold sands), also in Canada.

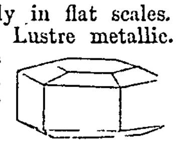

Fig. 266.

32. Sisserskite (*Iridosmium*), $IrOs_4$ (iridium 19·9, osmium 80·1) and $IrOs_3$ (iridium 24·8, osmium 75·2).

Rhombohedral; R = 84° 28′. H. = 7·5; G. = 21·12. Colour lead-grey to bluish. B.B. becomes black, with strong odour of osmic acid; in flame of spirit-lamp shines strongly, and colours flame yellowish red. Occurs in small quantity with newjanskite at all its localities, and in proportionally larger quantity at Sissersk in the Urals. It is used for pointing gold pens, and in the United States sells at 50 dollars an ounce.

COMPOUNDS OF FLUORINE, CHLORINE, BROMINE, AND IODINE (HALOID SALTS).

33. Fluorite (*Fluor-spar*), CaF.

Cubic (figs. 267 to 270, also figs. 31, 33, 36, 55, 56, 57, 58); also divergent crystalline, granular, and compact. Cl. octahedral; fracture conchoidal; brittle. H. = 4; G. = 3·1 to 3·2. Transparent to pellucid. Lustre vitreous. Colourless, but generally coloured purple, blue, green, yellow, white, black, and pink. Sometimes two or three colours disposed in layers in one crystal. Frequently phosphoresces with different tints of light, when heated. B.B. decrepitates and fuses to an opaque bead. Sol. in s. acid with evolution of hydrofluoric acid. C.c.: 51·3 calcium, 48·7 fluorine. Common in veins, generally associated with metallic ores. Shetland, Sutherland, on the Avon, and Ballater in Scotland; Cumberland, Northumberland, Derbyshire, and Cornwall; Saxony, Bohemia, Freiberg. Used to be turned into vases and other ornaments ("blue John"); formerly employed as a flux, now for etching and obscuring glass.

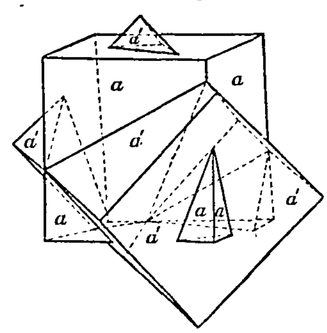

Fig. 267.

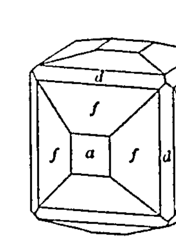

Fig. 268.

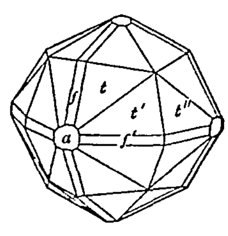

Fig. 269.

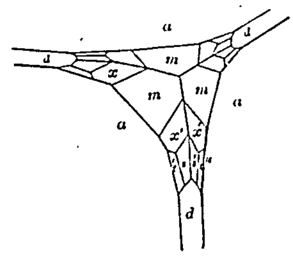

Fig. 270.

34. Yttrocerite.

In crystalline crusts. H. = 4 to 5; G. = 3·4 to 3·5. Translucent; vitreous. Violet-blue to grey or white. B.B. infusible. Evolves fluorine when heated with sulphuric acid. C.c: fluorides of cerium, yttrium, and calcium. Finbo and Broddbo near Falun (Sweden), Massachusetts and New York.

35. Fluocerite, $CeF + Ce_2F_3$.

Hexagonal. H. = 4 to 5; G. = 4·7. Opaque or translucent on the edges. Pale brick-red or yellowish; streak yellowish white. B.B. infusible. In closed tube gives out hydrofluoric acid. C.c.: 82·64 peroxide of cerium, 1·12 yttria, 16·24 hydrofluoric acid. Finbo and Broddbo.

36. Fluocerine, $Ce_2F_3 + (Ce_2O_3 + H_2O)$.

Massive; fracture conchoidal. H. = 4·5 to 5. Opaque; resinous. Bright yellow to reddish brown; streak brownish yellow. B.B. infusible, darkens with the heat; colour restored on cooling. C.c.: cerium 17·6, fluorine 10·9, sesquioxide of cerium 66·4 water 5·1. From Finbo.

37. Bastnaesite, $Ce_2F_3 + Ce_2O_3 + 4H_2O$, and

38. Hamartite, $2(LaO, CeO)3CO_2 + CeF_3$, are similar. The first is from Bastnaes in Sweden, the second from Pike's Peak in Colorado.

39. FLUELLITE, Al_2F_3.

Right prismatic. In acute rhombic octahedrons with truncated apex. Polar edges 109° 6′ and 82° 12′, middle 144°. H. = 3. Lustre vitreous. Colour white; transparent. Stenna-gwyn in Cornwall.

40. CRYOLITE, $3NaF + Al_2F_3$.

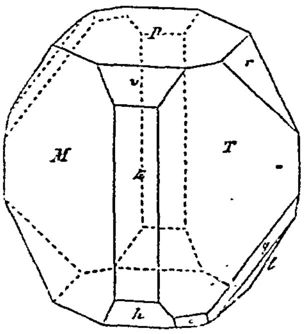

Fig. 271.

Anorthic; but mostly in cleavable masses. $M : T$ 91° 57′; $P : T$ 90° 2′; $P : M$ 90° 40′. Cl. P perfect, M and T imperfect; brittle. H. = 2·5; G. = 2·9 to 3·08. Vitreous, somewhat pearly on P. Translucent; after immersion in water transparent. Colourless and snow-white; but when deep-seated brown to black. Melts even in flame of candle to a white enamel. In open tube traces of hydrofluoric acid. Sol. in s. acid. C.c.: aluminium 13, sodium 32·8, fluorine 54·2. Arksutfiord, Greenland; Miask, Siberia. Used for manufacture of a white glass, and extraction of aluminium.

41. ARKSUTITE, $(CaNa)_2F + Al_2F_3$. Ca : Na = 1 : 3.

Massive granular. H. = 2·5; G. = 3·03 to 3·18. Cl. one distinct. Vitreous; white; translucent. C.c.: aluminium 18·6, sodium 23·3, calcium 6·8, fluorine 51·3. Arksutfiord.

42. CHIOLITE, $3NaF + 2Al_2F_3$.

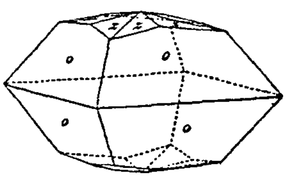

Fig. 272 (species 42).

Pyramidal, and twins (fig. 272). Middle edge 111° 14′. Mostly granular. Cl. imperfect. H. = 4; G. = 2·84 to 2·9. Resinous; white. Fuses more easily than cryolite; evolves hydrofluoric acid. C.c.: aluminium 18·6, sodium 23·4, fluorine 58. Ilmen Mts. near Miask.

43. CHODNEFFITE, $2NaF + Al_2F_3$.

G. = 3. Other characters like chiolite, and from same locality.

44. PACHNOLITE, $3(CaNa)F + Al_2F_3 + 2H_2O$. Ca : Na = 3 : 2.

Oblique prismatic. ∞P 98° 34′; always twins. Vitreous; white; semitransparent. C.c.: aluminium 12·3, calcium 16·1, sodium 12·4, fluorine 51·1, water 8·1. Evolves water with crackling, when heated; other characters like cryolite, along with which it occurs in Greenland.

45. THOMSENOLITE, $2(CaNa)F + Al_2F_3 + 2H_2O$. Ca : Na = 7 : 3.

Oblique prismatic. Prismatic planes striated; ∞P 89° (fig. 273). Cl. basal, perfect. H. = 2·5 to 4; G. = 2·74 to 2·76. Vitreous; cleavage face pearly. White with yellow crust; translucent. C.c.: aluminium 15, calcium 15·4, sodium 7·6, fluorine 52·2, water 9·8. B.B. fuses more easily than cryolite to clear glass, decrepitating violently. Along with cryolite in Greenland.

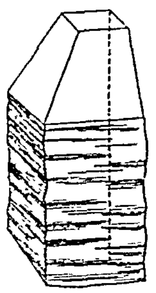

Fig. 273 (sp. 45).

46. GEARKSUTITE, $Ca_2F + Al_2F_3 + 4H_2O$.

Earthy. H. = 2. White; dull; opaque. C.c.: aluminium 15·5, calcium 19·3, sodium 2·5, fluorine 41·2, water 20·3. Along with cryolite.

47. EVIGTOKITE, $2CaF_2 + Al_2F_6 + 2H_2O$.

Crystalline. Soft; brittle; like kaolin. C.c.: calcium 22·39, aluminium 16·23, sodium ·43, fluorine 55·24, water 5·71. Arksutfiord, Greenland.

48. PROSOPITE.

Oblique prismatic. A hydrated silico-fluoride of aluminium and calcium. H. = 4; G. = 2·89. Colourless imbedded crystals. From the tin-mines of Altenberg.

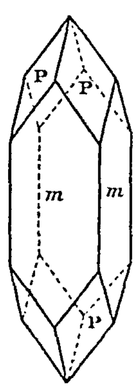

Fig. 274 (sp. 49).

49. CALOMEL, Hg_2Cl.

Pyramidal; P 135° 50′ (fig. 274). H. = 1 to 2; G. = 6·4 to 6·5. Translucent; adamantine. Yellowish white to grey. Sublimes unchanged in closed tube; with soda yields mercury. Insol. in n. acid. C.c.: mercury 85, chlorine 15. Moschellandsberg, Idria, Almaden.

50. SYLVITE, KCl.

Cubic (figs. 26, 30); also massive. Cl. cubic. H. = 2; G = 1·9 to 2. White or colourless. Vitreous; soluble; taste like common salt. C.c.: potassium 52·5, chlorine 47·5. B.B. fuses, and colours flame violet. Crater of Vesuvius, and salt beds of Stassfurt.

51. HALITE (*Common Salt*, *Rock-salt*), NaCl.

Cubic (fig. 21); generally granular, sometimes fibrous. Cl. cubic. H. = 2; G. = 2·1 to 2·2. Transparent to translucent; vitreous. Colourless or white; but often coloured red, yellow, or blue. Taste saline. B.B. fuses and partly evaporates; colours flame yellow. C.c.: sodium 39·3, chlorine 60·7. In great beds at Wieliczka, Salzburg, Bex, &c., on the Continent; Cheshire in England. As an efflorescence in Brazil, Abyssinia, the Caspian and Aral Seas. As a sublimation among lavas at Vesuvius and other volcanoes.

52. SALMIAC, NH_4Cl.

Cubic (figs. 30, 40, and 41 with 26, 33, 40). Cl. octahedral; also stalactitic, globular, and as an efflorescence. H. = 1·5 to 2; G. = 1·5 to 1·6. Pellucid; vitreous. Colourless, but sometimes stained. Taste pungent. B.B. directly volatile; in copper colours flame blue-green. C.c.: 32 ammonia, 66·4 chlorine. A sublimate on active volcanoes. Vesuvius, island of Volcano, Iceland. Near coal-seams which have taken fire, in Scotland and at Newcastle.

53. CHLORO-CALCITE, CaCl + (KCl, NaCl).

Cubic. Vesuvian bombs.

54. CERARGYRITE, AgCl.

Cubic (fig. 26). Twins on octahedral face. No cl.; chiefly massive in crusts. H. = 1 to 1·5; G. = 5·5 to 5·6. Fracture conchoidal. Malleable. Translucent; adamantine to resinous. Grey, yellowish, and greenish. B.B. fuses easily to a dark bead, reduced in inner flame. Soluble in ammonia. C.c.: silver 75, chlorine 25. Johann-Georgenstadt, Mexico, Peru.

55. EMBOLITE, 2AgBr + 3AgCl.

Cubic (fig. 29); also massive or concretionary. H. = 1 to 1·5; G. = 5·8. Adamantine to resinous. Green and yellowish green. C.c.: silver 67, chlorine 13, bromine 20. Chili, Mexico, Honduras.

56. BROMITE, AgBr.

Cubic (figs. 26, 30). H. = 1 to 2; G. = 5·8 to 6. Splendent. Yellow to olive-green; streak siskin-green. B.B. fusible easily. C.c.: silver 57·5, bromine 42·5. San Onofre and Plateros (Mexico).

57. IODITE, AgI.

Hexagonal. Cl. basal; also massive, and in crystalline plates some inches in width; these are flexible. H. = 1 to 1·5; G. = 5·5 to 5·7. Translucent; adamantine. Citron and sulphur-yellow; streak yellow. B.B. fusible, colours the flame purple-red, and leaves button of silver. C.c.: silver 46, iodine 54. Zacatecas in Mexico, Algodones in Chili, Arizona, rarely in Spain.

58. COCCINITE, HgI_2.

In grains of an adamantine lustre, from Casas-Viejas in Mexico. Colour red to yellow; in acute rhombic prisms. Also from Zimapan and Culebras.

59. TOCORNACLITE, $AgI + Hg_2I$.

Amorphous, yellow, soft. Chañarcillo in Chili.

60. COTUNNITE, PbCl.

Right prismatic. H. = 2; G. = 5·238. Transparent; high adamantine to pearly. White. C.c.: lead 74, chlorine 26. Crater of Vesuvius.

61. MOLYSITE, Fe_2Cl_3.

Incrusting. Brownish red and yellow. On lavas of Vesuvius. C.c.: iron 34·5, chlorine 65·5.

62. CARNALLITE, $KCl + 2MgCl + 12H_2O$.

Right prismatic. No cl. Conchoidal fracture. H. = 2 to 2·5; G. = 1·6. Colourless, generally red from iron. C.c.: 34·2 chloride of magnesium, 26·9 chloride of potassium, 38·9 water. Stassfurt, Galicia, Persia.

63. TACHHYDRITE, $CaCl + 2MgCl + 12H_2O$.

Massive. Yellow, translucent, very deliquescent. In anhydrite. C.c.: calcium 7·46, magnesium 9·51, chlorine 40·34, water 42·69. Stassfurt.

64. KREMERSITE, $KCl + NH_4Cl + Fe_2Cl_3 + 3H_2O$.

Cubic; in octahedra. Ruby-red. Soluble. Fumaroles of Vesuvius.

65. ERITHROSIDERITE, $2KCl + Fe_2Cl_3 + 2H_2O$.

Right prismatic. Vesuvian lava.

66. MATLOCKITE, PbCl + PbO.

Pyramidal; P 136° 17′. Crystals tabular. Cl. basal; fracture conchoidal. H. = 2·5; G. = 7·21. Translucent; adamantine. Yellowish white. B.B. fuses easily with decrepitation; colours flame blue. C.c.: chloride of lead 55·5, oxide of lead 44·5. Cromford in Derbyshire.

67. MENDIPITE, PbCl + 2PbO.

Right prismatic; chiefly massive. Cl. ∞P perfect 102° 36′. H. = 2·5 to 3; G. = 7· to 7·1. Fracture conchoidal. Translucent; adamantine to pearly. Yellowish or greyish white. BB. decrepitates, fuses

easily. Sol. in n. acid. C.c.: chloride of lead 40, protoxide of lead 60. Mendip Hills, and Brilon in Westphalia.

68. SCHWARTZEMBERGITE, $PbI + 2PbO$.

Rhombohedral; in thin crusts. H. = 2 to 2·5; G. = 5·7 to 6·3. Adamantine. Honey-yellow. Desert of Atacama.

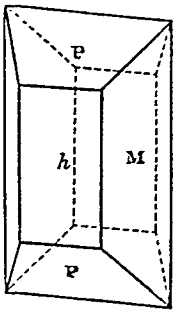

Fig. 275 (sp. 69).

69. ATACAMITE, $CuCl + 3CuO, H_2O$.

Right prismatic; ∞P (*M*) 112° 25′, $\breve{P}\infty$ (*P*) 106° 10′, $\infty\breve{P}\infty$ (*h*) (fig. 275); also reniform. Cl. h perfect. Semitransparent; vitreous. Emerald-green; streak apple-green. B.B. fuses, leaving copper. Easily soluble in acids. C.c.: copper protoxide 55·85, copper 14·86, chlorine 16·61, water 12·68. Atacama, Chili; Tarapaca, Peru; Bolivia; Burra-Burra, Australia; Serra de Bembe, Ambriz, Africa; Vesuvius and (?) Etna.

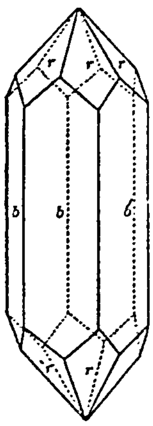

Fig. 276 (sp. 72).

70. TALLINGITE, $CuCl, H_2O + 4CuO, H_2O$.

In crusts. H. = 3; G. = 3·5. Bright blue to greenish blue. Translucent; brittle. Botallack in Cornwall.

71. PERCYLITE, $(PbCl + PbO) + (CuCl + CuO)$.

Cubic (com. of figs. 26, 30, 33, 36). H. = 2. Vitreous. Sky-blue. Sonora in Mexico.

72. CONNELLITE.

Hexagonal (fig. 276). $b : r$ 143° 10′; $r : r$ 132° 50′. Crystals acicular. Vitreous; translucent. Vitriol-blue. A chloride and sulphide of copper. Wheal Unity and Wheal Damsel (Cornwall).

OXIDES OF METALS.

1. SUBOXIDES AND PROTOXIDES.

73. CUPRITE, Cu_2O.

Cubic (figs. 22, 30, 33, 26, with 39, 40). Compact and granular. Cl. octahedral; brittle. H. = 3·5 to 4; G. = 5·7 to 6. Transparent and opaque; adamantine. When transparent, crimson; when opaque, cochineal or brick-red. Often tarnished grey. B.B. becomes black, fuses, and is reduced on charcoal. Soluble in acids and in ammonia. C.c.: 88·9 copper, 11·1 oxygen. Cornwall, Siberia, Banat, Chessy near Lyons, Linares in Spain, Urals, South Africa, Burra-Burra. Valuable copper ore. *Chalcotrichite* consists of cubes elongated so as to become fibrous. Tile-ore is a ferruginous variety. Hepatic copper, liver ore, or pitchy copper ore seems to be a product of the decomposition of chalcopyrite. *Delafossite*, $Cu_2O + Fe_2O_3$, from Bohemia and Siberia.

74. WATER, H_2O.

Hexagonal, when solid, in complex twins in snow crystals; rhombohedric by cleavage, in ice. H. = 1·5; G. = ·918. Hence 1000 of water = 1089·5 of ice, or water expands $\frac{1}{11}$th in freezing. Transparent; vitreous. Colourless, but in bulk pale emerald-green. R 117° 23″. Cl. basal. Water when pure colourless, in mass bluish green. Occurs in centre of geodes of chalcedony in China; of druses of quartz in California and many other countries; in zeolitic cavities to the amount of several gallons in the Faroes, also in the Hebrides, &c. Water of the ocean, from holding saline matters in solution, has G. = 1·027 to 1·0285. Waters of saline lakes contain sometimes 26 per cent. of salts, and have G. 1·212. Besides its vast bulk in the ocean, water occurs in enormous amount in the solid form, often as water of crystallization in rocks and minerals, *e.g.*, zeolites. Igneous rocks in some districts are converted largely into saponite, which contains 25 per cent. of water. Water is the standard for specific gravities of solids and liquids; 1 cubic inch at 60° F. and 30 inches of the barometer weighs 252·458 grains: 1 litre weighs 1000 grammes.

75. PERICLASE, MgO.

Cubic; in cubes and octahedrons. Cl. do. H. = 6; G. = 3·6 to 3·75. Transparent; vitreous. Grey to dark green. B.B. infusible. Sol. in acids. C.c.: magnesia, with 6 to 8 of iron oxide. Somma.

76. BUNSENITE, NiO.

Cubic; in octahedrons. H. = 5·5: G. = 6·4. Vitreous. Pistachio-green. Johann-Georgenstadt.

77. ZINCITE, ZnO.

Hexagonal and granular. Cl. basal. H. = 4 to 4·5; G. = 5·4 to 5·5. Adamantine; translucent. Blood- or hyacinth-red; streak orange-yellow. B.B. infusible, but phosphoresces. C.c.: zinc 80·26, oxygen 19·74; sometimes with manganese peroxide. Valuable ore of zinc. Franklin and Sterling in New Jersey.

78. MASSICOT, PbO.

Massive; scaly crystalline. H. = 2; G. = 7·8 to 8. Sulphur- or lemon-yellow; often contains iron. Popocatepetl in Mexico.

79. MELACONITE, CuO.

Cubic; compact. H. = 3 to 4; G. = 6 to 6·3. Black. B.B. infusible; soluble in acids. Cornwall, Leadhills, Lake Superior, Burra-Burra.

80. TENORITE, CuO.

Oblique prismatic; occurs in thin scales of metallic lustre on lava of Vesuvius. Colour black and dark-red.

2. SESQUIOXIDES.

81. CORUNDUM, Al_2O_3.

Hexagonal; R 86° 4′. Twins common. Cl. rhombohedral, and basal. Excessively tough, and difficultly frangible. H. = 9; G. = 3·9 to 4·2. Transparent or translucent; vitreous, but pearly to metallic on basal face. B.B. unchanged. As *Corundum*, white, grey, and greenish, frequently with bronzy lustre on basal face. C.c.: alumina, with a little peroxide of iron. China, Ceylon, Bohemia, Malabar, Macon in North Carolina (one crystal 300 lb weight). *Emery* is compact, crystalline, granular; grey to indigo-blue. Asia Minor, Naxos, Spain, Greenland, America. Corundum is used when crushed for cutting and polishing gems in China and India, emery in powder for grinding. Alumina occurs also in a purer state in transparent crystals of various tints of colour. When red and of the colour of pigeon's blood they are termed *Rubies*; these come from Syriam in Pegu, Ava, Ceylon, Bohemia, and near Expailly. When 5 carats in weight a ruby is twice the value of a diamond of the same size, when 10 carats three times the value. When blue the crystal is the *Sapphire*, found chiefly in Ceylon and Pegu; when green it is the *Oriental Emerald*, when yellow the *Oriental Topaz*, when purple the *Oriental Amethyst*,—the adjective here distinguishing them from the true or occidental stones of the same name. Other tints of colour also occur, but with the exception of the red and blue they are seldom pure or deep. The prism when cut with a hemispherical dome sometimes displays a six-rayed star, either of a bright gold or a silvery white colour, upon a greyish blue ground. These receive the name of *Asteria Sapphires*. The same crystal frequently shows portions of even three different tints. When perfectly devoid of colour, they are called *Water Sapphires*; such are little inferior to the diamond in brilliancy, but do not disperse rays of light to the same extent.

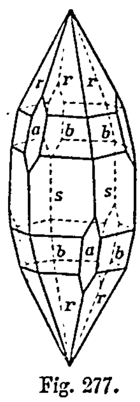

Fig. 277.

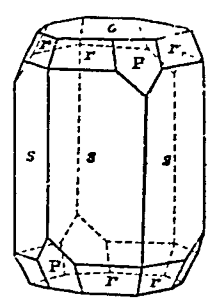

Fig. 278.

82. HÆMATITE, Fe_2O_3.

Hexagonal and rhombohedral; R 86°. Crystals rhombohedric, prismatic, and tabular. Twins with axes parallel. Cl. R, and basal; fracture conchoidal; brittle. H. = 5·5 to 6·5; G. = 5·1 to 5·3. Opaque, but in thin laminæ transparent and blood-red. Brilliant metallic lustre, iron-black to steel-grey, often brilliantly tarnished of red, yellow, green, and blue tints; streak cherry-red. B.B. in the inner flame becomes black and magnetic. Sol. in acids. C.c.: iron 70, oxygen 30. The following are varieties or subdivisions:—

Fig. 279.

Elba Iron Ore, highly modified rhombohedral crystals, often brilliantly tarnished. *Specular Iron Ore*, in thin flat crystals, often from volcanoes, as on the island of Ascension; this variety includes *Micaceous Iron*, thin, lamellar, and curved, and *Red Iron Froth*, scaly. *Red Hæmatite*, in botryoidal and stalactitic forms, which are internally composed of radiating fibres, and often have a concentric structure; the external surface has a dark red to a brownish red hue. *Compact* and *Ochrey* varieties, with more or less aluminous impurity, pass into *Reddle* or red chalk, and when still more earthy into jaspery and columnar ores. This ore is very commonly distributed:—micaceous iron at Pitfichie in Aberdeen and Birnam in Perthshire; red hæmatite at Leadhills and at

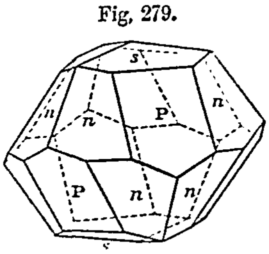

Fig. 280.

Ulverston in Lancashire; specular iron at Tavistock in Devonshire and in Cumberland. *Martite* seems to be the same substance in pseudomorphs after magnetite; it occurs in octahedra in Bute, Framont (Vosges), New York, and Brazil.

83. Ilmenite, $(Fe,Ti)_2O_3$.

Rhombohedral; R 86°. Crystals rhombohedral and tabular, also in twins. Cl. basal; fracture conchoidal. H. = 5 to 6; G. = 4·66 to 5. Opaque, semimetallic, iron-black to dark brown; streak black or reddish brown. Sometimes slightly magnetic. B.B. infusible, but with microcosmic salt forms a red glass. Slowly sol. in s. acid when powdered. C.c.: peroxide of iron, with from 8 to 53 per cent. oxide of titanium. Occurs in metamorphic rocks. Common in chloritic gneiss in Scotland; Menaccan (Cornwall), Ilmen Mountains, Salzburg, Egersund (Norway), Arendal, Dauphiné (*Crichtonite*), Massachusetts (*Washingtonite*).

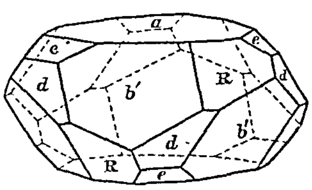

Fig. 281.

84. Iserine.

Cubic; in octahedra. Strongly magnetic; in other respects similar to ilmenite, but occurs in igneous rocks. Common as black ironsand in Scotland; Iserweise in Bohemia, Auvergne, Canada, New Zealand.

3. Compounds of Sesquioxides with Protoxides (Spinels).

85. Magnetite, FeO, Fe_2O_3.

Cubic (figs. 35, 30, 33, 29, 34, 37, with 40, 41, 36). Hemitropes common on octahedral face (fig. 169). Twins (fig. 261). Faces of ∞0 striated in long diagonal. Often compact and granular. Cl. octahedral; fracture conchoidal or uneven; brittle. H. = 5·5 to 6·5; G = 4·9 to 5·2. Opaque; lustre metallic. Iron-black to brown; streak black. Highly magnetic; often polar, forming natural magnets. B.B. becomes brown and non-magnetic, fusing with difficulty. Powder sol. in h. acid. C.c.: 31 protoxide and 69 peroxide of iron; or 72·4 iron, 27·6 oxygen; sometimes with titanic acid. In crystals in Shetland and Sutherland; also Cornwall and Antrim, Traversella (Piedmont), Tyrol, Styria. Massive at Dannemora and Taberg (Sweden), Norway, Urals, Harz, Saxony, Elba. This is the most important ore in Norway, Sweden, and Russia, and affords the finest iron.

86. Magnesio-Ferrite, MgO, Fe_2O_3.

Cubic (fig. 30). H. = 6 to 6·5; G. = 4·57 to 4·66. Other characters same as magnetite. C.c.: magnesia 20, peroxide of iron 87. Fumaroles of Vesuvius.

87. Jacobsite, (MnO, MgO), (Fe_2O_3, Mn_2O_3).

Cubic; O. Black; vitreous; streak red. Nordmark in Sweden.

88. Franklinite, (FeO, ZnO, MnO), (Fe_2O_3, Mn_2O_3).

Cubic (figs. 34, 64); also granular. Cl. octahedral; fracture conchoidal; brittle. H. = 5·5 to 6·5; G. = 5·07. Metallic lustre. Iron-black; streak reddish brown. Opaque; slightly magnetic. B.B. infusible, but shines and throws out sparks. On charcoal with soda a deposit of oxide of zinc. Sol. in h. acid with evolution of chlorine. C.c.: about 67 iron oxide, 17 manganese peroxide, 16 zinc oxide. Franklin and Sterling (New Jersey).

89. Chromite, FeO, Cr_2O_3.

Cubic; in octahedra, generally granular-massive. H. = 5·5; G. = 4·4 to 4·5. Opaque; semimetallic to resinous. Iron-black to dark brown; streak reddish brown. Fracture uneven; sometimes magnetic. B.B. unchanged; in red. flame becomes magnetic; with borax forms an emerald-green bead. Not soluble in acids. C.c.: 19 to 37 protoxide of iron, 0 to 15 magnesia, 36 to 64 peroxide of chromium, 9 to 21 alumina. Unst (Shetland), Towanrieff (Aberdeenshire), Silesia, Bohemia, Styria, Urals, Turkey, Baltimore, Massachusetts, and Hoboken. The ore of chromium; used for dyes. *Irite* is chromite mixed with iridosmium.

90. Uraninite (*Pitch Blende*), UO, U_2O_3.

Cubic (fig. 30); usually massive and botryoidal. H. = 5 to 6; G = 6·5 to 8. Lustre pitch-like to submetallic. Colour velvet-black, brownish black, and grey. B.B. infusible. Not sol. in h. acid, but easily in hot n. acid. C.c.: oxides of uranium 80, with a mixture of other oxides. Johann-Georgenstadt, Annaberg, Przibram, Redruth in Cornwall. The chief ore of uranium.

91. Gahnite, ZnO, Al_2O_3.

Cubic (figs. 166, 30, 33, and with 39, 40). Hemitropes like magnetite. Cl. O; brittle, with conchoidal fracture. H. = 7·5 to 8; G. = 4·3 to 4·9. Opaque; vitreous to resinous. Dark leek-green to blue; streak grey. B.B. unchanged. Unaffected by acids or alkalies. C.c.: 44 oxide of zinc, 56 alumina. Falun, Broddbo, Haddam in Connecticut, and Franklin in New Jersey. *Dysluite* contains 42 per cent. sesquioxide of iron; and *Kreittonite* contains 24 oxide of manganese.

92. Hercynite, FeO, Al_2O_3.

Cubic; generally granular massive. H. = 7·5 to 8; G. = 3·9 to 3·95. B.B. infusible. C.c.: oxide of iron 41·1, alumina 58·9. Ronsberg in the Böhmerwald.

93. Spinel, MgO, Al_2O_3.

Cubic (figs. 30, 33, 40 with 26); hemitropes united by face of O. Cl. octahedral; fracture conchoidal. H. = 8; G. = 3·4 to 4·1. Transparent to opaque; vitreous. Black, red, blue, green; streak white. B.B. infusible and unchanged. C.c.: 28 magnesia, 72 alumina; some with a little iron, and the red varieties some chromium. Varieties are—*Spinel Ruby* when scarlet, *Balas Ruby* when rose-red; both often sold as the true ruby, but not nearly so valuable; when of 4 carats valued at half the price of a diamond the same size. These

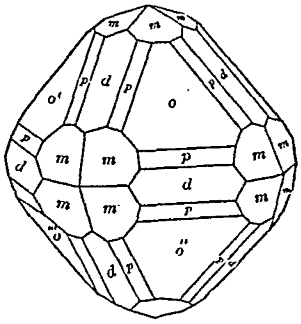

Fig. 282.

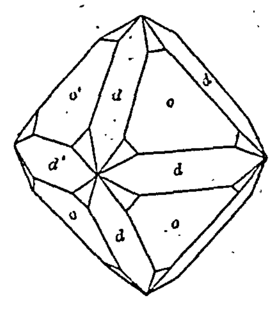

Fig. 283.

come from Pegu (native name Balachan). The violet-coloured is the *Alabandine ruby* from Alabandin in Caria, (Asia Minor). The orange red is the *Rubicella*. The above also occur at Ceylon, Ava, and Siam. *Sapphirine* is pale sapphire-blue to greenish or reddish blue; from Aker in Sweden, Greenland, and North America. *Pleonaste*, dark green or blue to black; from Candy in Ceylon. *Chlorospinel*, grass-green with a yellowish white streak; from Zlatoust. *Water-spinel* colourless; from Ceylon. *Picotite* is a dark blue chromiferous variety from serpentine.

94. Chrysoberyl, GlO, Al_2O_3.

Right prismatic (fig. 284). Twins common, united by a face of P∞ (fig. 285, also 156). Cl. brachydiagonal imperfect, macrodiagonal more so; fracture conchoidal. H. = 8·5; G. = 3·68 to 3·8. Transparent or translucent; vitreous. Greenish white, leek-green, and dark emerald-green. B.B. infusible. Not affected by acids. C.c.: glucina 20, alumina 80. Brazil, Ceylon, India, the Urals, Haddam in Connecticut. A very valuable gem. It sometimes possesses an opalescent band, which when the stone is cut *en cabochon* appears as a streak of floating light; whence it derives its name of *Cymophane*. It is then also called the chatoyant or Oriental chrysolite, and when fine is of extreme value. The emerald-green variety, or *Alexandrite*, is columbine-red by transmitted light.

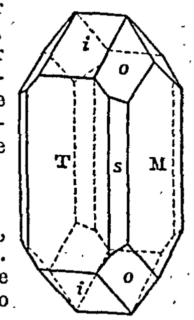

Fig. 284 (sp. 94).

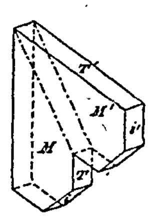

Fig. 285.

4. Deutoxides.

95. Rutile, TiO_2.

Pyramidal; prisms dominant. P 84 40′; P∞ 65° 35′ (figs. 286, 287). Hemitropes common, with axes of halves 114° 26′. Cl. ∞ P and ∞P∞, perfect. H. = 6 to 6·5; G. = 4·2 to 4·3. Transparent to opaque; adamantine lustre. Brown-red, red, pale yellow, and black; streak yellowish brown. B.B. unchanged; with borax in the ox. flame forms a greenish, in the red. flame a violet glass. Not affected by acids. C.c.: titanic acid, with some peroxide of iron. Craigcailleach and Ben-y-Gloe (Perthshire), The Cobbler and Ben-Bheula (Argyllshire), Alps, Limoges, Norway, Brazil. Large crystals at Titanium Mount (Lincoln county, Georgia). Used in porcelain painting, and for tinting artificial teeth. When attenuated crystals are imbedded in rock-crystal they are called Venus' hair.

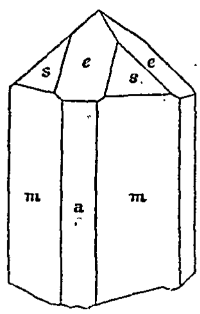

Fig. 286.

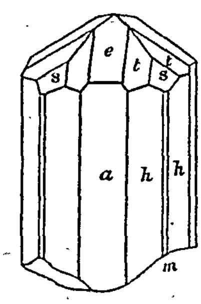

Fig. 287.

109. Manganite, Mn_2O_3, H_2O.

Right prismatic, sometimes hemihedric; ∞P (*M*) 99·40. Crystals prismatic (figs. 298 to 300); vertically striated; also columnar or fibrous. Hemitropes common. Cl. brachydiagonal, perfect; brittle. H. = 3·5 to 4; G. = 4·3 to 4·4. Opaque; metallic lustre. Steel-grey to iron-black; streak brown. B.B. infusible. Sol. in warm h. acid. C.c.: peroxide of manganese 89·9, water 10·1. Grandholm (Aberdeenshire), Cork, Upton Pyne (Exeter), Churchhill (Somerset), Warwickshire, Ihlefeld, Thuringia, Norway, Sweden, Nova Scotia.

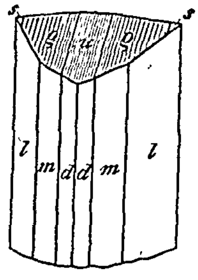

Fig. 298.

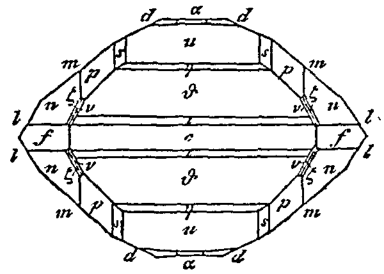

Fig. 299 (sp. 109).

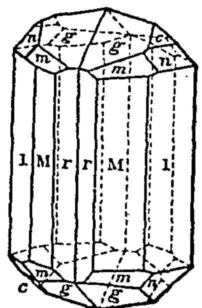

Fig. 300 (sp. 109).

110. Limonite, $2Fe_2O_3+3H_2O$.

Fibrous, botryoidal, and stalactitic, sometimes earthy. H. = 4·5 to 5·5; G. = 3·4 to 3·95. Opaque; lustre silky, glimmering, or dull. Brown, yellowish and blackish brown, often black on surface; streak ochre-yellow. In closed tube yields water and becomes red. B.B. in inner flame becomes magnetic, fusing to a glass. C.c.: peroxide of iron 85·6, water 14·4. Sandlodge (Shetland), Hoy (Orkney), Clifton, Bristol, Cornwall, Harz, Thuringia, Nassau, Styria, Carinthia, Siberia, United States.

111. Xanthosiderite, Fe_2O_3, $2H_2O$.

Fibrous, stellate, also as an ochre. H. = 2·5. Silky or greasy, pitch-like or earthy. In needles, golden-yellow or brown-red; as an ochre, yellow, red, or brown; streak ochre-yellow. B.B. like limonite. C.c.: peroxide of iron 81·6, water 18·4. Hoy (Orkney), Achavarasdale, Kilbride, Wicklow, Ilmenau, Goslar, and Elbingerode in the Harz.

112. Beauxite, $(3Al_2O_3, Fe_2O_3)$, $2H_2O$.

Oolitic, concretionary, disseminated; also earthy and clay-like. G. = 2·55. White, grey, ochre-yellow, brown, and red. C.c.: alumina 50·4, peroxide of iron 26·1, water 23·5. From Beaux (or Baux) near Arles, and elsewhere in France. In grains in compact limestone. Pure varieties used for manufacture of aluminium.

113. Eliasite, $U_2O_3+2H_2O$.

Amorphous masses; resin-like. H. = 3·5 to 4·5; G. = 4 to 5. Reddish brown to black; streak wax-yellow to olive-green. C.c.: 68·5 per cent. sesquioxide of uranium. 10 of water, with impurities. Elias mine (near Joachimsthal).

114. Brucite, MgO,H_2O.

Rhombohedral; R 82° 22′; also foliated and botryoidal columnar. Cl. basal, perfect; sectile; laminæ flexible. H. = 2; G. = 2·3 to 2·4. Translucent, pearly. Colourless. B.B. infusible. Easily soluble in acids. C.c.: 69 magnesia, 31 water. *Nemalite* is a fibrous variety with silky lustre. Swinaness and Quin Gio in Unst, Beresovsk in the Urals, Hoboken, New Jersey, Texas, Pennsylvania.

115. Pyrochroite, MnO, H_2O.

Foliated. H. = 2·5. Pearly, white, but changing through bronze to black. Flesh-red by transmitted light. In matrass becomes verdigris-green, finally black, yielding water. Sol. in h. acid. C.c.: protoxide of manganese 79·8, water 20·2. In veins in magnetite at Paisberg in Sweden.

116. Gibbsite (*Hydrargillite*), Al_2O_3, $3H_2O$.

Hexagonal. C.c.: 65·5 alumina, 34·5 water. The crystals are from Zlatoust in the Urals; stalactites from Richmond in Massachusetts and Villa Rica in Brazil.

117. Limnite, Fe_2O_3, $3H_2O$.

Massive in stalactites, also as a yellow ochre. Like limonite, but pitchy lustre. C.c.: peroxide of iron 74·8, water 25·2. Leadhills, Botallack (Cornwall), Novgorod (Russia).

118. Hydrotalcite, Al_2O_3, $3H_2O+6MgO$, H_2O+6H_2O.

Hexagonal. Cl. basal, foliated, and somewhat fibrous. H. = 2; G. = 2·04. White, pearly. Greasy to the touch. Translucent. C.c.: alumina 16·8, magnesia 39·2, water 44. Zlatoust, Urals; Snarum, Norway; New York.

119. Pyroaurite, Fe_2O_3, $3H_2O+6MgO$, H_2O+6H_2O.

Hexagonal; tables and scaly coatings. Lustre pearly to submetallic. Colour white to gold-yellow. Translucent. B.B. infusible, yields water. Sol. in h. acid. C.c.: peroxide of iron 23·9, magnesia 35·8, water 40·3. Haaf Grunay in Shetland, Långban in Wermland.

120. Gummite, U_2O_3, $3H_2O$.

In rounded lumps, resembling gum. H. = 2·5 to 3; G. = 3·9 to 4·2. Lustre greasy. Reddish yellow to yellowish brown. C.c.: 72 per cent. sesquioxide of uranium water 14·75, with impurities. Johann-Georgenstadt.

121. Psilomelane, (BaO, MnO) MnO_2+3H_2O, MnO_2+3H_2O.

Massive and botryoidal; fracture conchoidal. H. = 5·5 to 6; G. = 4·1 to 4·3. Bluish black. B.B. infusible. About 80 per cent. of oxide of manganese, with baryta, potash, and water. Hoy (Orkney), Leadhills, Cornwall, Devon, Schneeberg, Ilmenau, Vermont in France. *Wad* is similar, but sometimes soft and light. Leadhills, Cornwall, Harz, France.

122. Chalcophanite, $MnOZnO+2MnO_2+2H_2O$.

Hexagonal. R : R 114° 30′. Cl. basal. H. = 2·5; G. = 3·91. Metallic lustre. Blue-black; streak brown, dull. Opaque; flexible. C.c.: manganese binoxide 59·94, protoxide 6·6, zinc oxide 21·7, water 11·6. Sterling Hill (New Jersey).

OXIDES OF NON-METALS.

1. Oxides of Arsenic-Antimony Family (Teroxides).

123. Arsenolite, AsO_3.

Cubic; in octahedra; also botryoidal, stalactitic. H. = 1·5; G. = 3·7. Lustre vitreous. White; streak pale yellow. Translucent. Sublimes in closed tube, condensing in brilliant octahedra. C.c.: arsenic 75·76, oxygen 24·24. Cornwall, Andreasberg, Joachimsthal, Kapnik (Hungary), Nevada, California.

124. Senarmontite, SbO_3.

Cubic; in octahedrons. Cl. octahedral, also massive granular. H. = 2 to 2·5; G. = 5·22 to 5·3. Transparent; adamantine. White or grey. B.B. in inner flame fuses and colours the flame greenish blue. Sol. in h. acid. C.c.: antimony 83·56, oxygen 16·44. Endellion in Cornwall, Constantine in Algeria, Malaczka in Hungary.

125. Valentineite, SbO_3.

Right prismatic; ∞P 137°. Cl. ∞P, perfect. H. = 2·5 to 3; G. = 5·5 to 5·6. Translucent; adamantine to pearly. Yellowish white, brown-grey; streak white. Other properties and composition like senarmontite. Glendinning (Dumfriesshire), Przibram, Bräunsdorf (Saxony), Harz, Hungary, Allemont (Dauphiné), Siberia.

126. Bismite, BiO_3.

Massive, earthy. G. = 4·36. Grey, yellow, green. C.c.: bismuth 89·65, oxygen 10·35. St Agnes (Cornwall), Schneeberg, Siberia.

127. Molybdite, MoO_3.

Right prismatic; ∞P 136° 48′. In capillary crystals, also powdery. H. = 1 to 2; G. = 4·5. Straw-yellow to yellowish white. C.c.: molybdenum 65·71, oxygen 34·29. With molybdenite at many of its localities.

128. Tungstite, WO_3.

Earthy. Soft yellow or yellowish green. Sol. in alkalies. C.c.: tungsten 79·3, oxygen 20·7. Cumberland and Cornwall, Monroe in Connecticut.

129. Cervantite, SbO_3+SbO_5.

Right prismatic. Acicular, generally earthy. H. = 4 to 5; G. = 4·1. Isabel-yellow, reddish white. B.B. on charcoal reduced; unaltered *per se*. Sol. in h. acid. Harehill, Ayrshire; Endellion, &c., Cornwall; Cervantes, Spain; Felsöbanya, Hungary; Mexico; Canada; California.

130. Stibiconite, SbO_4, H_2O.

Massive, powdery. H. = 4 to 5·5; G. = 5·28. Pale yellow. In closed tube yields water. C.c.: antimony 74·9, oxygen 19·6, water 5·5. Goldkronach (Bavaria).

131. Volgerite, SbO_5, $5H_2O$.

Massive and powdery. White. In tube yields water, below redness. C.c.: antimony 58·9, oxygen 19·3, water 21·8. Constantine in Algeria.

132. Zundererz (*Tinder Ore*).

In soft, flexible, tinder-like masses. Colour dark cherry-red to blackish red; lustre glimmering. Two varieties:—one, from Klausthal, contains antimony oxide 33, iron oxide 40, lead 16, sulphur 4; the other, from Andreasberg and Klausthal, seems to be a mixture of jamesonite (82·04 per cent.), mispickel (13·46), and pyrargyrite (4·34).

133. Tellurite.

Yellowish or whitish. Radiated, spherical masses. Gives the reactions of tellurous acid. Facsebaya and Zalathna, Colorado.

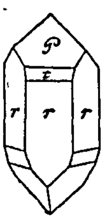
134. Tantalic Ochre.

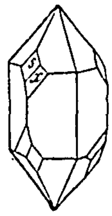
Powdery; brown; vitreous. Pennikoja in Finland.

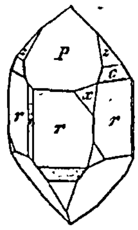
2. Oxides of Carbon-Silicon Family (Binoxides).

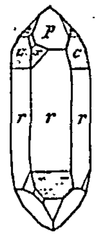
135. Quartz, SiO_2.

Hexagonal; the purest varieties tetartohedral. The primary pyramid P has the middle edge = 103° 34′, and the polar edges =









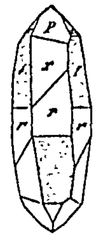


Fig. 301. Fig. 302. Fig. 303. Fig. 304. Fig. 305.

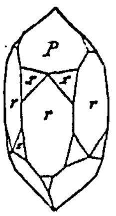
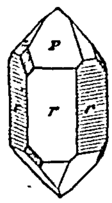
133° 44′, and is often perfect. Very frequently it appears as a rhombohedron R (or ½P), with polar edges = 94° 15′. Crystals often of ∞P, P or ∞P, P, 4P, the forms ∞P and 4P being combined in an oscillatory manner, producing striæ on the face of the prism (figs. 303, 304, 305); also ∞P, P, ¼(2P2), the last face appearing as a rhomb replacing the alternate angles between the two other forms (figs. 307, 308). They are prismatic, or pyramidal, or rhombohedral, when P is divided into R and −R; the latter very often wanting. Many faces plagihedral, as in figs. 302, 306, 309.





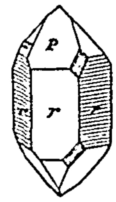


Fig. 306. Fig. 307. Fig. 308.

Twins common, with parallel axes, and either merely in juxtaposition (see fig. 178) or interpenetrating. Crystals often distorted, as in figs. 310 to 313. The crystals occur either single, attached, or imbedded, or in groups and druses. Most frequently granular, massive, fibrous, or columnar; also in pseudomorphs, petrifactions, and other forms. Cl. rhombohedral along R, very imperfect; prismatic along ∞P, still more imperfect; fracture conchoidal, uneven, or splintery. H. = 7; G. = 2·5 to 2·8; 2·65 in the purest varieties. Colourless, but more often white, grey, yellow, brown, red, blue, green, or even black. Lustre vitreous, inclining to resinous; transparent or translucent; when impure almost opaque. B.B. infusible alone; with soda effervesces, and melts into a clear glass. Insoluble in acids, except the hydrofluoric; when pulverized, slightly soluble in solution of potash. C.c.:

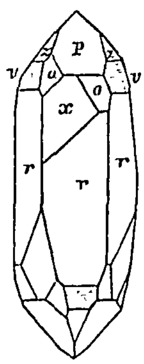

Fig. 309.

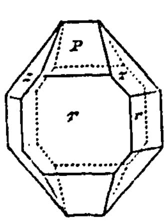

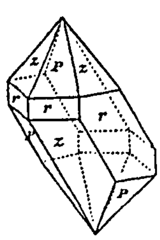

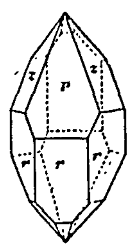

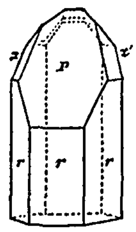

Fig. 310. Fig. 311. Fig. 312. Fig. 313.

48·05 silicon and 51·95 oxygen; but frequently a small amount of the oxides of iron or titanium, of lime, alumina, and other substances.

The following are varieties:—

Rock-crystal: highly transparent and colourless; Dauphiné, Switzerland, Tyrol, Hungary, Madagascar, and Ceylon.

Amethyst: violet-blue (from iron peroxide or manganese), and often marked by zigzag or undulating lines, and the colour disposed in clouds; Siberia, Persia, India, Ceylon, Brazil (white or yellow, named false topaz), Hungary, Ireland (near Cork), and Aberdeenshire. Wine-yellow (*Citrin* and *Gold Topaz*); the brown or *Smoky Quartz* (coloured by a substance containing carbon and nitrogen); and the black or *Morion*, from Siberia, Bohemia, Pennsylvania, and other places. *Cairngorm Stone*, black, brown, or yellow, from Aberdeenshire mountains. The above are valued as ornamental stones; those which follow are less so.

Rose Quartz: red inclining to violet-blue; Clashnaree Hill (Aberdeen), and Rabenstein in Bavaria. *Milk Quartz*: milk-white, and slightly opalescent; Greenland. *Prase*: leek and other shades of green; Saxony and Cedar Mountain in South Africa. *Cat's-eye*, inclosing asbestos: greenish white or grey, olive-green, red, brown, or yellow; Ceylon and Malabar. *Avanturine*, enclosing mica: yellow, red, green, or brown; India, Spain, and Scotland. *Siderite*: indigo or Berlin blue; Golling in Salzburg.

Common Quartz, crystallized or massive, white or grey, also red, brown, &c., is a frequent constituent in many rocks. Some impure varieties are properly rocks, as:—

(1) *Ferruginous Quartz*, or *Iron Flint*: red, yellow, or brown; often associated with iron ores.

(2) *Jasper*: red, yellow, brown, also green, grey, white, and black; alone, or in spots, veins, and bands (*Ribbon* or *Egyptian Jasper*); Urals, Tuscan Apennines, Harz, and many parts of Scotland.

(3) *Lydian Stone*, or *Flinty Slate*: black, grey, or white; has a splintery or conchoidal fracture, breaks into irregular fragments, and passes by many transitions into clay-slate, of which it is often merely an altered portion, as in Scotland; used as a touchstone for gold, and at Elfdal (Sweden) manufactured into ornaments.

(4) *Hornstone* or *Chert*: compact, conchoidal, splintery fracture; translucent on the edges; dirty grey, red, yellow, green, or brown; passes into flinty slate or common quartz; common in the Mountain limestone, Oolite, and Greensand formations; and often contains petrifactions, as shells, corals, and wood.

Other siliceous minerals seem intimate mixtures of quartz and opal, as:—

Flint: greyish white, grey, or greyish black, also yellow, red, or brown; sometimes in clouds, spots, or stripes; semitransparent; lustre dull; fracture flat conchoidal; occurs chiefly in the Chalk formation, as in England, Ireland, Aberdeenshire, France, Germany, and other countries; sometimes in beds or vertical veins, often in irregular lumps or concretions, inclosing petrifactions, as sponges, echinoids, shells, or siliceous *Infusoria*. The colour is partly derived from carbon, or organic matter. Used formerly for gun-flints, and still for the manufacture of glass and pottery; and cut into cameos or other ornaments.

Chalcedony: semitransparent or translucent; white, grey, blue, green, yellow, or brown; stalactitic, reniform, or botryoidal, and in pseudomorphs or petrifactions; Iceland, Faroes, Trevascus in Cornwall, Scotland, Hungary, Bohemia, Oberstein. *Carnelian*: chiefly blood-red, but also yellow, brown, or almost black; India, Arabia, Surinam, and Siberia; also Bohemia, Saxony, and Scotland (Fifeshire). *Plasma*: leek- or grass-green, and waxy lustre; Olympus, Black Forest, India, and China.

Chrysoprase: apple-green; Silesia, and Vermont in North America. *Moss-Agate* and *Heliotrope*: dark green and dendritic (called *Bloodstone* when sprinkled with deep red spots); India, Siberia, Bohemia, Fassa Valley, island of Rum and other parts of Scotland.

136. Tridymite, SiO_2.

Hexagonal; P middle edge 124° 4′, polar edges 127° 35′. Single crystals, very minute hexagonal tables of 0P, ∞P, but with the edges replaced by P and ∞P2, are rare (fig. 314). Mostly twinned

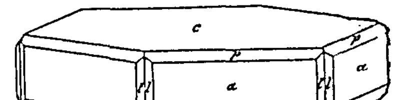

Fig. 314.

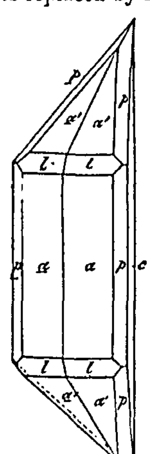

Fig. 315.

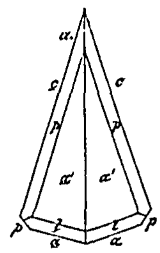

Fig. 316.

in double or (oftener) triple combinations (figs. 315 to 317). Cl. basal, indistinct; fracture conchoidal. H. = 7; G. = 2·282 to 2·326. Colourless and transparent; vitreous, pearly on the base. B.B. like quartz. C.c.: 96 silica, with some alumina, magnesia, and iron peroxide, probably from the matrix. Discovered by Von Rath in the trachyte of San Cristobal, near Pachuca, in Mexico; also in the trachyte of Mont-Dore (Puy-de-Dôme), the Drachenfels, and Hungary. Many opals, treated with solution of potash, leave crystals, as those from Zimapan, Kaschau, Silesia, and the cacholong from Iceland. Where such crystals are abundant, the opal becomes opaque or snow-white. Jenzsch regards these as still another variety of silica.

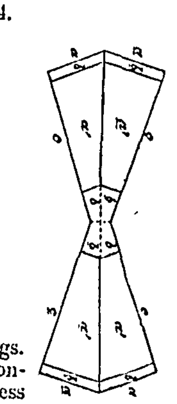

Fig. 317.

137. Opal, $9SiO_2$, H_2O to $3SiO_2$, H_2O.

Amorphous; fracture conchoidal; very brittle. H.=5·5 to 6·5; G.=2 to 2·2. Transparent to opaque; vitreous, inclining to resinous. Colourless, but often white, yellow, red, brown, green, or grey, with a beautiful play of colours. B.B. decrepitates and becomes opaque, but is infusible; in the closed tube yields water; almost wholly soluble in solution of potash. C.c.: silica, with 5 to 13 per cent. water. Most opals are mixtures of various minerals.

The following varieties may be noticed;—(1) *Hyalite, Glassy Opal*, or *Müller's Glass*: transparent, colourless, very glassy; small botryoidal, or incrusting; Kaiserstuhl in the Breisgau, Schemnitz, Silesia, Moravia, Mexico, and other places. (2) *Fire Opal* or *Girasol*: transparent; brilliant vitreous lustre; bright hyacinth-red or yellow; Zimapan in Mexico, and the Faroes. (3) *Noble Opal*, semi-transparent or translucent; resinous, inclining to vitreous; bluish or yellowish white, with brilliant prismatic colours; most show double refraction and are binaxal; in irregular masses or veins near Eperies in Hungary; Australia. (4) *Common Opal*: semitransparent, vitreous; white, yellow, green, red, or brown; Hungary, also Faroes, Iceland, the Giant's Causeway, and the Western Isles of Scotland. (5) *Semi-opal*: duller and less pellucid; *Wood Opal* or *Lithoxylon*: with the form and texture of wood distinctly seen; Hungary, Bohemia, and other countries. (6) *Menilite*: compact, reniform; opaque and brown or bluish grey; Menilmontant, near Paris. (7) *Opal Jasper*: blood-red, brown, or yellow. (8) *Cacholong*: opaque, dull, glimmering, or pearly, and yellowish or rarely reddish white; in veins or reniform and incrusting; Faroes, Iceland, the Giant's Causeway. One variety is named *Hydrophane*, from imbibing water, and becoming translucent. (9) *Siliceous Sinter*: deposited from the Geyser and other hot springs; and *Pearl Sinter*: incrusting volcanic tufa at Santa Fiora in Tuscany (*Fiorite*), and in Auvergne.

138. Zircon, ZrO_2, SiO_2.

Pyramidal; P 84° 20′. Crystals, ∞P, P; often with 3P3; also ∞P∞, P; or ∞P∞ (*s*), ∞P (*l*), P (*P*), 3P3 (*x*), P∞ (*t*), 4P4 (*y*), 5P5 (*z*), (fig. 318, also 86, 87, 585). Chiefly prismatic or pyramidal, and in rounded grains. Transparent to opaque; vitreous, often adamantine. Rarely white, generally grey, yellow, green, or frequently red and brown. B.B. loses its colour, but is infusible. Not affected by any acid except concentrated s. acid, after long digestion. C.c.: 66·3 zirconia and 33·7 silica, with 0 to 2 iron peroxide as colouring matter. Miask, Arendal, Sweden, Belgium (at Nil-St-Vincent), Carinthia, Tyrol, Ceylon, and North America; in Scotland, Scalpay in Harris (fig. 319), Lewis (*Hyacinth*), Sutherland, Ross. The colourless varieties are sold for diamonds. The more brilliantly coloured are named hyacinths, and are valuable gems.

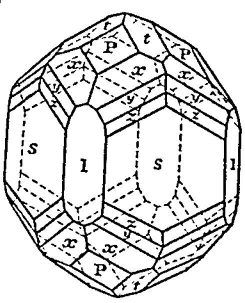

Fig. 318.

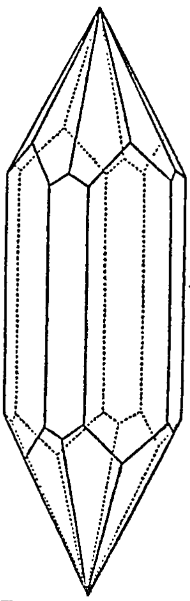

Fig. 319 (sp. 138).

SULPHIDES, SELENIDES, TELLURIDES, &c.

139. Pyrite, FeS_2.

Cubic; semitesseral dominant (figs. 320 to 323, also 67 to 77, and 26 to 34). Pentagonal-dodecahedron in excess; or striæ, produced by oscillation of it with faces of the cube, visible. Often distorted, as in the cubo-octahedral twin (fig. 323). Sometimes massive and in pseudomorphs. Cl. cubic or octahedral, difficult; brittle. H.=6 to 6·5; G.=4·9 to 5·2. Brass-yellow, often somewhat gold-yellow; streak brownish black, when broken emits smell of sulphur. In closed tube sulphur sublimes. B.B. on charcoal burns with blue flame, and odour of sulphurous acid. In inner flame fuses to magnetic bead. Sol. in n. acid, with deposition of sulphur. C.c.: iron 46·7, sulphur 53·3; often contains gold in visible grains, when broken. Common to rocks of all ages. Tomnadashin, Birnam, Scotland; Cornwall, England; Elba and Traversella; Peru; Rossie, Middletown, and Schoharie in U.S. Auriferous pyrites, Berezoff (Siberia), Adelfors (Sweden), Mexico. Used to be cut in facets and set as an ornament, under the name of marcasites; also for striking fire in the old firelocks, whence the name of firestone; now used for manufacture of sulphuric acid.

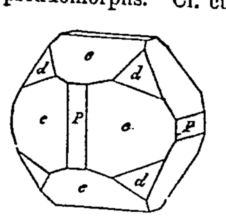

Fig. 320.

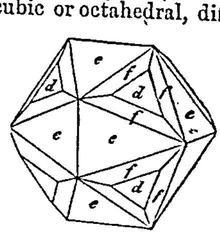

Fig. 321.

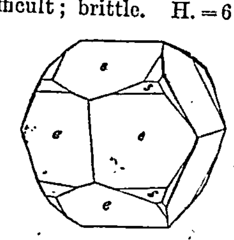

Fig. 322.

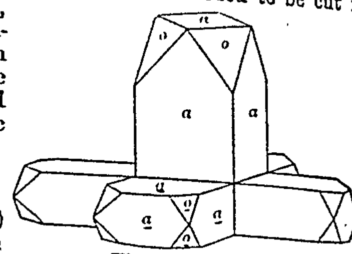

Fig. 323 (sp. 139).

140. Marcasite, FeS_2.

Right prismatic; ∞P (*M*) 106° 5′. Crystals tabular, thin prismatic, or pyramidal. Twins very frequent, also cockscomb-like groups, or spherical and stalactitic. Cl. ∞P; fracture uneven; brittle. G.=4·65 to 4·9. Greyish bronze-yellow to greenish grey, often with brown crust; streak greenish grey or brownish black. B.B., &c., like pyrite. Very prone to decomposition, being changed into green vitriol, which may be detected by the tongue. *Spear Pyrites* are twins like fig. 325; Littmitz, Przibram. *Hepatic Pyrites* or *Leberkies*, liver-brown, generally decomposing; Harz, Saxony, Sweden. *Cockscomb Pyrites*; Derbyshire and the Harz. *Kyrosite* contains arsenic.

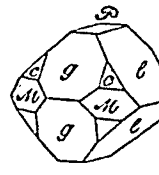

Fig. 324.

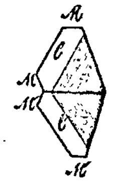

Fig. 325.

141. Mispickel, FeS_2+FeAs.

Right prismatic; ∞P (*M*) 111° 12′ (fig. 326). Twins common; also massive or columnar. Cl. ∞P; fracture uneven; brittle. H.=5·5 to 6; G.=6 to 6·2. Silver-white to steel-grey; streak black. In closed tube yields first a red then a brown sublimate, lastly metallic arsenic. B.B. on charcoal fuses to a black magnetic globule. Sol. in n. acid, with separation of arsenious acid and sulphur. C.c.: 34·3 iron, 46·1 arsenic, 19·6 sulphur; sometimes silver or gold, or 5 to 9 of cobalt. Cornwall, Freiberg, Zinnwald, Sweden, Franconia, America.

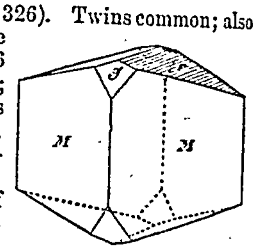

Fig. 326.

142. Leucopyrite, FeAs.

Right prismatic; ∞P (*d*) 122° 26′; P̄∞ (*o*) 51° 20′. Crystals like fig. 327; generally massive or columnar. Cl. basal; fracture uneven; brittle. H.=5 to 5·5; G.=7 to 7·4. Silver-white with darker tarnish; streak greyish black. B.B. emits strong smell of arsenic, and fuses to a black magnetic globule. C.c.: iron 27·2, arsenic 72·8; sometimes iron 32·2 and arsenic 66·8; always some sulphur, and often nickel and cobalt. Fossum in Norway, Andreasberg, Styria, and Silesia. *Spathiopyrite*, from Bieber in Hesse, seems a variety.

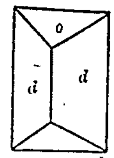

Fig. 327.

143. Cobaltite, CoS_2+CoAs.

Cubic and hemihedral; sometimes massive (figs. 67, 74). Cl. cubic, perfect; brittle. H.=5·5; G.=6 to 6·3. Brilliant lustre. Pinkish silver-white; tarnishes yellow or grey; streak greyish black. B.B. with borax blue glass; evolves smell of arsenic. C.c.: cobalt 35·9, arsenic 44·9, sulphur 19·2. St Just in Cornwall, Tunaberg in Sweden, Skutterud in Norway, Querbach in Silesia.

144. Glaucodote, (Co, Fe)S_2+(Co, Fe)As_2.

Right prismatic; ∞P 112° 36′. Cl. basal, perfect. H.=5; G.=6. Lustre metallic. Greyish white; streak black. C.c.: cobalt 24·7, iron 11·9, arsenic 43·2, sulphur 20·2. Huasco in Chili.

145. Smaltine, (Co, Fe, Ni) As_2.

Cubic; generally like fig. 27; also reticulated and granular compact. Cl. octahedral; fracture uneven; brittle. H.=5·5; G.=6·4 to 7·3. Tin-white to steel-grey, with dark or iridescent tarnish; streak greyish black. Evolves odour of arsenic, when broken or heated. C.c.: 71·4 arsenic, 28·6 cobalt; sometimes 3 to 19 iron, and 1 to 12 nickel, or 4 bismuth. Dolcoath and Redruth in Cornwall, Schneeberg, Annaberg, Tunaberg, Allemont, Chatham in Connecticut.

146. Chloantite (*White Nickel*), NiAs.

Cubic; generally fine granular or compact; fracture uneven; brittle. H.=5·5; G.=6·4 to 6·6. Tin-white, rapidly tarnishing black. In the closed tube yields a sublimate of arsenic, and becomes copper-red. Gives odour of arsenic when broken. B.B. fuses with much smoke, becomes coated with crystals of arsenious acid, and leaves a brittle grain of metal. C.c.: 28·2 nickel, 71·8 arsenic, but often with cobalt. Schneeberg, Riechelsdorf, Allemont, Chatham in Connecticut.

147. GERSDORFFITE, NiS_2+NiAs_2.

Cubic (figs. 74, 30, 26). Cl. cubic, generally granular. H. = 5·5; G. = 6·67. Lustre metallic. Silver-white to steel-grey, decrepitates in closed tube. B.B. fuses to a black slag; partially sol. in n. acid. C.c.: 35·2 nickel, 45·4 arsenic, and 19·4 sulphur; sometimes with cobalt. Craignuir, near Loch Fyne, with 23 nickel and 6 cobalt. The Harz, Sweden, Spain, and Brazil.

148. ULLMANNITE, $NiSb+NiS_2$.

Cubic (figs. 31, 29, 27); often tetrahedral, and in twins as in figs. 328, 329. Cl. cubic, perfect; fracture uneven. H. = 5 to 5·5; G. = 6·2 to 6·5. Lead-grey to tin-white, often with iridescent

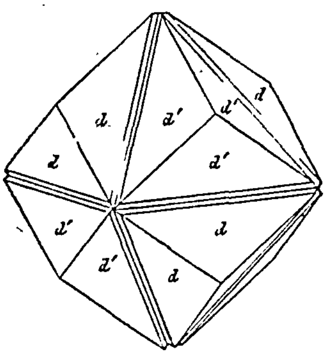

Fig. 328.

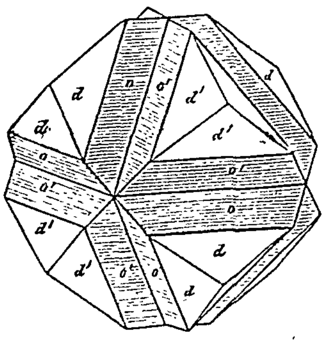

Fig. 329.

tarnish. B.B. fuses with dense fumes. Sol. in n. acid. C.c.: 27·4 nickel, 57·5 antimony, and 15·1 sulphur. Westerwald, Siegen, Harzgerode, Lölling (Carinthia), Lobenstein, and Bleiberg.

149. RAMMELSBERGITE, NiAs.

Right prismatic; ∞P 123° to 124°. Chiefly massive, or in radiating and botryoidal aggregates. H. = 5; G. = 7·2. Colour tin-white. Schneeberg, Reichelsdorf, and Wittichen in Baden.

150. HAUERITE, MnS_2.

Cubic (figs. 30, 30–26, 30–33–37). Crystals single or in spherical groups. Cl. cubic, perfect; H. = 4; G. = 3·46. Reddish brown to brownish black; streak brownish red. In closed tube yields sulphur, and leaves a green mass, which is sol. in h. acid. C.c.: 46 manganese and 54 sulphur. Kalinka in Hungary.

151. PYRRHOTITE (*Magnetic Pyrites*), Fe_7S_8.

Hexagonal; P 126° 48′. Crystals rare, sometimes hemihedral on $z\frac{1}{4}$, commonly massive or granular. Cl. ∞P, imperfect; brittle. H. = 3·5 to 4·5; G. = 4·5 to 4·6. Colour bronze-yellow with pinchbeck-brown tarnish; streak greyish black. More or less magnetic. C.c.:

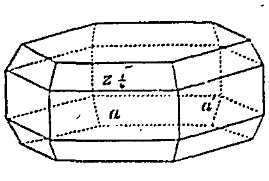

Fig. 330.

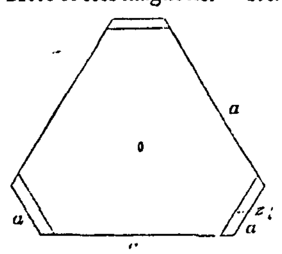

Fig. 331.

63·65 iron and 36·35 sulphur; sometimes with nickel. Common in primary limestones and diorites of Scotland. Crystallized in above forms at Askaig, on Loch Shin, Sutherland; Carnarvon, Cornwall, Fahlun, Bodenmais, Andreasberg. Distinguished by its colour and its solubility in h. acid.

152. LINNÆITE, $2(Co, Cu)S+CoS_2$.

Cubic (figs. 29, 30); often twinned; twin face O; also massive. Cl. cubic; brittle. H. = 5·5; G. = 4·9 to 5. Silver-white, with a yellow tarnish; streak blackish grey. B.B. fuses to a grey magnetic globule, which is bronze-yellow when broken. C.c.: cobalt 43·2, copper 14·4, iron 3·5, sulphur 38·5. Bastnaes (Sweden).

153. SIEGENITE, $CoS+Ni_2S_3$ (?).

Cubic; generally in crystals like fig. 29; also massive. Colour silver-white, inclining to pink. Other features like linnæite. C.c.: cobalt 40·8, nickel 14·6, sulphur 43·1. Müsen near Siegen, Maryland, and Missouri. The American mineral has 30·5 of nickel.

154. POLYDYMITE, Ni_4S_5.

Cubic; in minute octahedral crystals and flattened twins. Cl. cubic. H. = 4·5; G. = 4·81. C.c.: 39·45 nickel, 40·55 sulphur, but generally with 4 of iron. Westphalia. *Saynite* or *grunauite* seems to be a bismuthic and cobaltic variety; it is from Grunau in Sayn-Altenkirchen.

155. BEYRICHITE, $3NiS+2NiS_2$.

H. = 3 to 3·5; G. = 4·7. C.c.: 54·23 nickel, 2·79 iron, 42·86 sulphur. From the Westerwald.

156. HORBACHITE, $4Fe_2S_3+Ni_2S_3$.

Crystalline masses. H. = 4·5; G. = 4·43 to 4·7. Colour pinchbeck-brown; streak black. C.c.: nickel 11·98, iron 41·96, sulphur 45·87. Horbach in the Black Forest.

157. SKUTTERUDITE, $CoAs_3$.

Cubic (figs. 30, 26 with 33, 40) and granular. Cl. cubic; fracture conchoidal; brittle. H. = 6; G. = 6·74 to 6·84. Tin-white to lead-grey. Lustre brilliant. In closed tube gives sublimate of metallic arsenic, otherwise like smaltine. C.c.: 79 arsenic, 21 cobalt. Skutterud, near Modum in Norway.

158. GALENA, PbS.

Cubic; crystals chiefly cube, octahedron, and rhombic dodecahedron; rarely 2O and 2O2. Also massive and granular, compact, or laminar, and in pseudomorphs of pyromorphite and other minerals. Cl. cubic, very perfect; fracture scarcely observable; sectile. H. = 2·5; G. = 7·2 to 7·6. Lead-grey, with darker or rarely iridescent tarnish; streak greyish black. B.B. decrepitates, fuses, and leaves a globule of lead. Sol. in n. acid. C.c.: 86·7 lead, and 13·3 sulphur; but usually contains a little silver, ranging from 1 to 3 or 5 parts in 10,000; rarely 1 per cent. or more. Some contain copper, zinc, or antimony, others selenium, and others (the "supersulphuret") probably free sulphur (2 to 8 per cent.). Most common ore of lead in many countries. Leadhills, Pentland Hills, Linlithgow, Inverkeithing, Monaltrie, Tyndrum, Strontian, Islay, Orkney, Cornwall, Derbyshire (Castletown), Cumberland (Alston Moor), Durham (Allenhead), Wales, Isle of Man.

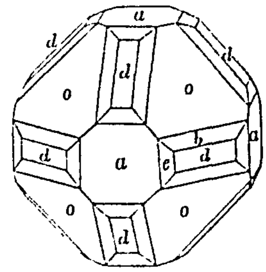

Fig. 332.

159. CUPROPLUMBITE, $2PbS+Cu_2S$.

Cubic. H. = 2·5; G. = 6·4. Bluish grey. Chili.

160. BEEGERITE, $6PbS+Bi_2S_3$.

Cubic. G. = 7·27. Cl. cubic. Light to dark grey. Lustre brilliant. C.c.: sulphur 15, bismuth 20·6, lead 64·2, with copper 1·7. Grant (Park county, Colorado).

161. CLAUSTHALITE, PbSe.

Cubic; but massive granular. H. = 2·5 to 3; G. = 8·2 to 8·8. Lead-grey; streak grey. B.B. fuses, smells of selenium, colours the flame blue, stains the support red, yellow, and white, and volatilizes, except a small residue, without fusing. C.c.: 72·7 lead, 27·3 selenium; but sometimes 11·7 of silver. Zorge, Lerbach, and Clausthal in the Harz. *Tilkerodite*, or *Selen-Cobalt-Blei*, containing 3 per cent. of cobalt, from Tilkerode, is a variety.

162. ZORGITE.

Massive granular; like clausthalite, but inclining to reddish, and often tarnished. There are four varieties. (*a*) *Selen-Blei-Kupfer*: G. = 7·4 to 7·5; 5PbSe + CuSe; with 4 copper, 65 lead, 30 selenium. (*b*) The same, but with G. = 5·6; 4Pb, 4Cu, 7Se; with 15·8 copper, 48·4 lead, and 35 selenium. (*c*) *Selen-Kupfer-Blei*: with G. = 7; 2PbSe + CuSe; with 8 copper, 57 lead, and 32 selenium. (*d*) 2PbSe + 9CuSe; with 46·64 copper, 16·58 lead, and 36·59 selenium. From Tilkerode and Zorge in the Harz, and near Gabel in Thuringia.

163. ALTAITE, PbTe.

Cubic and granular; fracture uneven; sectile. H. = 3 to 3·5; G. = 8·1 to 8·2. Tin-white to yellow, with yellow tarnish. B.B. colours the flame blue, fusing to a globule, which almost wholly volatilizes. C.c.: 61·9 lead and 38·1 tellurium. Zavodinski in the Altai, California, Colorado, and Chili.

164. REDRUTHITE (*Copper Glance*), Cu_2S.

Right prismatic. ∞P (*o*) 119° 35′; P (*P*) middle edge 125° 22′; $\frac{1}{3}\breve{P}$ (*a*) middle edge 65° 40′; $2\breve{P}\infty$ (*d*) middle edge 125° 40′; $\frac{2}{3}\breve{P}\infty$ (*e*) middle edge 65° 48′. Crystals 0P (*s*), ∞P (*o*), $\infty\breve{P}\infty$ (*p*) (figs. 333,

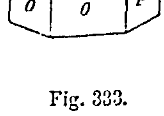

Fig. 333.

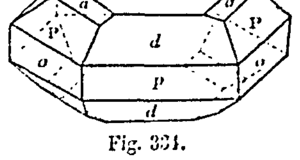

Fig. 334.

334); with hexagonal aspect; also twins; and massive. Cl. ∞P, imperfect; fracture conchoidal or uneven; sectile. H. = 2·5 to 3;

G. = 5·5 to 5·8. Rather dull; brighter on the streak. Blackish lead-grey, with a blue or other tarnish. B.B. colours the flame blue; on charcoal in the oxygen flame sputters, and fuses easily; in the red. flame becomes solid. With soda gives a grain of copper. Green solution in n. acid, leaving sulphur. C.c.: 79·8 copper, 20·2 sulphur. Fassnet Burn (Haddingtonshire), Ayrshire, Fair Island, near Redruth and Land's End in Cornwall, Saxony, Silesia, Norway, the Banat, Siberia, and the United States. Important copper ore.

165. STROMEYERITE, $Cu_2S + AgS$.

Right prismatic; isomorphous with redruthite. Crystals rare; usually massive; fracture flat, very sectile. H. = 2·5; G. = 6·2 to 6·3. Bright. Blackish lead-grey. C.c.: 53·1 silver, 31·2 copper, and 15·7 sulphur, but often indeterminate proportions of silver (3 to 53) and copper (30 to 75). Schlangenberg in Siberia, Rudelstadt in Silesia, and Catemo in Chili.

166. BERZELINITE, Cu_2Se.

Crystalline, in thin dendritic crusts, and imbedded in calcite. Silver-white with a black tarnish; streak shining. In open tube gives a red sublimate of selenium, with white crystals of selenious acid. B.B. on charcoal fuses to a grey, slightly malleable bead, giving odour of selenious acid; with soda a grain of copper. C.c.: 61·5 copper and 38·5 selenium. Skrikerum in Småland, Lerbach in the Harz.

167. CROOKESITE, $(CuTl)_2Se$.

In crystalline grains the size of peas. H. = 2·5 to 3; G. = 6 9. Brittle. Lead-grey. Metallic. B.B. colours the flame intense green. C.c.: 45·76 copper, 3·71 silver, 17·25 thallium, 33·27 selenium. From Skrikerum.

168. EUKAIRITE, $Cu_2Se + AgSe$.

Massive and granular crystalline. Cuts with knife. Lead-grey; streak shining. B.B. fuses to a brittle metallic grain. C.c.: 43·1 silver, 25·3 copper, and 31·6 selenium. Skrikerum, Atacama, Chili.

169. ARGENTITE, Ag_2S.

Cubic. ∞O∞; O; ∞O; and 2O2 (figs. 29, 56). Crystals generally misshapen, with uneven or curved faces; in druses, or linear groups; also arborescent, capillary, or in crusts. Cl. indistinct; fracture hackly; malleable and flexible. H. = 2 to 2·5; G. = 7 to 7·4. Rarely brilliant, more so on the streak. Blackish lead-grey, often with a black, brown, or rarely iridescent tarnish. B.B. on charcoal fuses, intumesces greatly, and leaves a grain of silver. Sol. in con. n. acid. C.c.: 87 silver and 13 sulphur. Huel Duchy, Dolcoath, Herland, and near Callington in Cornwall; Alva in Stirlingshire; Freiberg, Marienberg, Annaberg, Schneeberg, Johann-Georgenstadt, Joachimsthal, Schemnitz and Kremnitz, Kongsberg. Common ore at Guanajuato and Zacatecas in Mexico, in Peru, and at Blagodat in Siberia.

170. ACANTHITE, AgS.

Right prismatic. H. = 2·5; G. = 7·33. Iron-black. C.c. like argentite, thus dimorphous. Freiberg and Clausthal, on argentite; also at Copiapo.

171. JALPAITE, $3AgS + Cu_2S$.

Cubic; form O. Cl. cubic; malleable. H. = 2·5; G. = 6·88. Dark-grey. Metallic lustre. C.c.: silver 71·78, copper 14·04, sulphur 14·2. Jalpa in Mexico.

172. LAUTITE (CuAg) As.S.

Granular. Iron-black. H. = 3; G. = 4·96. C.c.: copper 28·3, silver 12, arsenic 41·8, sulphur 17·86. Lauta, near Marienberg.

173. NAUMANNITE, AgSe.

In thin plates and granular. Cl. hexahedral, perfect. Malleable. H. = 2·5; G. = 8. Iron-black. Splendent. C.c.: 73 silver and 27 selenium, with 4·91 lead. Tilkerode.

174. HESSITE, AgTe.

Cubic or anorthic (?); massive and granular. Slightly malleable. H. = 2·5 to 3; G. = 8·1 to 8·45. Blackish lead-grey to steel-grey. B.B. on charcoal fumes, fuses to a black grain with white spots, and leaves a brittle grain of silver. C.c.: 62·8 silver and 37·2 tellurium. Zavodinski (Altai), Nagyag, Rezbanya, California, and Chili.

175. PETZITE, 2AgTe + AuTe.

Like hessite. Two varieties:—(a) with G. = 8·72, containing 18 per cent. of gold, from Nagyag; (b) with G. = 9 to 9·4, and 24 to 26 of gold. Calaveras and Tuolumne in California, Colorado.

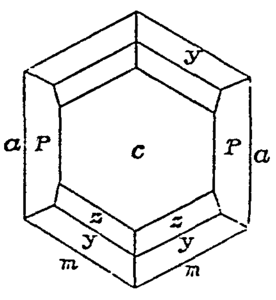

Fig. 335 (sp. 176).

176. DISCRASITE, Ag_2Sb; Ag_3Sb; and Ag_6Sb.

Right prismatic; P with polar edges 132° 42′ and 92°; ∞P 120° nearly (figs. 335, 336). Crystals short prismatic, or thick tabular, and vertically striated (fig. 335); twins united by a face of ∞P; often in stellar groups (fig. 336); also massive or granular. Cl. basal and P̆∞, distinct; ∞P imperfect; rather brittle, and slightly malleable. H. = 3·5; G. = 9·4 to 9·8. Silver-white to tin-white, with a yellow or blackish tarnish. B.B. fuses easily, fumes staining the charcoal white, and leaves a grain of silver. Sol. in n. acid. C.c.: 64 to 84 silver, and 36 to 16 antimony. Andreasberg, Allemont in Dauphiné, Spain, and Arqueras in Coquimbo (Chili). A valuable ore of silver. A variety from Chili contains 94·2 silver and 5·8 antimony, and is $Ag_{18}Sb$.

Fig. 336.

177. BLENDE, ZnS.

Cubic and tetrahedral (figs. 152, 153, 337). Twins remarkably common, united by a face of O, and several times repeated; frequently massive and granular. Cl. ∞O, perfect; very brittle. H. = 3·5 to 4; G. = 3·9 to 4·2. Semitransparent to opaque; adamantine and resinous. Brown or black, also red, yellow, and green, rarely colourless or white. B.B. decrepitates, often violently, but only fuses on very thin edges. Sol. in con. n. acid, leaving sulphur. C.c.: 67 zinc and 33 sulphur; but generally in the darker varieties with 1 to 15 iron, 0 to 3 cadmium. Very abundant. Glen Gairn (bright yellow and highly phosphorescent), Leadhills, Tyndrum, Cornwall, Derbyshire, Cumberland, the Harz, Freiberg, Przibram, Schemnitz, Kapnik, North America, Peru. Used for producing zinc vitriol and sulphur, and as an ore of zinc. Lithium, indium, thallium, and gallium have all been found in blende.

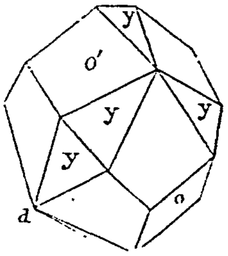

Fig. 337.

178. WURTZITE, 6ZnS + FeS.

Hexagonal; ∞P, P, with well-marked horizontal striæ. Cl. basal, and prismatic. H. = 3·5 to 4; G. = 3·9 to 4·1. Brownish black; streak light brown. C.c.: like blende, which is thus dimorphous. Oruro in Bolivia, and Przibram (radiated and cadmiferous).

179. GREENOCKITE, CdS.

Hexagonal, and generally hemimorphic. P 86° 21′; 2P 123° 54′. Crystals 2P, 0P, ∞P, P; or P, 2P, ∞P; attached singly. Cl. ∞P, imperfect; basal perfect. H. = 3 to 3·5; G. = 4·8 to 4·9. Translucent; brilliant resinous, or adamantine. Honey- or orange-yellow, rarely brown; streak yellow. B.B. decrepitates, and becomes carmine-red, but again yellow when cold; fused with soda forms a reddish brown coating on charcoal. Sol. in h. acid. C.c.: 77·6 cadmium, and 22·4 sulphur. Bishopton in Renfrewshire, Przibram, and Friedensville in Pennsylvania.

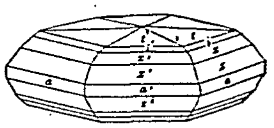

Fig. 338.

180. ALABANDINE, MnS.

Cubic; O and ∞O∞; usually massive and granular. Cl. hexahedral, perfect; fracture uneven; rather brittle. H. = 3·5 to 4; G. = 3·9 to 4. Opaque; semi-metallic. Iron-black to dark steel-grey, brownish black tarnish; streak dark green. B.B. fuses on thin edges to a brown slag. Sol. in h. acid. C.c.: 63 manganese and 37 sulphur. Nagyag, Kapnik, Alabanda in Caria, Mexico, and Brazil.

181. MILLERITE, NiS.

Hexagonal rhombohedral; R 144° 8′; in fine acicular prisms of ∞P2, R. Brittle. H. = 3·5; G. = 4·6 (or 5·26 to 5·65). Brass- or bronze-yellow, with a grey or iridescent tarnish. B.B. fuses easily to a blackish metallic globule, which boils and sputters. In nitro-hydrochloric acid forms a green solution. C.c.: 64·4 nickel and 35·6 sulphur. Morven (Argyllshire), Chapel (Fife), Ayrshire, near St Austell in Cornwall, at Merthyr-Tydvil, Johann-Georgenstadt, Joachimsthal, Przibram, Camsdorf, Riechelsdorf, Pennsylvania.

182. PENTLANDITE (*Eisennickelkies*), 2FeS + NiS.

Cubic; massive and granular; fracture uneven; brittle. H. = 3·5 to 4; G. = 4·6. Light pinchbeck-brown, with darker streak. Not magnetic. B.B. acts in general like pyrrhotite; the roasted powder forms with borax in the red. flame a black opaque glass. C.c.: 36 sulphur, 42 iron, and 22 nickel; but mixed with pyrrhotite and chalcopyrite. Lillehammer in southern Norway. *Inverarite*, 5FeS + NiS, with 11 of nickel, from near Inveraray, is a variety.

183. NICKELITE (*Copper Nickel*), NiAs.

Hexagonal; P 86° 50′. Crystals ∞P, 0P; rare. Arborescent, reniform, and massive; fracture conchoidal and uneven; brittle. H. = 5·5; G. = 7·5 to 7·7. Light copper-red, with a blackish tarnish. It forms no sublimate in the closed tube. B.B. fuses with strong

fumes to a white, brittle, metallic globule. C.c.: 43·6 nickel and 56·4 arsenic. Hilderston in Linlithgow, Pibble in Kirkcudbright, Leadhills, Pengelly and Huel Chance in Cornwall, Freiberg, Schneeberg, Joachimsthal, Sangerhausen, Andreasberg, Chatham in Connecticut. Used as an ore of nickel.

184. BREITHAUPTITE (*Antimonial Nickel*), NiSb.

Hexagonal; P 86° 56′. Crystals, thin striated hexagonal tables of 0P, ∞P. H.=5; G.=7·5 to 7·6. Brilliant. Light copper-red, generally with violet tarnish. B.B. fumes, but fuses with great difficulty. C.c.: 32·2 nickel and 67·8 antimony. Andreasberg.

185. STANNITE (*Tin Pyrites*), 2CuS, SnS_2+2(FeS, ZnS)+SnS_2.

Cubic; in cubes very rare, generally massive and granular. Cl. hexahedral, imperfect; fracture uneven or small conchoidal; brittle. H.=4; G.=4·3 to 4·5. Steel-grey; streak black. C.c.: 26 to 32 tin, 24 to 30 copper, 5 to 12 iron, 2 to 10 zinc, and 30 sulphur. Huel Rock near St Agnes, St Michael's Mount, and Carnbrea in Cornwall; Zinnwald. Bell-metal ore.

186. STERNBERGITE, (AgS+2FeS)FeS_3.

Right prismatic; P middle edge 118°. Crystals usually thin tabular; in twins, or in fan-like and spheroidal groups. Cl. basal, perfect; sectile, and flexible in thin laminæ. H.=1 to 1·5; G.=4·2 to 4·25. Dark pinchbeck-brown, often a violet-blue tarnish; streak black. C.c.: 34·2 silver, 35·4 iron, and 30·4 sulphur. Joachimsthal, Schneeberg, and Johann-Georgenstadt. *Flexible Sulphuret of Silver*, from Hungary and Freiberg, is identical. *Frieseite*, $Ag_2Fe_5S_8$, in twins (fig. 339), is a variety.

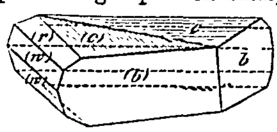

Fig. 339.

187. RITTINGERITE, AgAs.

Oblique prismatic. ∞P 126° 18′; ∞P∞ and 0P. Cl. basal; fracture conchoidal; brittle. H.=2·5 to 3; G.=5·63. C.c.: silver 57·7, the remainder being arsenic, with some selenium. Joachimsthal, Silesia, Felsöbanya in Hungary.

188. COVELLINE, CuS.

Hexagonal. Crystals ∞P, 0P; rare; usually reniform and granular. Cl. basal; sectile. Thin laminæ flexible. H.=1·5 to 2; G.=3·8 to 4·6. Resinous. Indigo-blue; streak black. B.B. burns with blue flame. Sol. in n. acid. C.c.: 66·7 copper, 33·3 sulphur. Cairnbeg in Cornwall, Vesuvius, Leogang (Austria), Chili, Angola, New Zealand, and Victoria.

189. CHALCOPYRITE (*Copper Pyrites*), CuS+FeS.

Pyramidal; and sphenoidal hemihedric; ½P (*P*) with polar edges 71° 20′; ∞P∞. Crystals generally small and deformed; twins very common, like fig. 340. P∞(*b*) 89° 10′, 2P∞(*c*) 126° 11′, 0P (*a*), P (fig. 89). Most commonly compact and disseminated; also botryoidal and reniform. Cl. pyramidal 2P∞; sometimes rather distinct; fracture conchoidal or uneven. H.=3·5 to 4; G.=4·1 to 4·3. Brass-yellow, often with a gold-yellow or iridescent tarnish (peacock copper ore); streak greenish black. B.B. on charcoal becomes darker or black, and on cooling red; fuses easily to a steel-grey globule, which at length becomes magnetic, brittle, and greyish red on the fractured surface; with borax and soda yields a grain of copper; moistened with h. acid, colours the flame blue. C.c. essentially 1 atom copper, 1 atom iron, and 2 atoms sulphur; with 34·5 copper, 30·5 iron, and 35 sulphur. The most abundant ore of copper. In Kirkcudbrightshire and Wigtownshire, Tyndrum in Perthshire, Inverness-shire, Lairg in Sutherland, Shetland, Anglesea (Parys mine), Derbyshire, Staffordshire, Cumberland, Gunnislake (Devonshire), St Austell (Cornwall), Wicklow, Falun, Röraas, Freiberg, Mansfeld, Goslar, Lauterberg, Müsen, Siberia. It is distinguished from pyrite by yielding readily to the knife, by its tarnish, and by forming a green solution in n. acid.

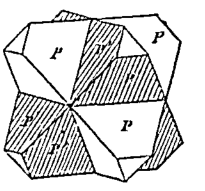

Fig. 340.

190. BORNITE (*Purple Copper*), $3Cu_2S$, Fe_2S_3.

Cubic. Crystals ∞O∞, and ∞O∞, O; but rare, and generally rough or uneven; also twins. Mostly massive. Cl. octahedral; fracture conchoidal; slightly brittle; sectile. H.=3; G.=4·9 to 5·1. Colour between copper-red and pinchbeck-brown, with tarnish at first red or brown, then violet or sky-blue; streak greyish black. B.B. acts like chalcopyrite. Soluble in con. h. acid, leaving sulphur. C.c.: 55·6 copper, 16·4 iron, and 28 sulphur. Crystals near Redruth and St Day in Cornwall; massive at Killarney in Ireland; also Norway, Sweden, Mansfeld, Silesia, Tuscany, and Chili. An ore of copper.

191. CUBAN, CuS, Fe_2S_3.

Cubic. H.=4; G.=4·1. Bronze-yellow; streak bronze-yellow and black. Barracanao in Cuba, Tunaberg and Kafveltorp in Sweden.

192. DOMEYKITE, Cu_6As.

Botryoidal or massive; fracture uneven; brittle. H.=3 to 3·5; G.=7 to 7·5. Tin- or silver-white, inclining to yellow, with an iridescent tarnish. Not affected by h. acid. C.c.: 71·63 copper and 28·37 arsenic. Calabazo in Coquimbo, and Copiapo in Chili. *Condurrite*, massive, seems an impure variety; from Condurrow mine and near Redruth (Cornwall). *Algodonite* from Lake Superior, *Whitneyite* from Mexico, and *Darwinite* (88 copper) are also identical or similar.

193. MELONITE, Ni_2Te_3.

Hexagonal; minute tabular crystals, foliated and granular. Metallic lustre. Reddish white; streak dark grey. C.c.: nickel 21, silver 4·1, tellurium 73·4. Stanislaus and Calaveras (California).

194. SYLVANITE, $AgTe_4$+$AuTe_3$.

Oblique prismatic, C 55° 21′. ∞P 94° 26′; −P∞ 19° 21′; P∞ 62° 43′. Crystals small, short acicular, and often twinned and grouped in rows like letters; sectile, but friable. H.=1·5 to 2; G.=7·99 to 8·33. Steel-grey to silver-white, and pale bronze-yellow. C.c.: 59·6 tellurium, with 0·6 to 8·5 antimony, 26·5 gold (in some 30), and 13·9 silver, with 0·2 to 15 lead. Offenbanya (*Graphic Tellurium*), Nagyag (*Yellow Tellurium*), and California.

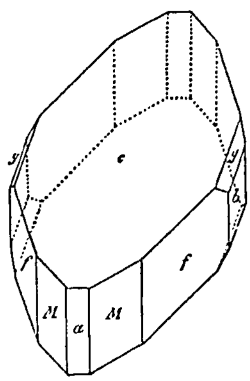

Fig. 341.

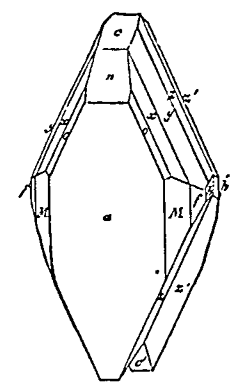

Fig. 342.

195. NAGYAGITE, *Black Tellurium*.

Pyramidal. P 137° 52′; P∞ 122° 50′; and 0P (fig. 343). Crystals tabular, rare; in general in thin plates or foliated. Cl. basal, perfect; sectile; thin laminæ flexible. H.=1 to 1·5; G.=6·85 to 7·2. Splendent. Blackish lead-grey. C.c.: 51 to 63 lead, 6 to 9 gold, 1 copper and silver, 13 to 32 tellurium, 3 to 12 sulphur, and 0 to 4·5 antimony. Nagyag and Offenbanya in Transylvania.

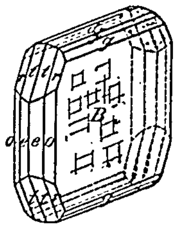

Fig. 343 (sp. 195).

196. MALDONITE, Au_2Bi.

H.=1·5 to 2; G.=8·2 to 9·7. Colour silver-white, with black tarnish. C.c.: gold 64·5, bismuth 35·5. Occurs in granite veins at Maldon in Victoria.

197. CHILENITE, $Ag_{10}Bi$.

Minute plates of metallic lustre. Silver-white, but tarnished red or yellow. Silver 83·9, bismuth 16·1. From the mine San Antonio near Copiapo in Chili.

198. CINNABAR, HgS.

Hexagonal and rhombohedral; R 71° 48′. R (*n*), 0R (*o*), ∞R (*m*). ⅔R (*i*) (fig. 344). Crystals rhombohedral; also granular, compact, and earthy. Cl. ∞R, perfect; fracture uneven and splintery; sectile. H.=2 to 2·5; G.=8 to 8·2. Transparent, with circular polarization. Adamantine. Cochineal-red; streak scarlet. C.c.: 86·2 mercury, 13·8 sulphur. Idria in Carniola, Almaden in Spain, Wolfstein in Bavaria, Saxony, Hungary, Tuscany, China, California, Mexico, Peru. Chief ore of mercury. Also a pigment. *Hepatic Cinnabar* is a bituminous mixture.

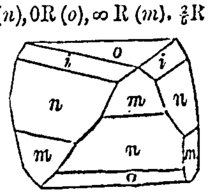

Fig. 344.

199. TIEMANNITE, HgSe.

Fine granular; brittle. H.=2·5; G.=7·1 to 7·4. Brilliant. Dark lead-grey. C.c.: 75 mercury, 25 selenium. Clausthal and Zorge.

200. LERBACHITE, (PbHg)Se.

Granular and massive. G.=7·8 to 7·88. Colour steel-grey to iron-black. Brittle. Lerbach, Tilkerode in the Harz.

201. GUANAJUATITE, Bi_2Se_3.

Massive; granular; foliated and fibrous. H.=2·5 to 3; G.=6·25. Blue-grey; streak grey and shining. Metallic; soft and malleable. C.c.: selenium 34·3, sulphur ·7, bismuth 65. Santa Rosa (Guanajuato, Mexico).

202. Coloradoite, HgTe.

Massive and granular. H. = 3; G. = 8·63. Metallic. Iron-black. Conchoidal fracture. C.c.: 61 mercury, 39 tellurium. Colorado.

203. Molybdenite, MoS_2.

Hexagonal (?). Crystals 0P, ∞P; and 0P, ∞P, P. Generally scaly. Cl. basal, perfect; sectile and flexible. Feels greasy. H. = 1 to 1·5; G. = 4·6 to 4·9. Lead-grey with red tinge; grey streak on paper, greenish on porcelain. B.B. colours flame siskin-green; on charcoal yields sulphurous fumes, and forms a white coating; in warm nitrochloric acid a greenish, and in boiling s. acid a blue solution. C.c.: 59 molybdenum, 41 sulphur. In granular limestones, and in granites in Sutherland, Ross, Aberdeen, Argyll, and Kirkcudbright; Shap in Westmoreland, Caldbeckfell in Cumberland, Arendal, Zinnwald, Mont Blanc, Maine, Connecticut, Yea in Victoria. Used for preparing blue carmine, for colouring porcelain.

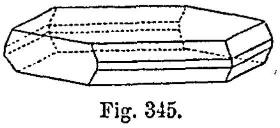

Fig. 345.

204. Laurite, $(RuOs)_2S_3$.

Cubic. Crystals O, $\infty O \infty$; ∞O3, $\infty O \infty$. Cl. octahedral. H. = 7·5; G. = 6·99. Metallic, bright. Dark iron-black. Powder grey. Brittle. C.c.: ruthenium 65·18, osmium 3·03, sulphur 31·79. From platinum grains, in Borneo and Oregon.

205. Realgar, AsS.

Oblique prismatic. ∞P (*M*) 74° 26′; P^c∞ (*n*) 132° 2′, ∞P^{o}2 (*l*) 113° 16′. Crystals (fig. 346) generally prismatic; sometimes massive. Cl. basal, also clinodiagonal; fracture splintery; sectile. H. = 1·5 to 2; G. = 3·4 to 3·6. Transparent to opaque; resinous. Aurora-red; streak orange-yellow. C.c.: arsenic 70, sulphur 30. Nagyag, Felsöbanya, St Gotthard, Vesuvius.

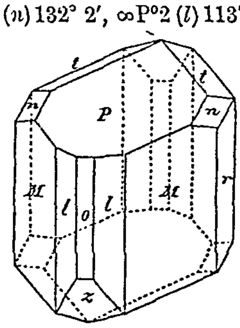

Fig. 346 (sp. 205).

206. Orpiment, As_2S_3.

Right prismatic. ∞P 117° 49′. Frequently foliated. Cl. brachydiagonal; striated vertically; sectile and flexible. H. = 1·5 to 2; G. = 3·4 to 3·5. Semi-transparent; resinous to pearly. Citron-yellow and orange-yellow. C.c.: arsenic 61, sulphur 39. Servia, Kapnik, Andreasberg, Solfatara, Zimapan in Mexico.

207. Dimorphite, As_4S_3.

Right prismatic. H. = 1·5; G. = 3·58. Orange-yellow. Solfatara.

208. Stibnite, Sb_2S_3.

Right prismatic. P polar edges 109° 26′ and 108° 21′; ∞P 90° 54′. Crystals (fig. 347) generally prismatic. Cl. brachydiagonal, perfect; sectile. H. = 2; G. = 4·6 to 4·7. Brilliant lead-grey, often tarnished. C.c.: antimony 71·8, sulphur 28·2. Maisley, Banffshire; Harehill, Ayrshire; Glendinning, Dumfriesshire; Endellion and Padstow, Cornwall; Wolfsberg, Harz; Przibram, Schemnitz, Auvergne, Spain, America, Melbourne. Chief ore of antimony.

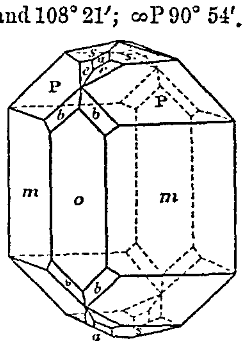

Fig. 347 (sp. 208).

209. Bismuthine, Bi_2S_3.

Right prismatic. ∞P 91° 30′. Crystals prismatic, striated; also granular and foliated. Cl. brachydiagonal; sectile. H. = 2 to 2·5; G. = 6·4 to 6·6. Lead-grey. C.c.: 81·2 bismuth, 18·8 sulphur. Caldbeckfell (Cumberland), Redruth (Cornwall), Riddarhyttan and Bastnaes (Sweden), Altenberg, Haddam (Connecticut), Ballarat (Victoria), Bolivia.

210. Frenzelite, Bi_2Se_3, or $2Bi_2Se_3 + Bi_2S_3$.

Right prismatic; ∞P 90°. Needle crystals, and massive. Cl. brachydiagonal. H. = 2·5 to 3; G. = 6·25. Bluish grey; streak greyish black, shining. Lustre metallic. Malleable. C.c.: bismuth 67·38, selenium 24·13, sulphur 6·6. Guanajuato (Mexico).

SULPHUR SALTS.

211. Guejarite, $Cu_2S + 2Sb_2S_3$.

Right prismatic. ∞P 101° 9′. Cl. brachydiagonal. H. = 3·5; G. = 5·03. Steel-green, with bluish streak. C.c.: copper 15·5, antimony 58·5, sulphur 25. Guejar in Sierra Nevada.

212. Miargyrite, $AgS + SbS_3$.

Oblique prismatic, C 81° 36′. P 90° 53′; −P 59° 59′. Crystals pyramidal, or tabular (fig. 348); massive; sectile. H. = 2 to 2·5; G. = 5·2 to 5·3. Metallic adamantine. Blackish lead-grey to steel grey; streak cherry-red. C.c.: 37 silver, 41 antimony, 22 sulphur. Freiberg, Przibram, Potosi.

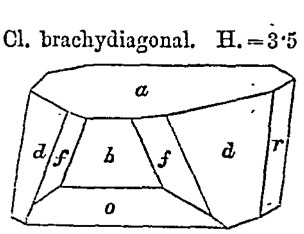

Fig. 348 (sp. 212).

213. Morocochite (*Silber-Wismuth Glanz*), $AgS + BiS_3$.

Massive. Colour grey; streak light green. G. = 6·92. C.c.: silver 28·3, bismuth 54·7, sulphur 17. Morococha in Peru.

214. Sartorite, $PbS + As_2S_3$.

Right prismatic. Crystals slender; ∞P 123° 20′. Cl. 0P. H. = 3; G. = 5·39. C.c.: lead 42·68, arsenic 30·93, sulphur 26·39. Binnenthal in Switzerland.

215. Zinckenite, $PbS + SbS_3$.

Right prismatic. ∞P (*d*) 120° 39′; $\breve{P}\infty$ (*o*) 150° 36′ (fig. 349). Crystals acicular; vertically striated, and twinned 3 or 6. Sectile. H. = 3 to 3·5; G. = 5·3 to 5·35. Steel-grey to lead-grey; with blue tarnish. C.c.: lead 35·9, antimony 42, sulphur 22·1. Wolfsberg.

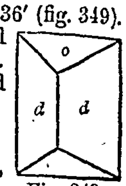

Fig. 349 (sp. 215).

216. Emplectite, $CuS + Bi_2S_3$.

Right prismatic. Tin-white. Saxony, Würtemberg, and Copiapo.

217. Wolfsbergite, $Cu_2S + Sb_2S_3$.

Right prismatic. ∞P 135° 12′; $\infty\breve{P}$2 111°. Crystals tabular; also fine granular. Cl. brachydiagonal, perfect; fracture conchoidal or uneven. H. = 3·5; G. = 4·748. Lead-grey to iron-black, sometimes iridescent; streak black, dull. C.c.: 25·4 copper, 49 antimony, and 25·6 sulphur. Wolfsberg.

218. Berthierite, FeS, SbS_3.

Massive; columnar or fibrous, with indistinct cleavage. H. = 2·3; G. = 4 to 4·3. Dark steel-grey, reddish. Tintagel and Padstow in Cornwall, Auvergne and Anglars (Creuse) in France, Bräunsdorf in Saxony. In France used as an ore of antimony.

219. Plagionite, Pb_4Sb_3.

Oblique prismatic, C 72° 28′. P 134° 30′ and 142° 3′; −2P 120° 49′. Crystals thick, tabular (fig. 350), minute, and in druses. Cl. −2P, perfect; brittle. H. = 2·5; G. = 5·4. Blackish lead-grey. C.c.: 41 lead, 38 antimony, and 21 sulphur. Wolfsberg.

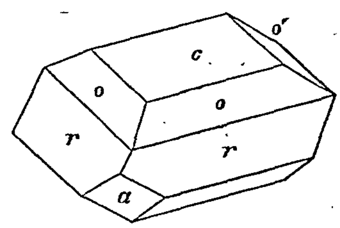

Fig. 350 (sp. 219).

220. Klaprothite, $3Cu_2S + 2Bi_2S_3$.

Right prismatic; long striated crystals; ∞P = 107°. Wittichen, Bulach. *Schirmerite*, from Colorado, $3(Ag_2Pb)S + 2Bi_2S_3$, with G. = 6·74, is similar.

221. Binnite, $3CuS + 2As_2S_3$.

Cubic. Typical forms ∞O, 2O2; O, $\infty O \infty$, 6O6; 4O4, 10O10 3O$\frac{3}{2}$. H. = 4·5; G. = 4·48. Metallic. Black. Binnen.

222. Jamesonite, $3PbS + 2Sb_2S_3$.

Right prismatic; ∞P 101° 20′. Crystals ∞P, $\infty\breve{P}\infty$, long-prismatic, parallel or radiating. Cl. basal perfect, ∞P and brachydiagonal imperfect; sectile. H. = 2 to 2·5; G. = 5·5 to 5·7. Steel-grey to dark lead-grey. B.B. decrepitates, fuses easily, and wholly volatilizes except a small slag. Sol. in warm n. acid. C.c.: 44·5 lead, with 2 to 4 iron, 34·9 antimony, and 20·6 sulphur. Cornwall, Estremadura, Hungary, Siberia, and Brazil.

223. Dufrenoysite, $2PbS + As_2S_3$.

Right prismatic. ∞P 93° 39′. Generally in thick rectangular tables. H. = 3; G. = 5·56. Lead-grey. Brittle. Binnen, St Gotthard.

224. Freieslebenite, $5(Pb, Ag_2)S + 2Sb_2S_3$.

Oblique prismatic, C 87° 46′. ∞P 119° 12′; P^o∞ 31° 41′ (fig. 351) in prisms with curved reed-like faces, and strong vertical striæ. Twins intersecting; also massive. Cl. ∞P, perfect; fracture conchoidal or uneven; rather brittle. H. = 2 to 2·5; G. = 6·2 to 6·4. Steel-grey to dark lead-grey. C.c.: 22·5 silver, 32·4 lead, 26·8 antimony, and 18·3 sulphur. Freiberg (Saxony), Hiendelaencina (Spain).

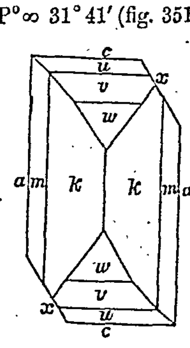

Fig. 351 (sp. 224).

225. Pyrargyrite, $3Ag_2S + Sb_2S_3$.

Hexagonal rhombohedral; R (*P*) 108° 42′; −½R 137° 58′; 0R; −2R (*r*); R3; ∞P2 (*s*); and ∞R (*l*). Crystals prismatic (fig. 352); twins common, of various kinds; also massive, dendritic, or investing. Cl. R, rather perfect; fracture conchoidal to uneven and splintery; sectile. H. = 2 to 2·5. Crimson-red to blackish lead-grey; streak cochineal to cherry-red. Huel Brothers and Huel Duchy in Cornwall, Andreasberg, Freiberg, Johann-Georgenstadt, Annaberg,

Schneeberg, Marienberg, Przibram, Schemnitz and Kremnitz, Kongsberg, Mexico, Nevada, &c.

226. Proustite, $3Ag_2S + As_2S_3$.

Rhombohedral, like pyrargyrite, except R 107° 50′ (fig. 353). G. = 5·5 to 5·6. Semi-transparent to translucent on the edges. Cochineal to crimson-red. C.c.: 65·5 silver, 15·1 arsenic, and 19·4 sulphur. Streak aurora-red. B.B. arsenical odour, and difficultly reduced to metallic silver. At the same localities as pyrargyrite; both are valuable ores of silver. Red orpiment has a lower specific gravity, and yellow streak; cinnabar volatilizes before the blowpipe.

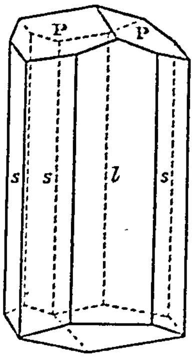

Fig. 352 (sp. 225).

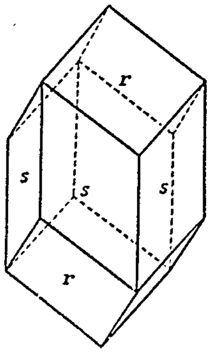

Fig. 353 (sp. 226).

227. Boulangerite, $3PbS + SbS_3$.

Fine granular, columnar, radiating, or fibrous; slightly sectile. H. = 3; G. = 5·8 to 6. Silky, metallic. Blackish lead-grey, with darker streak. B.B. like jamesonite. C.c.: 59 lead, 22·8 antimony, and 18·2 sulphur. Molières in France, Oberlahr (Rhenish Prussia), Lapland, and Siberia. *Plumbostib* or *Embrelhite*, from Nertchinsk, is only a variety.

228. Kobellite, $3PbS$, $Bi_2S_3 + 3PbS$, Sb_2S_3.

Radiated columnar; soft. G. = 6·2 to 6·3. C.c.: 53 lead, 20 bismuth, 10 antimony, and 17 sulphur. Hvena in Nerike (Sweden).

229. Wittichenite (*Cupreous Bismuth*), $3CuS + Bi_2S_3$.

Right prismatic; in tabular crystals like bournonite. Wittichen in the Black Forest.

230. Bournonite $(3CuS + Sb_2S_3) + 2(3PbS + Sb_2S_3)$.

Right prismatic. ∞P (*d*) 93° 40′; $\breve{P}\infty$ (*n*) 96° 13′; $\bar{P}\infty$ (*e*) 92° 34′; 0P (*r*); $\infty\breve{P}\infty$ (*s*); $\infty\bar{P}\infty$ (*k*) (fig. 354). Cl. brachydiagonal, imperfect; fracture uneven to conchoidal; rather brittle. H. = 2·5 to 3; G. = 5·7 to 5·9. Lustre brilliant metallic. Steel-grey. C.c.: 42·4 lead, 13 copper, 25 antimony, and 19·6 sulphur. Redruth and Beeralston; Harz (Neudorf), Bräunsdorf, Kapnik, Servoz; Alais and Pontgibaud in France.

Wölchite from Wölch in Carinthia is only a variety.

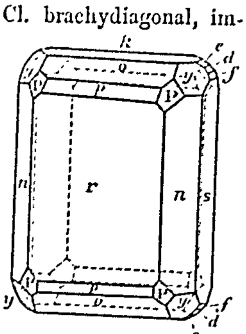

Fig. 354 (sp. 230).

231. Aikinite (*Needle-ore*), $2(3PbS + Bi_2S_3) + 3(CuS + Bi_2S_3)$.

Right prismatic; long thin crystals imbedded in quartz, often bent or broken; rather brittle. H. = 2·5; G. = 6·7 to 6·8. Blackish lead-grey or steel-grey, with a brownish tarnish. C.c.: 36 lead, 11 copper, 36 bismuth, and 17 sulphur. Berezoff (Siberia), Georgia.

232. Stylotyp, $3(CuAgFe)S + Sb_2S_3$.

Right prismatic. 0P 92° 30′. H. = 3; G. = 4·8. Black. Copiapo, Chili.

233. Annivite, $4CuS + (As_2S_3, Sb_2S_3, Bi_2S_3)$.

Massive, similar to the foregoing. From Anniver in Valais. *Studerite* is similar, but with 15·5 of antimony.

234. Julianite, $3Cu_2S + As_2S_3$.

Cubic. G. = 5·12. Metallic. Reddish grey. Rudelstadt in Silesia.

235. Meneghinite, $4PbS + Sb_2S_3$.

Oblique prismatic, C 72° 8′. ∞P 140° 24′; $P^o\infty$ 70°. Crystals small, acicular, chiefly of $\infty P^o\infty$, $\infty P^o\infty$, ∞P; rare; mostly fibrous. H. = 3; G. = 6·4. Bottino in Tuscany, Schwarzenberg in Saxony.

236. Jordanite, $4PbS + As_2S_3$.

Right prismatic; ∞P 123° 29′. Cl. brachydiagonal, perfect. Streak black. G. = 6·38. C.c.: lead 68·9, arsenic 12·5, sulphur 18·6. Binnen and Nagyag.

237. Tetrahedrite (*Fahlerz*), $4Cu_2S + Sb_2S_3$.

Tesseral and tetrahedral. In crystals $\frac{O}{2}$, $-\frac{O}{2}$, ∞O, $\frac{2O2}{2}$ (figs. 355 to 358, also 65, 66, 206). Twins (figs. 164, 207); generally massive. Cl. octahedral; fracture conchoidal; brittle. H. = 3·44; G. = 4·5 to 5·2. Steel-grey to iron-black; streak black (dark red when containing zinc). B.B. on charcoal boils slightly, and fuses to a steel-grey slag, usually magnetic, and with soda gives copper. C.c. essentially Cu_2S in combination with Sb_2S_3. Airthrey near

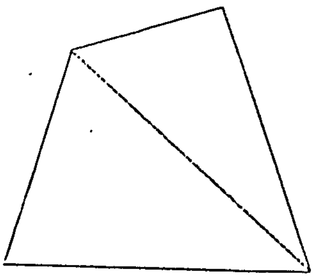

Fig. 355.

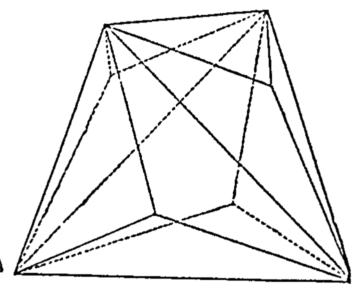

Fig. 356.

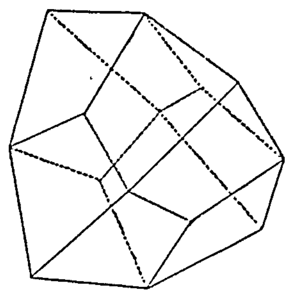

Fig. 357.

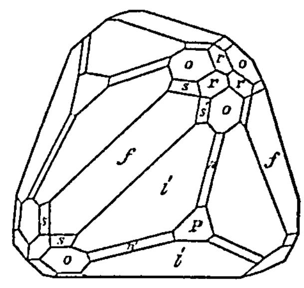

Fig. 358.

Stirling, Sandlodge in Shetland, Tomnadashin on Loch Tay, Kirkcudbright; Crinnis and other Cornish mines near St Austell; Harz, Müsen, Freiberg, Camsdorf, Alsace, Kremnitz, and Kapnik. Those with 17 to 31 silver are the *Silver Fahlore* (Freiberg). Ore of copper and silver.

238. Tennantite, $(CuS, FeS)\ As_2S_3$.

Cubic (like fig. 237). Cl. ∞O. Brittle. H. = 4; G. = 4·3 to 4·5. Iron-black; streak dark red, grey. C.c.: 49 copper, 4 iron, 19 arsenic, and 28 sulphur. Redruth and St Day (Cornwall), and Skutterud. *Copper-blende*, with brownish red streak; G. = 4·3; contains 8·9 zinc; Freiberg.

239. Polytelite (*Weissgiltigerz*), $4RS + Sb_2S_3$.

Like tetrahedrite. H. = 2·5; G. = 5·4 to 5·7. C.c.: silver 6 to 22, lead 38 to 52, antimony 8·5 to 22, sulphur 13 to 22·5. Freiberg.

240. Stephanite, $5Ag_2S + Sb_2S_3$.

Right prismatic. ∞P (*o*) 115° 39′; P (*P*) middle edge 104° 20′; $2\breve{P}\infty$ (*d*) middle edge 107° 48′; 0P (*s*); $\infty\breve{P}\infty$ (*p*) (figs. 333, 334). Cl. *d* and *p*, both imperfect; fracture conchoidal or uneven; sectile. H. = 2 to 2·5; G. = 6·2 to 6·3. Iron-black to blackish lead-grey. C.c.: 68·5 silver, 15·3 antimony, and 16·2 sulphur. Cornwall, Freiberg, Schneeberg, Annaberg, Joachimsthal, Przibram, Schemnitz, Mexico, Peru, and Siberia. Valuable ore of silver.

241. Geocronite, $5PbS + (Sb, As)_2S_3$.

Right prismatic. Fracture conchoidal; sectile. H. = 2 to 3; G. = 6·45 to 6·54. Pale lead-grey. C.c.: 67 lead, with 1 to 2 copper and iron, 16 antimony, with 4·7 arsenic, and 17 sulphur. Sala in Sweden, Meredo (Oviedo) in Spain, and near Pietrosanto in Tuscany.

242. Kilbrickenite, $6PbS + Sb_2S_3$.

Massive; granular or foliated. C.c.: 70·01 lead, 13·76 antimony, and 16·23 sulphur. County Clare in Ireland.

243. Polybasite, $9(Ag_2, Cu_2)S + (Sb, As)_2S_3$.

Hexagonal; P 117°. Crystals 0P, ∞P; and 0P, P, tabular. Cl. basal, imperfect; sectile, and easily frangible. H. = 2 to 2·5; G. = 6 to 6·25. Iron-black, in very thin lamellæ, translucent, red. C.c.: 64 to 72 silver, 3 to 10 copper, 16 to 17 sulphur, 0·2 to 8 antimony, and 1 to 6 arsenic. Freiberg, Joachimsthal, Schemnitz, Guanajuato, Nevada, and Idaho. Rich ore of silver.

244. Polyargyrite, $12AgS + Sb_2S_3$.

Cubic. Typical form O, $\infty O\infty$, ∞O, mOm. Cl. cubic. H. = 2·5; G. = 6·97. Metallic, iron-black; streak black. Malleable. C.c.: 78·2 silver, 7·4 antimony, 14·5 sulphur. Wolfach in Baden.

245. Enargite, $3Cu_2S + As_2S_5$.

Right prismatic. Cl. ∞P 97° 53′ perfect, brachydiagonal 100° 58′ and macrodiagonal less so. Typical form ∞P, 0P, $\infty\bar{P}\infty$, $\infty\breve{P}\infty$. Brittle. H. = 3; G. = 4·3 to 4·5. Iron-black. C.c.: 48·3 copper, 19·1 arsenic, and 32·6 sulphur. Morococha in Peru.

246. Clarite, $3CuS+AsS$.

Oblique prismatic. Cl. clinodiagonal. Ordinary form ∞P, $\infty P^c\infty$, $0P$, mP. H. = 3·5; G. = 4·46. Dark bluish grey. Kinzigthal in Baden. *Luzonite* is similar.

247. Famatinite, $3CuS+SbS$.

Right prismatic. Typical form $0P$, ∞P, $\infty \bar{P}\infty$, $\infty \breve{P}3$. Massive or reniform. H. = 3·5; G. = 4·57. Copper-red to grey; streak black. Famatina Mts. in the Argentine Republic, and Cerro de Pasco in Peru.

248. Chiviatite, $2PbS+3Bi_2S_3$.

Foliated, massive. G. = 6·9. Metallic. Lead-grey. Chiviato in Peru.

249. Epigenite, $6RS+As_2S_5$.

Right prismatic. ∞P 110° 50′. Steel-grey. H. = 3·5. Wittichen.

250. Epiboulangerite, $3PbS+Sb_2S_5$.

Right prismatic. G. = 6·3. Metallic. Blue-black. Altenburg in Silesia.

251. Xanthocon, $2(3AgS+As_2S_3)+(3AgS+As_2S_5)$.

Hexagonal rhombohedral. R : 0R 110° 30′. Crystals thin hexagonal tables; brittle, easily frangible. H. = 2 to 2·5; G. = 5 to 5·2. Translucent; adamantine. Orange-yellow or brown; streak darker. In the closed tube fuses easily, becomes lead-grey. C.c.: 63·4 silver, 14·7 arsenic, and 21·9 sulphur. Himmelsfürst mine at Freiberg.

252. Pyrostilpnite (*Fire-blende*).

Oblique prismatic; crystals like stilbite. $0P$ 139° 12′. Twins on orthodiagonal. H. = 2; G. = 4·2. Lustre pearly, and adamantine. Colour hyacinth-red and bright-yellow. Sectile. C.c.: 62·3 silver, with sulphur and antimony. Freiberg, Andreasberg, Przibram.

OXYSULPHURETS.

253. Kermesite, SbO_3+2SbS_3.

Oblique prismatic; crystals $\infty \bar{P}\infty$, $0P$, acicular and diverging; sectile. H. = 1 to 1·5; G. = 4·5 to 4·6. Translucent; adamantine. Cherry-red; streak similar. Sol. in h. acid. In potash solution becomes yellow, and dissolves. C.c.: 75·3 antimony, 19·8 sulphur, 4·9 oxygen. Bräunsdorf, Przibram, Pernek near Bösing (Hungary), Allemont, Southham (Canada).

254. Voltzine, $ZnO+4ZnS$.

Incrusting. H. = 4·5; G. = 3·7. Yellow. Pontgibaud and Joachimsthal.

255. Karelinite, $3BiO+BiS$.

H. = 2; G. = 6·6. Metallic. Lead-grey. Zavodinski in the Altai.

256. Bolivite, $Bi_2O_3+Bi_2S_3$.

Rhombohedral. From Bolivia.

SELENITES.

257. Chalcomenite, $\dot{C}u\ddot{S}e+2\dot{H}_2[=CuO,\ SeO_2+2H_2O]$.

Oblique prismatic, C 108° 20′. G. = 3·76. Bright blue. Transparent. C.c.: selenious acid 48·2, copper oxide 35·4, water 15·3. Cerro de Cacheuta (Mendoza, Argentine Republic).

NITRATES AND BORATES.

258. Nitratine, $\dot{N}a_2\ddot{\ddot{N}}_2[=Na_2O,\ N_2O_5]$.

Rhombohedral; R. 106° 30′. Tarapaca in Peru. Used in the arts as a substitute for nitre; but deliquesces in moist air.

259. Nitre (*Saltpetre*), $\dot{K}_2\ddot{\ddot{N}}_2[=K_2O,\ N_2O_5]$.

Right prismatic. ∞P (*M*) 118° 49′; $2\breve{P}\infty$ (*P*) 70° 55′; $\breve{P}\infty$ 109° 52′; $\infty \breve{P}\infty$ (*h*) (fig. 275); isomorphous with aragonite. Acicular, capillary, or pulverulent. Cl. indistinct; fracture conchoidal. H. = 2; G. = 1·9 to 2. Semitransparent; vitreous or silky. Colourless, white, or grey. Taste saline and cooling. Deflagrates when placed on hot charcoal; and B.B. on platina wire melts very easily, colouring the flame violet. C.c.: 46·6 potash and 53·4 nitric acid, but always more or less impure. In the limestone caves of many countries; Hungary, Spain, India. Used for producing nitric acid, in glass making, medicine, and the manufacture of gunpowder.

260. Nitrocalcite, $\dot{C}a\ddot{\ddot{N}}_2+\dot{H}_2$.

Fibrous or pulverulent. White or grey. C.c.: 30·8 lime, 59·3 nitric acid, and 9·9 water. Limestone caves of Kentucky; on old walls and limestone rocks.

261. Nitromagnesite, $\dot{M}g\ddot{\ddot{N}}_2+\dot{H}_2$.

Taste bitter. In the same places, and similar to nitrocalcite.

262. Boracite, $2\dot{M}g_3\ddot{B}_4+MgCl$.

Tesseral and hemihedral (figs. 63, 253, 359). Cl. octahedral, imperfect; fracture conchoidal; brittle. H. = 7; G. = 2·9 to 3. Transparent or translucent; vitreous or adamantine. Colourless or white, often greyish, yellowish, or greenish. Becomes polar electric by heat. B.B. fuses with difficulty to a clear yellowish bead, which on cooling forms a white opaque mass of needle-like crystals; at the same time colours the flame green. Sol. in h. acid. C.c.: 62·5 boracic acid, 26·9 magnesia, 7·9 chlorine, and 2·7 magnesium. Lüneberg, Segeberg in Holstein, Stassfurt.

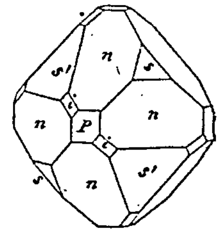

Fig. 359.

263. Stassfurtite.

In very minute prismatic crystals. White. C.c. same as boracite, and thus perhaps dimorphous. Stassfurt.

264. Rhodizite, $2\dot{C}a_3\ddot{B}_4$ (?).

H. = 8 and G. = 3·3 to 3·42; agrees in most characters with boracite. Pyro-electric. Mursinsk in Siberia.

265. Ludwigite, $2\dot{M}g\ddot{B}+\dot{F}e\ddot{F}e_2$.

Fibrous masses. From limestone at Morawitza in the Banat.

266. Borax (*Tinkal*), $\dot{N}a_22\ddot{B}+10\dot{H}_2$.

Oblique prismatic, C 73° 25′. ∞P 87°; P 122° 34′ (fig. 360). Almost isomorphous with augite; brittle. H. = 2 to 2·5; G. = 1·7 to 1·8. Pellucid; resinous. Colourless, or yellowish, greenish, and greyish white. Taste feebly alkaline and sweetish. C.c.: 16·4 soda, 36·5 boracic acid, and 47·1 water; but often with 2 phosphoric acid or other impurities. Shores of salt lakes in Tibet and Nepal, in California, and near Potosi.

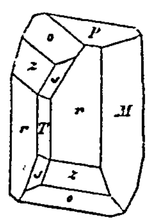

Fig. 360 (sp. 266).

267. Borocalcite, $\dot{C}a2\ddot{B}+6\dot{H}_2$.

Similar to ulexite (sp. 268); and from same locality.

268. Ulexite, $\dot{N}a_22\ddot{B}+2\dot{C}a2\ddot{B}+18\dot{H}_2$.

Fibrous. H. = 1; G. = 1·6. White. Tasteless. Iquique and Nova Scotia.

269. Szaibelyite, $2\dot{M}g_52\ddot{B}+3\dot{H}_2$.

H. = 3·5; G. = 2·7. Werksthal in Hungary.

270. Hydroboracite, $2\dot{C}a3\ddot{B}_3+2\dot{M}g3\ddot{B}_3+12\dot{H}_2$.

Radiating and foliated. Caucasus. A similar mineral, with soda in place of magnesia, is found in Peru.

271. Sussexite, $(\dot{M}n,\ \dot{M}g)_2\ddot{B}+\dot{H}_2$.

Fibrous, silky. White. H. = 3; G. = 3·4. Franklin (Sussex county, New Jersey).

ANHYDROUS CARBONATES.

272. Calcite (*Calc-spar, Calcareous Spar*), $\dot{C}a\ddot{C}$.

Hexagonal and rhombohedral; R 105° 5′ (fig. 101). The forms and combinations exceed those of any other mineral. Among them are more than fifty rhombohedrons, especially $-\frac{1}{2}R$ 135°; R; $-2R$ 79°; and 4R 66°; with 0R and ∞R as limiting forms. There are one hundred and fifty-five distinct scalenohedrons, as R3; R2; $\frac{1}{4}$R3; and the second hexagonal prism $\infty P2$. Hexagonal pyramids are among the rarer forms. Some of the most usual combinations are ∞R, $-\frac{1}{2}R$ (*c*, *g*, fig. 179); or $-\frac{1}{2}R$, ∞R, very frequent; also ∞R, 0R; likewise $-2R$, R (*f*, *P*, fig. 107); R3, ∞R, $-2R$; R5 (*y*), R3 (*r*), R (*P*), 4R (*m*), ∞R (*c*) (fig. 109); R, R3 (fig. 108). Several hundred distinct combinations are known.

Hemitropes and twins are not uncommon. These occur with the axes parallel (figs. 106, 146, 148, 180, 366, 367). Others

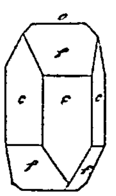

Fig. 361.

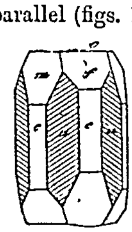

Fig. 362.

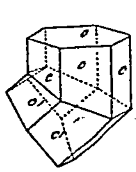

Fig. 363.

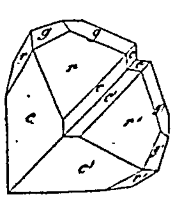

Fig. 364.

are conjoined by a face of R, the axes being almost at right angles, 89° 8′ (figs. 183, 369) or by a face of $-\frac{1}{2}R$, in which the chief axes form an angle of 127½°; and usually many times repeated, so that the centre crystals appear in lamellæ not thicker than paper (fig. 181); at an obtuse angle, as figs. 149, 363, or an acute

angle, as figs. 364, 368. Also occurs granular, lamellar, parallel or radiated fibrous, compact and earthy. Cl. rhombohedral along R, very perfect and easily obtained, so that the conchoidal fracture is rarely observable; brittle. H.=3; G.=2·6 to 2·8; pure transparent crystals=2·72. Pellucid in all degrees. Very distinct double refraction. Lustre vitreous, but several faces resinous, and 0R pearly. Most frequently colourless or white, but often grey, blue, green, yellow, red, brown, or black; streak greyish white. B.B. infusible, but becomes caustic and emits a bright light. Effervesces, and is entirely sol. in h. or n. acid. The fine powder, ignited on platina-foil over the spirit-lamp, forms a somewhat connected mass, and even adheres to the platina. C.c. of the purest varieties, carbonate of lime, with 44 carbonic acid and 56 lime, but usually contains magnesia and protoxide of iron or of manganese. Remarkable specimens of the crystallized variety or proper calc-spar are found at Alston Moor in Cumberland (flat rhombic crystals) and in Derbyshire (pale yellow

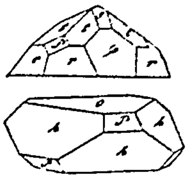

Fig. 365.

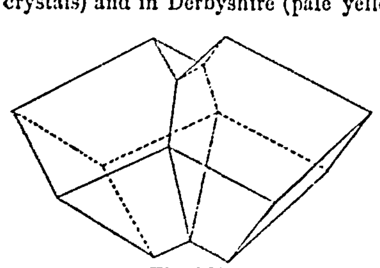

Fig. 366.

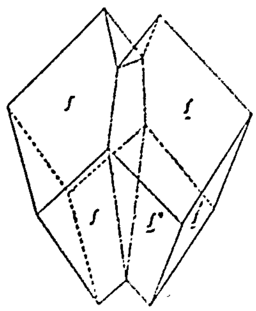

Fig. 367.

transparent pyramids), at Strontian, Elie in Fife (figs. 370, 371, 372), Andreasberg and other parts of the Harz (six-sided prisms), and at Freiberg, Tharand, and Maxen in Saxony.

Certain varieties are distinguished. *Iceland Spar*, remarkable for its transparency and double refraction, occurs massive and in huge crystals in a trap rock in Iceland. *Slate Spar*, thin lamellar, often with a shining white pearly lustre and greasy feel; Abergairn and Glen

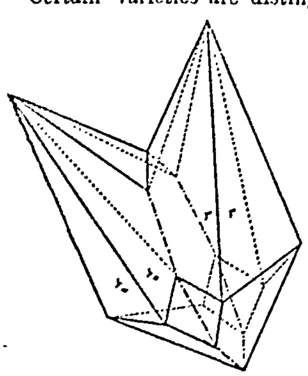

Fig. 368.

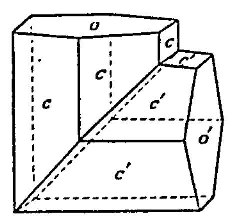

Fig. 369.

Tilt in Scotland, Wicklow in Ireland, and Norway. *Aphrite*, fine scaly; from Hesse and Thuringia. *Marble* is the massive crystalline variety of this mineral, produced by igneous action on compact limestone. Paros, Naxos, and Tenedos furnished the chief supply to the Grecian artists; Carrara, near the Gulf of Genoa, to those of modern times. Some of the coloured marbles

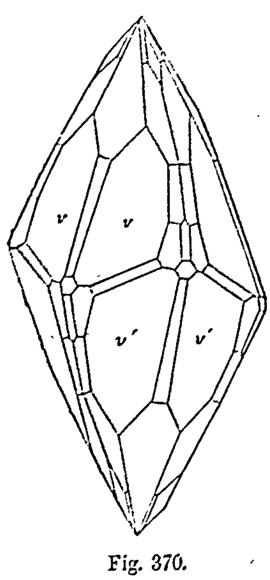

Fig. 370.

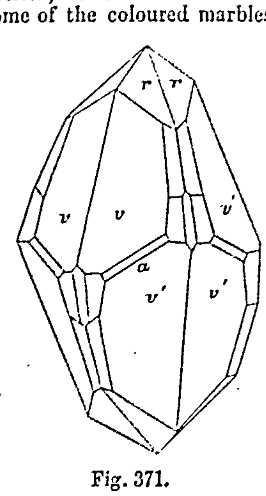

Fig. 371.

of the ancients were impure limestones, as the *Cipollino*, zoned with green talc or chlorite, and *Verde Antique*, mixed with green serpentine. *Ruin Marble* shows irregular markings like ruins; Val d'Arno (Florentine marble), and Bristol (Cotham marble). *Lucullite* from Egypt, and *Anthraconite*, from Campbelltown and Kilkenny, are black from carbon. *Lumachello*, from Bleiberg in Carinthia, exhibits beautiful iridescent colours from fossil shells, sometimes deep red or orange (*Fire Marble*). *Hislopite*, from Poonah, is green, from celadonite.

Limestone occurs in all formations under various names, as *Oolite*, egg-stone, or roe-stone,—round concretions with a concentric structure like the roe of a fish; *Pisolite*, or peastone, similar structure; *Chalk*, soft earthy; *Lithographic Stone*, yellowish and compact, from Solenhofen; and *Marl*, calcareous matter more or less mixed with clay. *Calcareous Tufa*, generally a recent deposit from calcareous springs, has often a loose friable texture, but at other times is hard and compact; and in the neighbourhood of Rome forms the common building stone *Travertino*. The sandstone of Fontainebleau is carbonate of lime ($\frac{1}{3}$) mixed with quartz sand ($\frac{2}{3}$), and occasionally crystallizing in rhombohedrons.

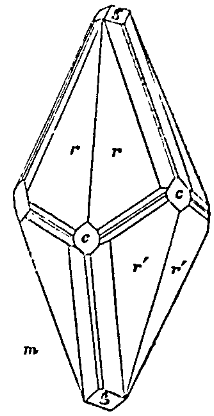

Fig. 372.

This mineral is employed in many ways:—the coarser varieties, when burnt to drive off the carbonic acid, as lime, for mortar, manure, tanning; as a flux in melting iron and other ores, or in preparing glass, and for similar purposes; the finer, as marbles, for sculpture, architecture, and ornamental stone-work; the chalk for writing, white-washing, or producing carbonic acid.

Plumbocalcite.—Cl. 104° 53′. White and pearly; softer than calc-spar; but G.=2·824. Contains 2·3 to 7·3 carbonate of lead. Wanlockhead and Leadhills (Scotland).

273. Dolomite (*Bitter-spar*), $\dot{\mathrm{Ca}}\ddot{\mathrm{C}}+\dot{\mathrm{Mg}}\ddot{\mathrm{C}}$.

Hexagonal rhombohedral; R 106° 15′–20′; most frequent form R. The rhombohedrons often curved and saddle-shaped; also granular or compact, often cellular and porous. Cl. rhombohedral. H.=3·5 to 4·5; G.=2·85 to 2·95. Translucent; vitreous, but often pearly. Colourless or white, but frequently pale red, yellow, or green. B.B. infusible, but becomes caustic, and often shows traces of iron and manganese. Fragments effervesce very slightly or not at all in hydrochloric acid; the powder is partially soluble, or wholly when heated. C.c.: 54·3 carbonate of lime and 45·7 carbonate of magnesia, but generally carbonate of lime with more than 20 per cent. carbonate of magnesia and less than 20 per cent. carbonate of iron.

Varieties are—*Dolomite*, massive-granular, easily divisible, white; *Rhomb* or *Bitter-spar*, larger grained, or distinctly crystallized and cleavable, often inclining to green; and *Brown-spar* and *Pearl-spar*, in simple crystals generally curved (fig. 231), or in imitative forms, of colours inclining to red or brown, more distinct pearly lustre, and under 10 per cent. carbonate of iron. Leadhills and Charlestown in Scotland, Alston in Cumberland, in Derbyshire, Traversella in Piedmont, St Gotthard, Gap in France. Greenish, twinned; Miemo in Tuscany (*Miemite*), and Tharand in Saxony (*Tharandite*).

The massive and compact varieties are very common, and are valued as building stones (cathedral of Milan, York Minster, and the Houses of Parliament at Westminster). The Parian marble, and also the Sutherland and Iona marbles, belong to this species.

274. Ankerite, $\dot{\mathrm{Ca}}\ddot{\mathrm{C}}+(\dot{\mathrm{Mg}}\dot{\mathrm{Fe}})\ddot{\mathrm{C}}$.

R 106° 12′. Usually massive and granular. G.=2·9 to 3·1. Otherwise like siderite. Unst (Shetland), Styria.

275. Magnesite, $\dot{\mathrm{Mg}}\ddot{\mathrm{C}}$.

Rhombohedral; 107° 10′–30′. Reniform or massive. H.=3·5; G.=2·85 to 2·95. Subtranslucent or opaque; streak shining. Snow-white, greyish or yellowish white, and pale yellow. Tyrol, Norway, North America.

276. Breunnerite (*Giobertite*), $\dot{\mathrm{Mg}}\ddot{\mathrm{C}}+(\dot{\mathrm{Mn}}\dot{\mathrm{Fe}})\ddot{\mathrm{C}}$.

Hexagonal rhombohedral; R 107° 10′–30′. Granular or columnar. Cl. R, very perfect. H.=4 to 4·5; G.=2·9 to 3·1. Transparent or translucent on the edges; highly vitreous. Colourless, but often yellowish brown or blackish grey. C.c. essentially carbonate of magnesia, with 51·7 carbonic acid and 48·3 magnesia, but often mixed with 8 to 17 carbonate of iron or manganese. Unst, Tyrol (in Fassa Valley, &c.), St Gotthard, Harz.

277. Siderite (*Sparry Iron, Chalybite*), $\dot{\mathrm{Fe}}\ddot{\mathrm{C}}$.

Hexagonal and rhombohedral; R 107°. Chiefly R, often curved, saddle-shaped (fig. 232), or lenticular. Cl. rhombohedral along R, perfect; brittle. H.=3·5 to 4·5; G.=3·7 to 3·9. Translucent in various degrees, becoming opaque when weathered; vitreous or pearly. Rarely white, generally yellowish grey or yellowish brown. changing

to red or blackish brown on exposure. B.B. infusible, but becomes black and magnetic; with borax and salt of phosphorus shows reaction for iron; with soda often for manganese. In acids soluble with effervescence. C.c. carbonate of iron, with 62·1 protoxide of iron and 37·9 carbonic acid, but usually 0·5 to 10 or even 25 protoxide of manganese, 0·2 to 15 magnesia, and 0·1 to 2 lime. Unst, Kintyre. In beds or masses in Beeralston in Devonshire, Alston Moor in Cumberland, and in many of the tin-mines in Cornwall, in Styria, Carinthia, and Westphalia; in veins in Anhalt and the Harz; also in the Pyrenees and the Basque provinces of Spain, as near Bilboa; in crystals at Joachimsthal, Freiberg, Klausthal.

Clay Ironstone, grey, blue, brown, or black,—G. = 2·8 to 3·5, H. = 3·5 to 4·5,—is an impure variety.

278. Dialogite (*Red Manganese*), ṀnC̈.

Hexagonal rhombohedral; R 106° 56′. Crystals often curved, lenticular, or saddle-shaped; also spherical, reniform, and columnar or granular. Cl. R, perfect. H. = 3·5 to 4·5; G. = 3·3 to 3·6. Translucent; vitreous or pearly. Rose-red to flesh-red; streak white. C.c.: 62 manganese protoxide and 38 carbonic acid. Freiberg, Schemnitz, Kapnik, Nagyag, Elbingerode, and near Sargans.

279. Cobaltspath, ĊoC̈o.

Rhombohedral and spheroidal. H. = 4; G. = 4 to 4·13. Peach-blossom-red; but dark externally. Schneeberg.

280. Smithsonite (*Calamine*), ŻnC̈.

Hexagonal rhombohedral; R 107° 40′. Usually reniform, stalactitic, and laminar or granular. Cl. R, perfect, but curved; fracture uneven, conchoidal; brittle. H. = 5; G. = 4·1 to 4·5. Translucent or opaque; pearly or vitreous. Colourless, but often pale greyish yellow, brown, or green. C.c.: 64·8 zinc oxide and 35·2 carbonic acid. Mendip in Somersetshire, Matlock in Derbyshire, compact at Alston Moor, Chessy near Lyons, Altenberg near Aix-la-Chapelle, Brilon in Westphalia, Tarnowitz in Silesia, Hungary, Siberia.

281. Aragonite, ĊaC̈.

Right prismatic. ∞P 116° 10′; P̆∞ 108° 26′. The most common combinations are ∞P̆∞ (*h*), ∞P̆ (*M*), P∞ (*k*, *P*) (fig. 275), generally long prismatic (like the separate crystals in fig. 184); ∞P̆∞, ∞P, 0P, generally short prismatic; crystals of 6P̆$\frac{3}{2}$, ∞P, P̆∞, 6P̆∞ (*q*) (fig. 373) acute pyramidal. But simple crystals are rare, from the great tendency to form twins, conjoined by a face of ∞P, and repeated either in linear arrangement (fig. 185) or in rosette grouping (fig. 186). Also columnar, fibrous, and in crusts, stalactites, and other forms. Cl. brachydiagonal, distinct; fracture conchoidal or uneven. H. = 3·5 to 4; G. = 2·9 to 3 (massive 2·7). Transparent or translucent; vitreous. Colourless, but yellowish white to brick-red; also light green, violet-blue, or grey. In the closed tube, before reaching a red heat, it swells, and falls down into a white coarse powder, evolving a little water. Unst and Leadhills; Valencia, Molina and elsewhere in Aragon; Leogang in Salzburg, and Antiparos. *Flos-ferri*, coralloid, in the iron-mines of Styria. *Satin-spar*, fine fibrous silky, at Dufton (Westmoreland). Stalactitic, coast of Galloway, Leadhills, Buckinghamshire, and Devonshire. Also deposited as tufa by the Carlsbad and other hot springs.

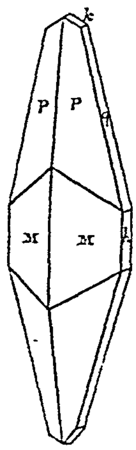

Fig. 373.

282. Witherite, ḂaC̈.

Right prismatic. ∞P (*g*) 118° 30′; 2P̆∞ (*P*) 112°. Crystals not common like fig. 275, but generally with quite an hexagonal aspect from being twinned like aragonite (fig. 374). Oftener spherical botryoidal, or reniform, with radiated-columnar structure. Cl. ∞P, distinct; fracture uneven. H. = 3 to 3·5; G. = 4·2 to 4·3. Semitransparent or translucent; vitreous, or resinous on the fracture. Colourless, but generally yellowish or greyish. B.B. fuses easily to a transparent globule, opaque when cold; on charcoal boils, becomes caustic and sinks into the support; soluble with effervescence in n. or h. acid. C.c.: 22·3 carbonic acid and 77·7 baryta. Alston Moor and Hexham in Northumberland, also in Styria, Salzburg, Hungary, Sicily, Siberia, and Chili.

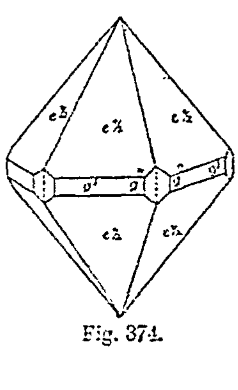

Fig. 374.

283. Alstonite, ḂaC̈ + ĊaC̈.

Right prismatic. ∞P 118° 50′; 2P̆∞ 111° 50′; usual combination P, 2P̆∞, ∞P, resembling an hexagonal pyramid (fig. 375). Cl. ∞P and ∞P̆∞, rather distinct. H. = 4 to 4·5; G. = 3·65 to 3·76. Translucent; weak resinous. Colourless or greyish-white. C.c.: 66 carbonate of baryta and 34 carbonate of lime. Fallowfield near Hexham, and Alston Moor.

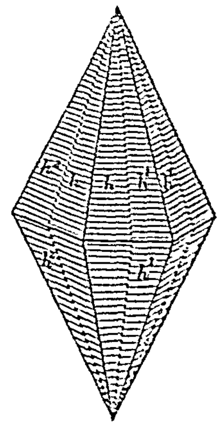

Fig. 375 (sp. 283).

284. Strontianite, ṠrC̈.

Right prismatic. ∞P 117° 19′; P̆∞ 108° 12′. Crystals (fig. 376) and twins like aragonite; also broad columnar and fibrous. Cl. prismatic along ∞P (*M*). H. = 3·5; G. = 3·6 to 3·8. Translucent or transparent; vitreous or resinous on fracture. Colourless, but often light asparagus- or apple-green, more rarely greyish, yellowish, or brownish. B.B. fuses in a strong heat only on very thin edges, intumesces in cauliflower-like forms, shines brightly, and colours the flame red; easily soluble in acids, with effervescence. C.c.: 30 carbonic acid and 70 strontia, but often contains carbonate of lime (6 to 8). Strontian in Argyllshire, Sutherland, Leogang in Salzburg, Bräunsdorf in Saxony, Hamm in Westphalia, the Harz; at Schoharie (N.Y.) and elsewhere in United States (*Emmonite*). It is used to produce red fire in pyrotechnic exhibitions.

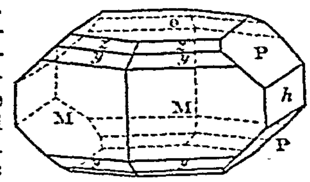

Fig. 376.

285. Manganocalcite, (Ṁn, Ċa, Ḟe) C̈.

Right prismatic; in prisms like aragonite, and bears the same relation to dialogite that aragonite does to calc-spar. H. = 4 to 5; G. = 3·03. Red or reddish white. Vitreous. Schemnitz.

286. Cerussite (*Lead Spar*), ṖbC̈.

Right prismatic; isomorphous with aragonite and nitre. ∞P (*M*) 117° 14′; P̆∞ 108° 16′; 2P̆∞ (*u*) 69° 20′; also 0P; P (*t*); ½P̆∞ (*s*); ∞P̆∞ (*l*); ∞P̆3 (*c*) (fig 377). Twins common (figs. 158, 159, 378, 379). Also granular or earthy. Cl. ∞P and 2P̆∞, rather distinct; fracture conchoidal; easily frangible. H. = 3 to 3·5; G. = 6·4 to 6·6. Transparent or translucent; adamantine or resinous. Colourless and often white, but also grey, yellow, brown, black, rarely green, blue, or red; streak white. B.B. decrepitates violently, but easily fused and reduced; soluble with effervescence in n. acid. C.c.: 83·5 protoxide of lead and 16·5 carbonic acid. Very common. Leadhills, Wanlockhead, Keswick, Alston Moor, Beeralston in Devonshire, St Minver in Cornwall; Przibram, Mies, and Bleistadt; Tarnowitz, Johann-Georgenstadt, Zellerfeld, Klausthal, and many other places.

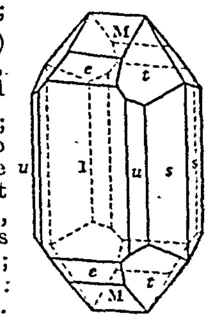

Fig. 377.

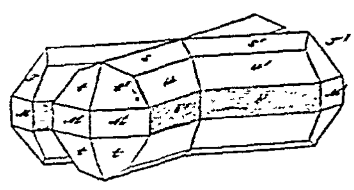

Fig. 378.

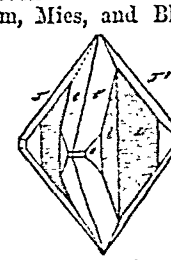

Fig. 379.

287. Baryto-Calcite, ḂaC̈ + CaC̈.

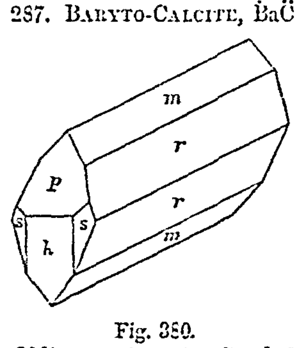

Fig. 380.

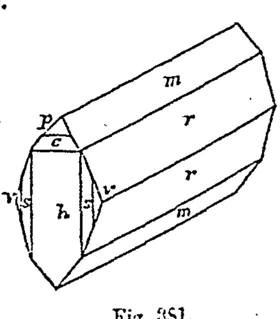

Fig. 381.

Oblique prismatic, C 69° 30′. ∞P (*m*) 84° 52′, P (*s*) 106° 54′,

$P^{\circ}\infty$ (*h*) 61° (figs. 380, 381); also columnar and granular. Cl. P perfect, $P^{\circ}\infty$ less perfect. H. = 4; G. = 3·6 to 3·7. Transparent or translucent; vitreous, inclining to resinous. Yellowish white. C.c.: like alstonite. Alston Moor.

288. Bismuto-sphærite, $\dddot{B}i_2\ddot{C}$.

Small fibrous brown concretions from Neustädtel, near Schneeberg.

HYDROUS CARBONATES.

289. Thermonatrite, $\dot{N}a_2\ddot{C}+\dot{H}_2$.

Right prismatic. $\infty\breve{P}2$ (*d*) 107° 50′; $\breve{P}\infty$ (*o*) 83° 50′; with $\infty\breve{P}\infty$ (*P*) in rectangular tables (fig. 382). Cl. brachydiagonal, perfect. H. = 1·5; G. = 1·5 to 1·6. Colourless. B.B. like natron, but does not melt. C.c.: 50·1 soda, 35·4 carbonic acid, and 14·5 water. Natron lakes of Lagunilla in Venezuela, of Lower Egypt, and of the steppes between Urals and Altai.

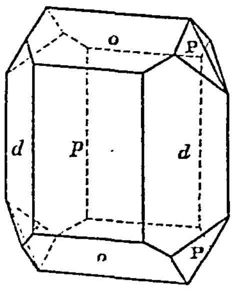

Fig. 382 (sp. 289).

290. Natron, $\dot{N}a_2\ddot{C}+10\dot{H}_2$.

Oblique prismatic, C 57° 40′. Crystals artificial; with ∞P 79° 41′; P 76° 28′. Cl. orthodiagonal, distinct. H. = 1 to 1·5; G. = 1·4 to 1·5. Pellucid; vitreous. Colourless or greyish white. B.B. melts easily, colouring the flame yellow. C.c.: 22 soda, 15 carbonic acid, and 63 water; but mixed with chloride of sodium and other salts. Only as an efflorescence on the ground or rocks (lava of Vesuvius and Etna) in various countries (Hungary, Egypt, Tartary), and in mineral springs and lakes. Used in the manufacture of soap, in dyeing, and in bleaching.

291. Trona, Urao, $\dot{N}a_2\ddot{C}_3+4\dot{H}_2$.

Oblique prismatic. Crystals 0P (*T*), $\infty P^{\circ}\infty$ (*M*), P (*n*). *T* : *M* 103° 15′ (fig. 383). Cl. orthodiagonal, perfect. H. = 2·5 to 3; G. = 2·1 to 2·2. Transparent to translucent. Colourless. Does not decompose in the air. Taste alkaline. C.c.: 38 soda, 40 carbonic acid, and 22 water. Fezzan and Barbary (*Trona*), Lagunilla (*Urao*).

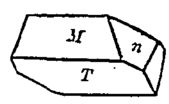

Fig. 383.

292. Gaylussite, $\dot{N}a_2\ddot{C}+\dot{C}a\ddot{C}+5\dot{H}_2$.

Oblique prismatic, C 78° 27′. Cl. ∞P, imperfect; fracture conchoidal. H. = 2·5; G. = 1·9 to 1·95. Transparent; vitreous. Colourless. C.c.: 34·5 carbonate of soda, 33·6 carbonate of lime, 30·4 water, with 1·5 clay. Lagunilla.

293. Hydromagnesite, $\dot{M}g_4\ddot{C}_3+4\dot{H}_2$.

Oblique prismatic. ∞P 88° nearly. Crystals small, rare; also massive. H. = 1·5 to 3; G. = 2·14 to 2·18. Vitreous or silky. White. C.c.: 36·2 carbonic acid, 44 magnesia, and 19·8 water. Unst (Shetland), Moravia, Kumi in Negropont, Hoboken in New Jersey, and Texas in Pennsylvania.

294. Azurite (*Blue Copper*), $\dot{C}u_3\ddot{C}_2+\dot{H}_2$.

Oblique prismatic, C 87° 39′. ∞P (*M*) 99° 32′; − P (*k′*) 106° 14′. Crystals 0P, ∞P, $\infty P^{\circ}\infty$, − P (or *h*, *M*, *s*, *k′*, in fig. 384, but in another position); also radiated and earthy. Cl. clinodomatic (*P*) 59° 14′, rather perfect; fracture conchoidal or splintery. H. = 3·5 to 4·2; G. = 3·7 to 3·8. Translucent or opaque; vitreous. Azure-blue, the earthy varieties (and streak) smalt-blue. B.B. on charcoal fuses and yields a grain of copper; soluble with effervescence in acids, and also in ammonia. C.c.: 69·1 protoxide of copper, 25·7 carbonic acid, and 5·2 water. Crystals at Redruth, Alston Moor, Chessy near Lyons, in Siberia, Moldawa in the Banat, Burra-Burra (Australia). Valued as an ore of copper.

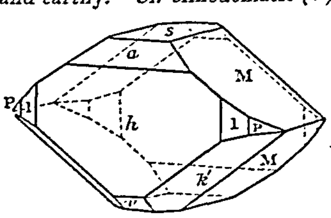

Fig. 384.

295. Malachite, $\dot{C}u_2\ddot{C}+\dot{H}_2$.

Oblique prismatic, C 61° 50′. ∞P 104° 20′. Crystals ∞P (*M*), $\infty P^{\circ}\infty$ (*s*), 0P (*P*), in hemitropes (fig. 385). In general acicular, scaly, or reniform, stalactitic, and radiated fibrous. Cl. basal and clinodiagonal, very perfect. H. = 3·5 to 4; G. = 3·6 to 4. Transparent or translucent on the edges; adamantine, vitreous, silky, or dull. Emerald and other shades of green; streak apple-green. B.B. and with acids like azurite. C.c.: 71·8 copper protoxide (= 57·5 copper), 20 carbonic acid, and 8·2 water. Crystalline at Rheinbreitenbach on the Rhine and Zellerfeld in the Harz; fibrous and compact at Sandlodge in Shetland, Leadhills, Cornwall, Wales, and Ireland, at Chessy in France, Siberia, the Urals, Saalfeld in Thuringia, Moldawa in the Banat, in North America, Africa, and Australia. Frequently pseudomorphous after copper and its ores, also after calcite and cerussite. Valuable ore of copper; the finer varieties are prized for ornamental purposes.

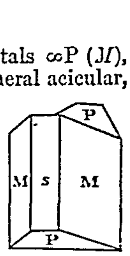

Fig. 385.

296. Hydrozincite, $\dot{Z}n\ddot{C}+2\dot{Z}n\dot{H}_2$.

Massive. C.c.: zinc oxide 75·3, carbonic acid 13·6, water 11·1. Spain, Westphalia, Bavaria, Persia, United States. Valuable ore.

297. Aurichalcite, $2\dot{C}u\ddot{C}+3\dot{Z}n\dot{H}_2$.

Acicular. H. = 2. Translucent, pearly, and verdigris-green. C.c.: 29·2 copper protoxide, 44·7 zinc oxide, 16·2 carbonic acid, and 9·9 water. Leadhills, Matlock, Loktevski in the Altai.

298. Emerald-Nickel (*Zaratite*), $\dot{N}i\ddot{C}+6\dot{H}_2$.

Amorphous, reniform, and incrusting. H. = 3; G. = 2·6 to 2·7. Translucent; vitreous. Emerald-green. C.c.: 59·3 nickel protoxide, 11·7 carbonic acid, and 29 water. On chromite at Hagdale in Unst, Texas in Pennsylvania; also Cape Ortegal in Spain, Tyrol, and Ekaterinburg in the Urals.

299. Lindakerite, $\ddot{U}_2\ddot{C}+2\dot{C}a\ddot{C}+10\dot{H}_2$.

In small siskin-green crystalline aggregates. H. = 2·5 to 3. From Elias mine near Joachimsthal, implanted on pitch-blende.

300. Voglite, $4\ddot{U}\ddot{C}+7\dot{C}a\ddot{C}+3\dot{C}u\ddot{C}+24\dot{H}_2$.

Rhomboidal. Emerald-green scales with pearly lustre. Elias mine, Joachimsthal.

301. Liebigite, $\ddot{U}_2\ddot{C}+\dot{C}a\ddot{C}+20\dot{H}_2$.

Mammillary concretions. H. = 2 to 2·5. Apple-green. Adrianople, Joachimsthal, and Johann-Georgenstadt.

302. Bismuthite, $\dddot{B}i_4\ddot{C}_3+4\dot{H}_2$.

Disseminated, investing or acicular; fracture conchoidal or uneven; very brittle. H. = 4 to 4·5; G. = 6·8 to 6·91. Opaque; dull vitreous. Grey, yellow, or green. C.c.: 90·1 bismuth oxide, 6·4 carbonic acid, and 3·5 water. Ullersreuth (Reuss), Schneeberg, Johann-Georgenstadt; also Chesterfield in South Carolina.

303. Lanthanite, $\dot{L}a\ddot{C}+3\dot{H}_2$.

Right prismatic. ∞P 92° 46′. Small tabular crystals; usually granular or earthy. Cl. basal. H. = 2; G. = 2·7. Dull or pearly. White or yellowish. C.c.: 21 carbonic acid, 55 lanthanum oxide, and 24 water. Bastnaes in Sweden, Lehigh in Pennsylvania.

CARBONATES WITH HALOID SALTS, &c.

304. Phosgenite, $PbCl+\dot{P}b\ddot{C}$.

Pyramidal. P 113° 56′. Crystals short-prismatic or sharp-pyramidal. Cl. ∞P, rather perfect; fracture conchoidal. H. = 2·5 to 3; G. = 6 to 6·2. Transparent or translucent; resinous adamantine. White, yellow, green, or grey. C.c.: 51 chloride and 49 carbonate of lead. Very rare. Stottfield near Elgin in Scotland, Matlock and Cromford in Derbyshire, Tarnowitz.

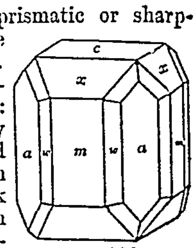

Fig. 386.

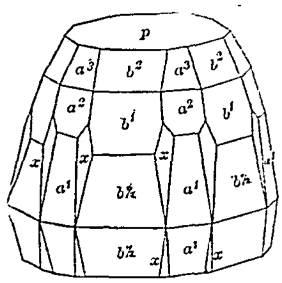

Fig. 387 (sp. 305).

305. Parisite, $3\dot{C}e\ddot{C}+CaF$.

Hexagonal. P 164° 58′. Cl. basal, perfect. H. = 4·5; G. = 4·35. Vitreous; on cleavage-plane pearly. Brownish yellow, inclining to red. C.c.: 23·5 carbonic acid, 42·5 protoxide of cerium, 8·2 lanthanum oxide, 9·6 didymium oxide, 2·8 lime, 10·1 fluoride of calcium, and 2·2 fluoride of cerium. Emerald mines of the Muzo Valley in Colombia, Urals.

306. Leadhillite (*Maxite*), $Pb_{18}C_5S_5O_{51}+5\dot{H}_2$.

Right prismatic. P middle edge 137°; ∞P 120° 20′; $2\breve{P}\infty$ 43° 12′.

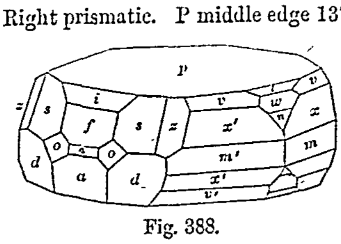

Fig. 388.

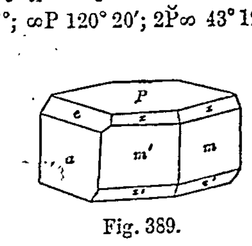

Fig. 389.

Mostly tabular; also twins. Cl. basal, perfect; slightly brittle. H. = 2·5; G. = 6·26 to 6·44. Transparent or translucent; resinous

acid with effervescence. C.c.: sulphate of lead 57·6, oxide of lead 42·4. Leadhills; rare.

HYDROUS SULPHATES.

318. MIRABILITE (*Glauber Salt*), $\dot{N}a_2\dddot{S}+10\dot{H}_2$.

Oblique prismatic, C 72° 15′. Cl. orthodiagonal; fracture conchoidal. H.=1·5 to 2; G.=1·4 to 1·5. Pellucid and colourless. C.c.: 19·2 soda, 24·8 sulphuric acid, and 56 water. As an efflorescence in quarries, on old walls, or on the ground; in the waters of lakes and springs in Russia and Egypt, and on Vesuvius on lava.

319. GYPSUM, $\dot{C}a\dddot{S}+2\dot{H}_2$.

Oblique prismatic, C 80° 57′. The most common forms are ∞P 111° 30′; P 138° 40′; −P 143° 30′; and ∞P∞. Two common combinations are ∞P(*f*), ∞P∞ (*p*), −P (*l*) (fig. 129), and this with P. Lenticular crystals often occur; hemitropes frequent (figs. 161, 150, 151); also granular, compact, fibrous, scaly, or pulverulent. Cl. clinodiagonal perfect, along P much less perfect; sectile; thin plates flexible. H.=1·5 to 2 (lowest on P); G.=2·2 to 2·4. Transparent or translucent; vitreous, on cleavage pearly or silky. Colourless, and snow-white, but often red, grey, yellow, brown, and more rarely greenish or bluish. In the closed tube yields water. B.B. becomes opaque and white; soluble in 400 to 500 parts of water, scarcely more so in acids. C.c.: 46·5 sulphuric acid, 32·6 lime, and 20·9 water.

Transparent crystals, or *Selenite*, occur in the salt-mines of Bex in Switzerland, of the Tyrol, Salzburg, and Bohemia, in the sulphur-mines of Sicily, at Lockport in New York, in porphyry at Gourock, in the clay of Shotover Hill near Oxford, at Chatley near Bath, and many other localities. Fibrous gypsum at Campsie, Matlock in Derbyshire, and at Ilfeld in the Harz. Compact gypsum in whole beds in many parts of England, Germany, France, and Italy, at Volterra in Tuscany (*Alabaster*) often with rock-salt. The finer qualities (or alabaster) are cut into various ornamental articles.

320. KIESERITE, $\dot{M}g\dddot{S}+\dot{H}_2$.

Rhombic, but chiefly massive. G.=2·52. Pellucid; greyish white. C.c.: magnesia 29, sulphuric acid 58, water 13. In beds at Stassfurt.

321. EPSOMITE (*Epsom Salt*), $\dot{M}g\dddot{S}+7\dot{H}_2$.

Right prismatic. P mostly hemihedric; ∞P 90° 38′. ∞P (*M*), ∞P̆∞ (*o*), P (*l*) (fig. 399). Granular, fibrous, or earthy. Cl. brachydiagonal, perfect. H.=2 to 2·5; G.=1·75. Pellucid; vitreous; and white. Taste bitter. C.c.: 16·32 magnesia, 32·53 sulphuric acid, and 51·15 water. Efflorescence on various rocks, as at Hurlet near Paisley, Idria, Montmartre, and Freiberg; on the ground in Spain and the Russian steppes; in mineral waters, as at Epsom in Surrey, Saidschitz and Seidlitz in Bohemia. Used in medicine.

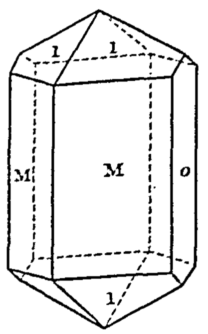

Fig. 399 (sp. 321).

322. GOSLARITE (*White Vitriol*), $\dot{Z}n\dddot{S}+7\dot{H}_2$.

Right prismatic. ∞P 90° 42′; isomorphous with epsomite. ∞P, ∞P̆∞, P (*M*, *o*, *l*) (fig. 399). Mostly granular or stalactitic; reniform and incrusting. Cl. brachydiagonal, perfect. H.=2 to 2·5; G.=2 to 2·1. Pellucid; vitreous. White, inclining to grey, yellow, green, or red. Taste nauseous-astringent. C.c.: 28·2 zinc oxide, 27·9 sulphuric acid, and 43·9 water. Holywell in Flintshire, Cornwall, Rammelsberg near Goslar in the Harz, Falun, Schemnitz. Used in dyeing and medicine.

323. MORENOSITE, $\dot{N}i\dddot{S}+7\dot{H}_2$.

Acicular, fibrous, and as an efflorescence. H.=2 to 2·25; G.=2. Lustre vitreous. Apple-green; streak white. Soluble. Morvern in Argyllshire, Cape Ortegal (Spain), Lake Huron, Pennsylvania.

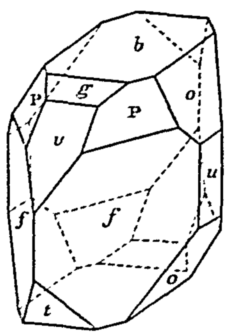

Fig. 400 (sp. 324).

324. MELANTERITE (*Green Vitriol, Copperas*), $\dot{F}e\dddot{S}+7\dot{H}_2$.

Oblique prismatic, C 75° 45′. ∞P (*f*) 82° 22′; −P (P) 101° 34′; P∞ (*o*) 67° 30′ (fig. 400); chiefly stalactitic, reniform, or in crusts. Cl. basal, perfect; prismatic less so. H.=2; G.=1·8 to 1·9. Translucent, rarely transparent; vitreous. Leek- or mountain-green, often with a yellowish coating; streak white. C.c.: 26 protoxide of iron, 29 sulphuric acid, and 45 water. Hurlet near Paisley, Bodenmais, Rammelsberg, Falun, Schemnitz, Bilin. Used in dyeing, and in manufacturing ink, Prussian blue, and sulphuric acid.

325. SMIKITE, $\dot{M}n_2\dddot{S}+\dot{H}_2$.

Stalactitic aggregates. Rose to white. Felsöbanya (Hungary).

326. MALLARDITE, $\dot{M}n\dddot{S}+7\dot{H}_2$.

Crystalline foliated masses; apparently oblique prismatic. Lucky Bay mine in Utah.

327. BIEBERITE (*Cobalt Vitriol*), $\dot{C}o\dddot{S}+7\dot{H}_2$.

Oblique prismatic; usually stalactitic, or an efflorescence. Pale rose-red. C.c.: 20 cobalt oxide, 4 magnesia, 29 sulphuric acid, and 47 water. Bieber near Hanau, and Leogang.

328. ALUNOGENE (*Hair-Salt*), $\dddot{A}l\,3\dddot{S}+18\dot{H}_2$.

Capillary or acicular, in crusts or reniform masses. H.=1·5 to 2; G.=1·6 to 1·7. Silky. White, inclining to green or yellow. C.c.: 36 sulphuric acid, 15·4 alumina, 48·6 water. Volcanoes of South America, in coal and lignite in Germany, and on old walls.

329. ALUMINITE (*Websterite*), $\dddot{A}l\dddot{S}+9\dot{H}$.

Reniform, and very fine scaly, or fibrous. Fracture earthy; sectile or friable. H.=1; G.=1·7. Opaque; dull or glimmering; snow-white or yellowish white. C.c.: 29·8 alumina, 23·2 sulphuric acid, and 47 water. Newhaven in Sussex; Epernay, Auteuil, and Lunel Vieil in France; Halle and Morl in Prussia. *Felsöbanyite*, from Hungary, in rhombic tubes, is similar, but has 10 per cent. of water.

330. COQUIMBITE, $\dddot{F}e\,3\dddot{S}+9\dot{H}_2$.

Hexagonal. P 58°. Crystals 0P; with ∞P and P; usually granular. Cl. ∞P, imperfect. H.=2 to 2·5; G.=2 to 2·1. White, also brown, yellow, red, and blue. C.c.: 28·5 iron peroxide, 42·6 sulphuric acid, and 28·9 water. Copiapo in Chili, and Calama in Bolivia.

331. COPIAPITE, $2\dddot{F}e_2 5\dddot{S}+13\dot{H}_2$.

Six-sided tables, but system uncertain; also granular. Cl. perfect. Translucent; pearly. Yellow. C.c.: 34 iron peroxide, 42 sulphuric acid, and 24 water. Copiapo in Chili. Also radiated-fibrous masses, dirty greenish yellow, incrusting the former, with 32 sulphuric acid and 37 water. Both probably mixtures.

Fibroferrite, also from Chili, and *Yellow Iron Ore*, from the brown coal at Kolosoruk in Bohemia and Modum in Norway, are both reniform, or compact and earthy. H.=2·5 to 3; G.=2·7 to 2·9. Colour ochre-yellow. *Apatelite*, reniform-earthy, yellow, from Auteuil near Paris, is similar; also *Vitriol Ochre* from Falun. *Misy*, from Rammelsberg in the Harz, containing sulphates of iron, copper, zinc, and other metals, is a product of decomposition.

332. PISSOPHANE, $(\dddot{A}l_2\dddot{F}e_2)_2\dddot{S}+15\dot{H}_2$.

Stalactitic; fracture conchoidal; very easily frangible. H.=2; G.=1·9 to 2. Transparent or translucent; vitreous. Olive-green to liver-brown; streak greenish white to pale yellow. C.c.: 7 to 35 alumina, 10 to 40 iron peroxide, 12 sulphuric acid, and 41 water. Saalfeld and Reichenbach in Saxony.

Carphosiderite, reniform, opaque, resinous, and straw-yellow, with a greasy feel, is related. H.=4·5; G.=2·5. Consists of hydrous sulphate of iron. Labrador.

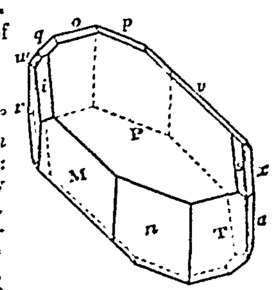

Fig. 401 (sp. 333).

333. CHALCANTHITE, $\dot{C}u\dddot{S}+5\dot{H}_2$.

Anorthic. ∞P̆∞ (*n*) : ∞P̆∞ (*r*) 79° 19′. P′ (*P*) : ∞P′ (*T*) 127° 40′. *P* : *n* 120° 50′. *P* : *r* 103° 27′. ∞P′ (*T*) : ∞′P (*M*) 123° 10′ (fig. 401). Generally incrusting. Cl. *T* and *M*, imperfect. H.=2·5; G.=2·2. Blue. C.c.: 32 protoxide of copper, 32 sulphuric acid, 36 water. Cornwall, Wicklow, Hungary, Tyrol, Falun, and on lava of Vesuvius.

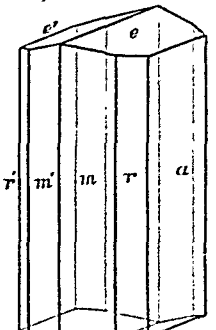

Fig. 402 (sp. 334).

334. BROCHANTITE, $\dot{C}u\dddot{S}+3\dot{C}u\dot{H}_2$.

Right prismatic. ∞P 104° 32′; P̆∞ 152° 37′; and ∞P̆∞; also reniform. Cl. brachydiagonal, perfect. H.=3·5 to 4; G.=3·75 to 3·9. Transparent or translucent; vitreous. Emerald or blackish green; streak bright green. C.c.: 70 copper protoxide, 18 sulphuric acid, and 12 water. Sandlodge (Unst), Roughton Gill in Cumber-

land, Rezbanya, Ekaterinburg; also Krisuvig in Iceland (*Krisuvigite*).

335. LANGITE, $\dot{C}u\dddot{S}+3\dot{C}u\dot{H}_2+2\dot{H}_2$.

Right prismatic. ∞P 123° 44′. Crystals long-tabular, mostly in twins. Also in fibro-lamellar and concretionary crusts, with earthy surface. Cl. basal and brachydiagonal. H. = 2·5; G. = 3·5. Vitreous. Greenish blue. C.c.: 65·1 copper protoxide, 16·4 sulphuric acid, and 18·5 water. Cornwall.

Warringtonite is similar; also *Konigine* from Siberia.

336. JOHANNITE (*Uran-vitriol*).

Oblique prismatic, C 85° 40′. ∞P 69°. Crystals similar to trona (No. 291, fig. 383), but minute; arranged in concretionary and reniform masses. H. = 2 to 2·5; G. = 3·19. Semitransparent; vitreous. Soluble. Taste bitter. Bright grass-green. C.c.: oxides of uranium 67·72, oxide of copper 5·99, sulphuric acid 20·02, water 5·59. Joachimsthal (Bohemia), Johann-Georgenstadt.

337. BLÖDITE (*Astrakanite*), $(\dot{M}g\dot{N}a_2)\dddot{S}+2\dot{H}_2$.

Oblique prismatic, C 100° 43′. $\infty P^{o}2$ 112° 55′; ∞P (*m*), $\infty P^{c}\infty$ (*b*), $\infty P^{o}2$ (*n*), $\infty P^{o}\infty$ (*a*), $-P$ (*p*), $P^{c}\infty$ (*d*), 0P (*c*) (fig. 403). In prismatic crystals, or efflorescent. H. = 3·5; G. = 2·2. Transparent. White or red. C.c.: 47·9 sulphuric acid, 8·5 soda, 12 magnesia, and 21·5 water. Salt lakes on the Volga near Astrakhan, Ischl, Stassfurt, and near Mendoza in South America.

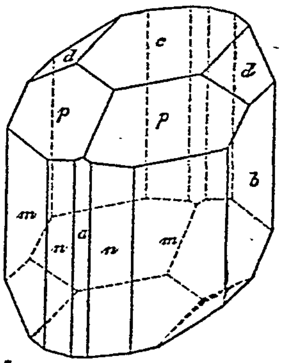

Fig. 403 (sp. 337).

Reussine from Seidlitz is similar, but a mixture.

338. LOWEITE, $2(\dot{N}a_2\dddot{S}+\dot{M}g\dddot{S})+5\dot{H}_2$.

Pyramidal, but only compact. Cl. basal, distinct; also octahedral, with angles 110° 44′ and 105° 2′. H. = 2·5 to 3; G. = 2·376. Vitreous. Yellowish white to flesh-red. C.c.: 20 soda, 13 magnesia, 52 sulphuric acid, and 15 water. Ischl.

339. SYNGENITE, $\dot{K}_2\dddot{S}+\dot{C}a\dddot{S}+\dot{H}_2$.

Oblique prismatic, C 76°. ∞P 73° 55′. Crystals $\infty P^{o}\infty$ (*a*), $\infty P^{c}\infty$ (*b*), 0P (*c*), ∞P (*p*), $\infty P^{o}2$ (*p″*), $\infty P^{o}3$ (*p‴*), $2P^{o}2$ (*c′*), P (*o′*), 2P (*o″*), $P^{c}\infty$ (*q*) $-P^{o}\infty$ (*r*), $P^{o}\infty$ (*r′*), $2P^{o}\infty$ (*r″*), $-\frac{2}{3}P^{o}\infty$ (*ρ*). Cl. ∞P, perfect; fracture conchoidal. H. = 2·5; G. = 2·25. Colourless to milk-white. C.c.: lime 16·88, potash 28·55, sulphuric acid 48·45, water 5·47. Soluble in 400 parts of water. In cavities in halite at Kalusz (Galicia).

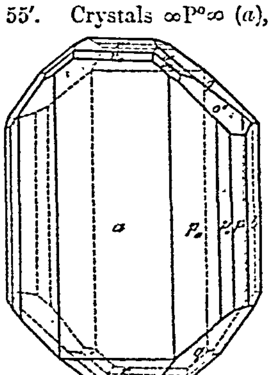

Fig. 404 (sp. 339).

340. POLYHALITE, $2\dot{C}a\dddot{S}+\dot{M}g\dddot{S}+\dot{K}_2\dddot{S}+2\dot{H}_2$.

Right prismatic. ∞P 115°. Mostly fibrous. H. = 3·5; G. = 2·7 to 2·8. Translucent; resinous. Colourless, generally brick-red. C.c.: sulphate of lime 45, of magnesia 20·5, of potash 29, water 5·5. Ischl, Aussee, and Berchtesgaden.

341. ALUM, $\dot{R}\dddot{S}+(\ddot{A}l_2\ddot{F}e_2)\dddot{S}_3+24\dot{H}_2$.

Cubic. O, sometimes with $\infty O\infty$ and $O\infty$. Generally efflorescent in fibrous crusts. Cl. octahedral; fracture conchoidal. H. = 2 to 2·5; G. = 1·75 to 1·9. Translucent. White. Taste sweetish-astringent. Soluble. B.B. evolves sulphurous fumes. (*a*) *Potash Alum*: $\dot{R}O = K_2O$; 33·7 sulphuric acid, 10·9 alumina, 9·9 potash, and 45·5 water. In the coal formation at Hurlet and Campsie in Scotland; the Tertiary brown coals of Hesse and the Rhine; the Lias near Whitby; Silurian alum slates of Scotland, Norway, and Sweden; the volcanic formations of the Lipari Islands, Sicily, and the Azores. (*b*) *Ammonia Alum*: $RO = (NH_4O)_2$; about 4 per cent. oxide of ammonium and 48 water. In closed tube forms a sublimate of sulphate of ammonia. Tschermig in Bohemia. (*c*) *Soda Alum*: $RO = Na_2O$; with 7 of soda and 48 water. Mendoza in South America, Solfatara near Naples, and Milo. (*d*) *Magnesia Alum*: $RO = MgO$. Translucent and silky. South Africa, Iquique in Peru (*Pickeringite*). (*e*) *Iron Alum* (*Feather Alum*): $RO = FeO$. Hurlet near Paisley, Mörsfeld in Bavaria, Krisuvig in Iceland. (*f*) *Manganese Alum*: $RO = MnO$. From Delagoa Bay in South Africa. An alum with 3·7 oxide of zinc occurs at Felsöbanya, and has been termed *Dietrichite*.

342. VOLTAITE, $3(\dot{F}e, \dot{K}_2)\dddot{S}+2(\ddot{F}e_2\ddot{A}l_2)\dddot{S}+12\dot{H}_2$.

Cubic. O; $\infty O\infty$; $O\infty$. Black, brown, or green. H. = 3; G. = 2·79. Solfatara near Naples, Goslar in the Harz, and Kremnitz.

343. ALUNITE, $\dot{K}_2\dddot{S}+3\ddot{A}l_2\dddot{S}+6\dot{H}_2$.

Rhombohedral; R 89° 10′. Crystals R and 0R (fig. 405); also earthy. Cl. basal. H. = 3·5 to 4; G. = 2·6 to 2·8. Translucent; vitreous, pearly on O. Colourless, but often stained. Hungary, Tolfa (near Civita Vecchia), Lipari Islands, Auvergne, and Milo.

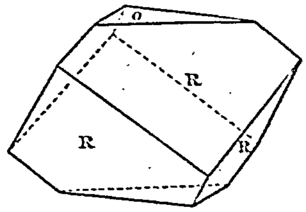

Fig. 405 (sp. 343).

344. JAROSITE, $\dot{K}_2\dddot{S}+\ddot{F}e_2 3\dddot{S}+2(\ddot{F}e_2 3\dot{H}_2)$.

Rhombohedral; R 88° 58′. Cl. basal; also fibrous in nodules or incrusting. H. = 2·5 to 3·5; G. = 3·24. Colour ochre-yellow. Spain, Saxony, and Mexico.

345. GELBEISENERZ, $\dot{K}_2\dddot{S}+4\ddot{F}e_2\dddot{S}+9\dot{H}_2$.

Foliated and massive. H. = 2·5 to 3; G. = 2·7 to 2·9. Bohemia, Norway, and Tcheleken Island in the Caspian Sea.

346. URUSITE, $\ddot{F}e_2\dddot{S}+2\dot{N}a_2 3\dddot{S}+8\dot{H}_2$.

Tcheleken Island in the Caspian.

347. BOTRYOGENE (*Red Vitriol*), $\dot{F}e_3\dddot{S}_2+3(\ddot{F}e_2 2\dddot{S})+36\dot{H}_2$.

Oblique prismatic, C 62° 26′. ∞P 119° 56′. Commonly botryoidal. H. = 2 to 2·5; G. = 2. Translucent; vitreous. Hyacinth-red and orange-yellow. Falun in Sweden.

348. HERRENGRUNDITE.

Oblique prismatic, C 88° 50′. Dark emerald-green crystals. H. = 2·5; G. = 3·13. C.c.: 57·22 oxide of copper, 23·04 sulphuric oxide, 19·44 water, sometimes with lime. Herrengrund (Hungary).

349. LINARITE, $(\dot{P}b\dddot{S}+\dot{H}_2\dot{P}b)+(\dot{C}u\dddot{S}+\dot{H}_2\dot{C}u)$.

Oblique prismatic, C 77° 22′. ∞P (*M*) 61° 41′; $2P^{o}\infty$ (*u*) 52° 31′. Crystals $\infty P^{o}\infty$ (*a*), 0P (*c*), and the above forms generally. Hemitropes united by $\infty P^{o}\infty$ (*a*). Cl. orthodiagonal, perfect; fracture

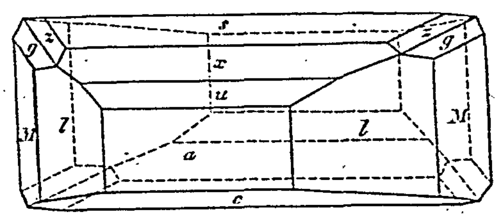

Fig. 406.

conchoidal. H. = 2·5 to 3; G. = 5·2 to 5·45. Translucent; adamantine. Azure-blue to dark blue; streak pale blue. C.c.: oxide of lead 55·69, oxide of copper 19·83, sulphuric acid 19·98, water 4·5. Leadhills, Red Gill and Roughton Gill (Cumberland), Linares in Spain, and Nertchinsk.

350. CALEDONITE, $5\dot{P}b\dddot{S}+2(\dot{H}_2\dot{P}b)+3(\dot{H}_2\dot{C}u)$.

Right prismatic. ∞P (*m*) 95°; $\breve{P}\infty$ (*c*) 70° 57′; $2\bar{P}\infty$ (*x*) 36° 10′. Crystals frequently as in fig. 407, but generally hemihedral. Cl. brachydiagonal, *a* distinct; *m*, *c* imperfect. H. = 2·5 to 3; G. = 6·4. Transparent; resinous. Verdigris-green and mountain-green; streak greenish white. C.c.: 68·42 oxide of lead, 10·17 oxide of copper, 17·3 sulphuric acid, 4·05 water. Leadhills, Red Gill in Cumberland, Rezbanya in Transylvania.

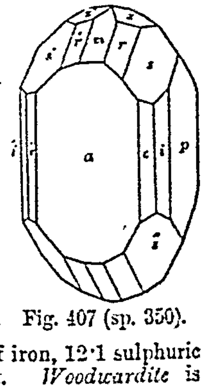

Fig. 407 (sp. 350).

351. LETTSOMITE, $3\dot{C}u_3\dddot{S}+2(\ddot{A}l_2 3\dot{H}_2)+15\dot{H}_2$.

Right prismatic; but in tufts of capillary crystals with velvet-like appearance. Colour smalt-blue to sky-blue. C.c.: 49 oxide of copper, 2·97 lime, 11·21 alumina, 1·41 oxide of iron, 12·1 sulphuric acid, 22·5 water. Moldawa in the Banat. *Woodwardite* is probably an aluminous variety of the above. Turquoise-blue to greenish blue. Cornwall.

352. KAINITE, $\dot{M}g\dddot{S}+KCl+3\dot{H}_2$.

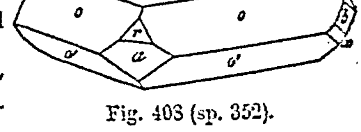

Fig. 408 (sp. 352).

Oblique prismatic, C 85° 5′ (fig. 408). G. = 2·13. Cl. orthodiagonal. White to reddish. C.c.: 16·1 magnesia, 15·7 potash, 32·2 sulphuric acid, 14·3 chlorine, 21·7 water. Stassfurt.

TELLURATES AND CHROMATES.

353. MONTANITE, $\ddot{B}i_2\dddot{T}e + 2\dot{H}_2$.

Incrusting, earthy. Lustre waxy. Yellowish. Opaque. C.c. bismuth 66·8, tellurium 26·8, water 5·9. Highland in Montana.

354. MAGNOLITE, $\dot{H}g\dddot{T}e$.

White acicular crystals from Keystone mine in Colorado.

355. CROCOISITE, $\dot{P}b\dddot{C}r$.

Oblique prismatic, C 77° 27′. ∞P 93° 42′ (*M*), − P 119° 12′ (*t*), ∞P^c^2 (*f*) 56° 10′, ∞P^c^∞ (*g*), (fig. 409). Cl. ∞P, distinct; sectile. H. = 2·5 to 3; G. = 5·9 to 6·1. Translucent; adamantine. Hyacinth- or aurora-red; streak orange-yellow. C.c.: 31 chromic acid, and 69 lead protoxide. Berezoff, Mursinsk, and Nijni-Tagilsk in the Urals, Congonhas do Campo in Brazil, Rezbanya, Moldawa, and Tarnowitz. Used as a pigment, but not permanent.

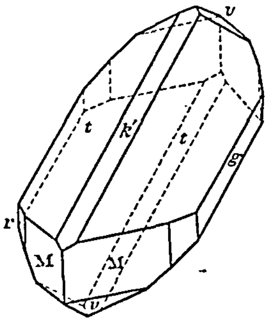

Fig. 409 (sp. 355).

356. PHŒNICO-CHROITE, $2\dot{P}b\dddot{C}r + \dot{P}b$.

Right prismatic; dimensions unknown. H. = 3 to 3·5; G. = 5·75. Translucent on the edges; resinous or adamantine. Cochineal- to hyacinth-red; streak brick-red. C.c.: 23 chromic acid, and 77 protoxide of lead. Berezoff.

357. VAUQUELINITE, $2(2\dot{P}b\dddot{C}r + \dot{P}b) + (2\dot{C}u\dddot{C}r + \dot{C}u)$.

Oblique prismatic, C 67° 15′. Crystals 0P, − P, − P^o^∞ (or *P*, *f*, *h*), always twinned (fig. 410), the faces of 0P forming an angle of 134° 30′; also botryoidal or reniform. H. = 2·5 to 3; G. = 5·5 to 5·8. Semi-translucent or opaque; resinous. Blackish or dark olive-green; streak siskin-green. C.c.: 61 lead protoxide, 11 copper protoxide, 28 chromic acid. Leadhills, Berezoff, Congonhas do Campo (Brazil).

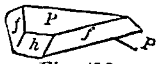

Fig. 410.

MOLYBDATES AND TUNGSTATES.

358. WULFENITE, $\dot{P}b\dddot{M}o$.

Pyramidal. P 131° 48′. 0P (*a*), ⅓P (*b*), P, ∞P (*m*), ∞P2 (*r*) (figs. 411–414). Cl. P; brittle; fracture uneven, or conchoidal. H. = 3; G. = 6·3 to 6·9. Pellucid; resinous to adamantine. Orange-yellow, honey-yellow, and colourless. C.c.: protoxide of lead 61·5, molybdic acid 38·5; red varieties have some chromic acid. Lackentyre in Kirkcudbright (fig. 412), Bleiberg, Rezbanya, Pennsylvania, Zacatecas. $2PbOMoO_3$ + $CaOMoO_3$, with 6·88 of lime, occurs in Chili.

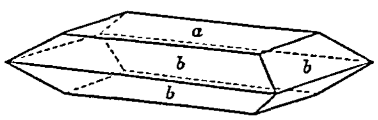

Fig. 411.

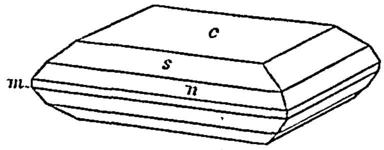

Fig. 412.

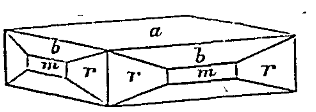

Fig. 413 (sp. 358).

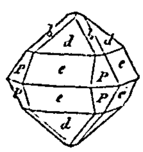

Fig. 414 (sp. 358).

359. EOSITE.

Pyramidal. 0P (*c*) : *p′* 117° 10′; *p′* : *p* 125° 40′ (fig. 415). H. = 3 to 4. Colour deep aurora-red. Streak orange-yellow. A vanadio-molybdate of lead. Leadhills.

360. MEGABASITE, $\dot{M}g_4\dddot{W}_3$.

Oblique prismatic; similar to wolframite. In fine needles. H. = 3·5 to 4; G. = 6·45 to 6·97. Vitreous to adamantine. Yellowish brown to brownish red, translucent hyacinth-red; streak ochre-yellow. C.c.: protoxide of manganese 23·1, protoxide of iron 5·4, tungstic acid 71·5. Schlaggenwald, Sadisdorf, Morococha in Peru.

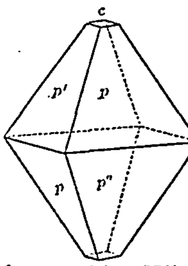

Fig. 415 (sp. 359).

361. SCHEELITE, $\dot{C}a\dddot{W}$.

Pyramidal; with many of the modifying planes hemihedric. P. 113° 32′. Cl. 2P∞ (*n*) 130° 33′, perfect; P and 0P less so. Fracture conchoidal. H. = 4 to 4·5; G. = 5·9 to 6·2. Translucent; resinous to adamantine. Colourless, and grey, yellow, or brown; streak white. C.c.: 19·4 lime, 80·6 tungstic acid. Caldbeckfell near Keswick, Pengelly in Cornwall, Zinnwald, Schlaggenwald, Salzburg, Chili, Siberia, Connecticut. Employed for the extraction of yellow tungstic acid, a fine pigment.

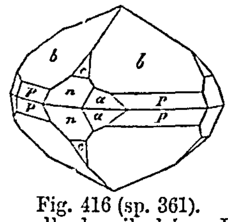

Fig. 416 (sp. 361).

362. STOLZITE, $\dot{P}b\dddot{W}$.

Pyramidal, generally hemihedric. P. 131° 25′. Crystals sometimes spindle-shaped. Cl. P, imperfect. H. = 3; G. = 7·9 to 8·1. Translucent; resinous. Grey, yellow, brown. C.c.: 48·4 protoxide of lead, 51·6 tungstic acid. Keswick, Zinnwald, Coquimbo (Brazil).

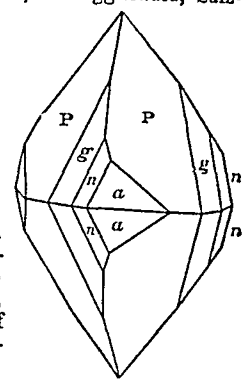

Fig. 417 (sp. 361).

363. REINITE, $\dot{F}e\dddot{W}$.

Pyramidal. P 103° 32′; basal angle 122° 8′. Cl. ∞P. H. = 4; G. = 6·64. C.c.: protoxide of iron 23·4, tungstic acid 75·45. Kimbosan in Japan.

364. WOLFRAMITE, $(\dot{F}e, \dot{M}n)\dddot{W}$.

Oblique prismatic, C 89° 22′. ∞P (*M*) 100° 37′, − ½P^o^∞ (*P*) 61° 54′, P^c^∞ (*u*) 98° 6′, ∞P∞ (*r*), ∞P^o^2 (*b*), − P (*a*), ½2P^c^2(*s*). Twins common. Also laminar. Cl. clinodiagonal, perfect; fracture uneven. H. = 5 to 5·5; G. = 7·1 to 7·5. Opaque; resinous, metallic, adamantine on the cleavage. Brownish black; streak black (varieties with most iron) to reddish brown (most manganese). C.c.: 76 tungstic acid, 9·5 to 20 protoxide of iron, and 4 to 15 protoxide of manganese, in some with 1·1 niobic acid. East Pool, Carnbrae, and mines near Redruth; Godolphin's Ball in Cumberland; Altenberg, Geyer, Ehrenfriedersdorf, Schlaggenwald, Zinnwald, the Harz; also Urals, Ceylon, and North America. *Ferberite*, with 26 protoxide of iron and $2\dot{F}e\dddot{W} + \dot{F}e$ (H. = 4 to 4·5; G. = 6·7 to 6·8), from Spain, may be different.

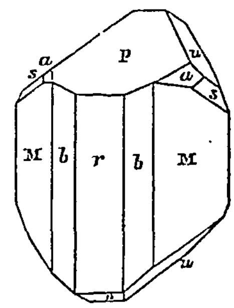

Fig. 418.

365. HÜBNERITE, $\dot{M}n\dddot{W}$.

Right prismatic. ∞P (*M*). *M* : *M* 105°. Cl. ∞P̆∞, perfect; usually foliated or columnar. H. = 4·5; G. = 7·14. Adamantine on cleavage; elsewhere greasy. Brown-red; streak yellow-brown. C.c.: protoxide of manganese 23·4, tungstic acid 76·6. Mammoth district in Nevada.

ANHYDROUS PHOSPHATES, ARSENIATES, AND VANADIATES.

366. XENOTIME, $\dot{Y}_3\dddot{\dot{P}}$.

Pyramidal. P 82° 22′ middle angle; polar angle 124° 30′. Crystals P; ∞P; ∞P∞. Cl. ∞P. H. = 4·5; G. = 4·6 to 4·55. Translucent in thin splinters; resinous. Yellowish and flesh-red. C.c.: 62 yttria, and 38 phosphoric acid; but some with 8 to 11 cerium protoxide. Lindesnaes and Hitterö in Norway, Ytterby (Sweden), Georgia, and (*Wiserine*) St Gotthard.

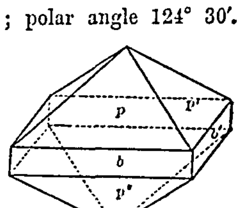

Fig. 419 (sp. 366).

367. CRYPTOLITE, $\dot{C}e_3\dddot{\dot{P}}_2$.

Acicular crystals, embedded in apatite. G. = 4·6. Transparent. Pale wine-yellow. Powder sol. in con. s. acid. Wöhler found 73·70 cerium protoxide, 27·37 phosphoric acid, and 1·51 iron protoxide. Occurs in the apatites of granite in Scotland, but not in those of limestones. Also at Arendal.

368. MONAZITE, $(\dot{C}e, \dot{L}a, \ddot{T}h)_3\dddot{\dot{P}}_2$.

Oblique prismatic, C 76° 14′. ∞P 93° 23′; crystals (fig. 420) generally thick or tabular. Cl. basal, perfect; translucent on edges. Flesh-red and reddish brown. C.c.: 28 phosphoric acid, 37 to 46 cerium protoxide, 24 to 27 lanthanum oxide; that from Zlatoust from 18 to 32·5 of thoria. Nöterö in Norway, Miask, Norwich in Connecticut, and the Rio Chico in Colombia. *Turnerite*, from Dauphiné, in complex transparent honey-yellow crystals, is monazite.

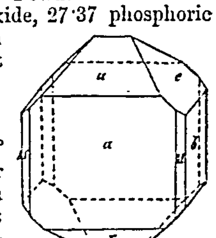

Fig. 420 (sp. 368).

369. TRIPHYLITE, $(2\dot{F}e+\dot{L}i_2)\dddot{P}_2$.
Right prismatic. ∞P 133°; chiefly granular. H. = 5; G. = 3·6. Resinous. Greenish grey with blue spots. C.c.: iron protoxide 40, manganese protoxide 5·5, lithia 7·5, phosphoric acid 45. Bodenmais in Bavaria, Norwich in Massachusetts. *Lithiophilite*, from Fairfield (Connecticut), is a manganesian triphylite.

370. BERZELIITE (*Kuhnite*), $(\dot{C}a\dot{M}g)_3\dddot{A}s_2$.
Massive. H. = 5 to 6; G. = 2·52. C.c.: lime 23, magnesia 15, arsenic acid 60. Sol. in n. acid. Långban (Sweden).

371. ARSENIATE OF NICKEL, $\dot{N}i_3\dddot{A}s_2$.
Amorphous. H. = 4; G. = 4·98. Sulphur-yellow. C.c.: oxide of nickel 48·2, arsenic acid 50·5. Johann-Georgenstadt.

372. NICKELERZ, $\dot{N}i_3\dddot{A}s_2+2\dot{N}i$.
Crystalline massive. G. = 4·84. Dark grass-green; streak lighter. C.c.: oxide of nickel 62·1, arsenic acid 36·6. Johann-Georgenstadt.

373. DECHENITE, $(\dot{P}b\dot{Z}n)\dddot{V}_2$.
Botryoidal and stalactitic. H. = 3 to 4; G. = 5·82. Lustre resinous to greasy. Yellowish red, deep red; streak orange to pale yellow. C.c.: 57·7 oxide of lead, 15·8 oxide of zinc, 24·2 of vanadic acid. Wanlockhead, Freiburg (in Baden), Lauter Valley.

374. PSITTACINITE, $3(\dot{P}b_3\dddot{V}_2)+\dot{C}u_3\dddot{V}_2+6\dot{C}u\dot{H}_2$.
Mammillated and incrusting. Siskin- to olive-green. C.c.: vanadic acid 19·3, lead oxide 53·2, copper oxide 18·95, water 8·58. Silver Star (Montana).

375. PUCHERITE, $\dddot{B}i_2\dddot{V}_2$.
Right prismatic. ∞P 123° 55′. H. = 4; G. = 6·25. Cl. basal, perfect; vitreous. Red or reddish brown; streak yellow. Easily soluble in acids. C.c.: bismuth oxide 71·7, vanadic acid 28·3. Schneeberg.

376. ATOPITE, $\dot{C}a_3\dddot{S}b_2$.
Cubic (figs. 30 with 26 and 33). H. = 5·5 to 6; G. = 5. Lustre greasy; yellow to resin-brown. Translucent. C.c.: antimonic acid 73·2, lime 17·5, iron protoxide 2·7, magnesia 1·5, soda 4·3. Långban (Wermland).

HYDROUS PHOSPHATES, &c.

377. BRUSHITE, $(\frac{2}{3}\dot{C}a+\frac{1}{3}\dot{H}_2)_3\dddot{P}_2+4\dot{H}_2$.
Oblique prismatic, C 62° 45′. Needle crystals. H. = 2 to 2·5; G. = 2·21. Vitreous. C.c.: lime 32·6, phosphoric acid 41·3, water 26·4. Aves Islands and Sombrero (Antilles).

378. NEWBERYITE, $\dot{M}g_2\dot{H}_2,\ \dddot{P}_2+6\dot{H}_2$.
Right prismatic. Cl. brachydiagonal. C.c.: phosphoric acid 41·25, magnesia 23, water 35·7. From guano, Skipton Caves, Victoria.

379. HAIDINGERITE. $\dot{C}a_2\dddot{A}s_2+3\dot{H}_2$.
Right prismatic. ∞P 100°. Cl. perfect; sectile, flexible. H. = 2 to 2·5; G. = 2·8 to 2·9. Otherwise like pharmacolite (sp. 381). C.c.: 85·68 arseniate of lime, and 14·32 water. Joachimsthal.

380. ROSELITE, $\dot{R}_3\dddot{A}s_2+2\dot{H}_2$.
Anorthic. Cl. macrodiagonal. Rose-red; streak white. H. = 3·5; G. = 3·46. C.c.: 25·5 lime, 10·3 cobalt oxide, 3·6 magnesia, 52·4 arsenic acid, 8·2 water. Schneeberg.

381. PHARMACOLITE, $2\dot{C}a\dddot{A}s_2+6\dot{H}_2$.
Oblique prismatic, C 65° 4′ (fig. 421). ∞P (f) 117° 24′, $-P$ (l) 139° 17′, $-\frac{1}{2}P$ (n) 141° 8′, $\frac{1}{2}P^o\infty$ (o) 83° 14′, ∞P^o3 (g) 157° 5′. Crystals generally acicular and radiated. Cl. clinodiagonal, perfect; sectile and flexible. H. = 2 to 2·5; G. = 2·6 to 2·8. Translucent; vitreous. Pearly white. Yields water in the closed tube. C.c.: arsenic acid 51, lime 25, water 24. Andreasberg, Bieber, Markirchen, Wittichen. Generally mixed with erythrite or annabergite.

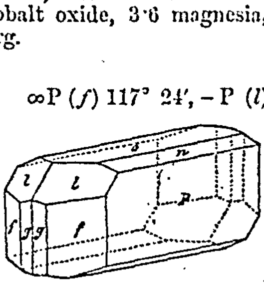

Fig. 421.

382. WAPPLERITE, $2\dot{C}a\dddot{A}s+8\dot{H}_2$.
Anorthic; $\infty P'$ (m), $\infty'P$ (M), $\infty\bar{P}'2$ (n), $\infty'\bar{P}.2$ (N), $,\bar{P}'\infty$ (d), $'P,\infty$ (D), $3,\breve{P}'\infty$ (t), $3'\breve{P},\infty$ (T), $2\bar{P}'2$ (p), $3\breve{P}'\frac{3}{2}$ (g), $3'\breve{P}\frac{3}{2}$ (G), $4,\bar{P}4$ (ω), $2,\bar{P}2$ (π), $\infty\breve{P}\infty$ (b) (fig. 422); also incrusting and globular. Cl. clinodiagonal. H. = 2 to 2·5; G. = 2·48. Colourless. Vitreous. C.c.: lime 15·6, magnesia 7·4, arsenic acid 47·5, water 29·5. Joachimsthal.

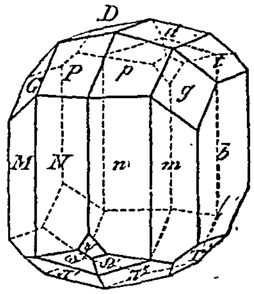

Fig. 422 (sp. 382).

383. HÖRNESITE, $\dot{M}g_3\dddot{A}s_2+8\dot{H}_2$.
Oblique prismatic. ∞P 107°. H. = 5 to 1; G. = 2·47. White. Translucent; pearly. C.c.: 24·3 magnesia, 29·14 water, 46·56 arsenic acid. Probably from Hungary.

384. VIVIANITE, $3\dot{F}e\dddot{P}_2+8\dot{H}_2$.
Oblique prismatic, C 75° 34′. ∞P (m) 108° 2′; P (v) 120° 26′, $P^o\infty$ (w) 54° 40′. Crystals prismatic (figs. 423, 424); also fibrous or earthy. Cl. clinodiagonal, perfect; thin laminæ flexible. H. = 2; G. = 2·6 to 2·7. Translucent or transparent; vitreous, or bright pearly on cleavage. Indigo-blue to blackish green; streak bluish white, but soon becomes blue on exposure. C.c.: 33·1 iron protoxide, 12·2 iron peroxide, 29 phosphoric acid, and 25·7 water. Transparent indigo-coloured crystals at St Agnes in Cornwall, and Allentown and Imleytown in New Jersey; earthy in Cornwall, Styria, North America, Greenland, and New Zealand; and in peat mosses in northern Germany, Sweden, Norway, and Shetland.

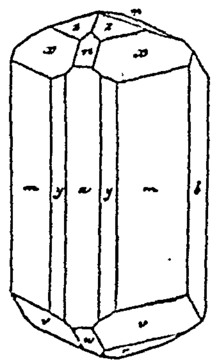

Fig. 423.

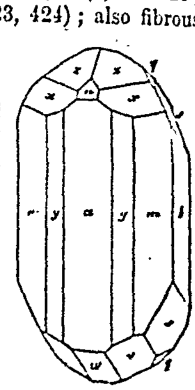

Fig. 424.

385. SYMPLESITE, $\dot{F}e_3\dddot{A}s_2+8\dot{H}_2$.
Oblique prismatic; in minute acicular crystals. Cl. clinodiagonal. H. = 2·5; G. = 2·96. Vitreous. Cleavage face pearly. Celadon-green to pale indigo; streak bluish white. Lobenstein in Reuss, and Lölling in Carinthia.

386. ERYTHRITE, $\dot{C}o_3\dddot{A}s_2+8\dot{H}_2$.
Oblique prismatic, C 55° 9′. $\infty P^c\infty$ (P), $\infty P^o\infty$ (T), $P\infty$ (M); also $\infty P3$ (k), and P (l) 118° 23′ (fig. 425). Cl. clinodiagonal (P), perfect; sectile; thin laminæ flexible. H. = 1·5 to 2·5; G. = 2·9 to 3. Translucent; vitreous, pearly on the cleavage. Crimson or peachblossom-red. C.c.: 38·2 arsenic acid, 37·8 cobalt protoxide, 24 water, but often with nickel 9. Cornwall, Alston in Cumberland, Alva in Stirlingshire, Schneeberg, Saalfeld, Allemont, Riechelsdorf, the Pyrenees, and Modum in Norway. *Kobaltbeschlag* or *Earthy Incrusting Cobalt*, reniform, is a mixture of erythrine with arsenious acid. *Lavendulan*, thin reniform lavender-blue crusts, translucent, resinous, or vitreous (H. = 2·5 to 3; G. = 2·95 to 3·1), consisting of arsenic acid, protoxides of cobalt, nickel, and copper, with water; from Annaberg.

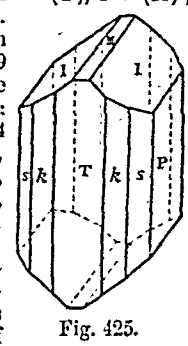

Fig. 425.

387. KÖTTIGITE, $(\dot{Z}n,\ \dot{C}o,\ \dot{N}i)_3\dddot{A}s_2+8\dot{H}_2$.
Oblique prismatic; massive or in crusts, with crystalline surface and fibrous structure. Cl. clinodiagonal, perfect. H. = 2·5 to 3; G. = 3·1. Lustre of fracture silky. Colour light carmine and peach-blossom-red, of different shades; streak reddish white. Translucent to subtranslucent. C.c.: 30·52 zinc oxide, 6·91 cobalt oxide, 2 nickel oxide, with arsenic acid. Schneeberg.

388. ANNABERGITE (*Nickel Ochre*), $\dot{N}i_3\dddot{A}s+8\dot{H}_2$.
Oblique prismatic; in capillary crystals, also earthy; sectile. H. = 2 to 2·5; G. = 3 to 3·1. Dull or glistening. Apple-green or greenish white; streak greenish white and shining. C.c.: 38·7 arsenic acid, 37·3 nickel protoxide, and 24 water, but with a little cobalt or iron. Leadhills, Pibble in Kirkcudbright, Andreasberg, Saalfeld, Riechelsdorf.

389. LUDLAMITE, $\dot{F}e_7 2\dddot{P}_2+9\dot{H}_2$.
Oblique prismatic, C 79° 27′. ∞P 131° 23′; 0P; P 111° 29′ (fig. 426). Cl. 0P, perfect. H. = 3·5; G. = 3·12. C.c.: 53·05 oxide of iron, 29·88 phosphoric acid, 17·0 water. Cornwall.

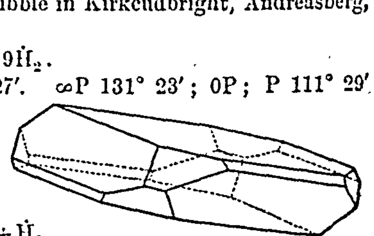

Fig. 426 (sp. 389).

390. FILLOWITE, $3(\dot{R}_3\dddot{P}_2)+\dot{H}_2$.
Oblique prismatic, C 89° 51′; pseudo-rhombohedral. P; $-2\bar{P}8$; 0P. Cl. basal. H. = 4·5; G. = 3·43. Resinous to greasy. Wax-yellow to red-brown, or colourless; streak white; translucent. C.c.: phosphoric acid 40·2, iron protoxide 6·8, manganese protoxide 40·2, lime 5·2, soda 5·8, water 1·7. Branchville (Connecticut).

391. HUREAULITE, $5(\dot{M}n,\ \dot{F}e)2\dddot{P}_2+5\dot{H}_2$.
Oblique prismatic, C 89° 27′. ∞P 61°. Fracture conchoidal. H. = 3·5; G. = 3·2. Translucent; resinous. Reddish yellow or brown. B.B. fuses easily to a black metallic globule. Soluble in acids. C.c.: 39 phosphoric acid, 8 iron protoxide, 42 manganese protoxide, and 12 water. Hureaux near Limoges.

Heterozite. H. = 5; G. = 3·5. Opaque; vitreous or resinous. Dark violet or blue to greenish grey; streak violet-blue or crimson-red. Contains more iron and less manganese than the above. Hureaux.

392. DICKINSONITE, $4(\dot{R}_3\dddot{\bar{P}}_2)+3\dot{H}_2$.
Oblique prismatic, C 60° 30′. Crystals tabular. Cl. basal, perfect. H. = 3·5 to 4; G. = 3·34. Vitreous; pearly on cleavage. Olive- to oil-green, and grass-green; streak white. Transparent; brittle. C.c.: phosphoric acid 40, iron protoxide 12·7, manganese protoxide 25, lime 11·8, soda 6·6, water 3·8. Branchville (Connecticut).

393. TRIPLOIDITE, $(\dot{M}n, \dot{F}e)_3\dddot{\bar{P}}_2+\dot{H}_2(\dot{M}n, \dot{F}e)_2$.
Oblique prismatic, C 51° 56′. Generally fibrous; transparent; resinous to adamantine. H. = 4·5 to 5; G. = 3·7. Yellowish-brown. C.c.: 48·45 oxide of manganese, 14·88 protoxide of iron, 32·1 phosphoric acid, 4·1 water. Fairfield (Connecticut).

394. FAIRFIELDITE, $\dot{R}_3\dddot{\bar{P}}_2+2\dot{H}_2$.
Anorthic; usually foliaceous. H. = 3·5; G. = 3·15. White to straw-yellow; streak white. Pearly to brilliant-adamantine on cleavage. Transparent; brittle. C.c.: phosphoric acid 38·4, iron protoxide 5·6, manganese protoxide 15·6, lime 30, soda ·7, water 10. Fairfield (Connecticut).

395. CHONDRARSENITE, $\dot{M}n_5\dddot{\bar{A}}s_2+\frac{5}{2}\dot{H}_2$.
In small grains. H. = 3. Yellow to reddish-yellow. Translucent; brittle; fracture conchoidal. Paisberg mines (Wermland).

396. REDDINGITE, $\dot{M}n_3\dddot{\bar{P}}_2+3\dot{H}_2$.
Right prismatic. P; $\breve{P}2$; $\infty\breve{P}\infty$. H. = 3 to 3·5; G. = 3·1. Vitreous; rose-pink to yellowish white. Translucent; fracture uneven; brittle. C.c.: phosphoric acid 34·5, iron protoxide 5·43, manganese protoxide 46·3, lime ·8, water 13·1. Branchville.

397. SCORODITE, $\ddot{\bar{F}}e_2\dddot{\bar{A}}s_2+4\dot{H}_2$.
Right prismatic. P with polar edges 102° 52′ and 114° 40′. Crystals P (*p*), $\infty\bar{P}\infty$ (*a*), and $\infty\breve{P}\infty$ (*b*); also 0P, $\frac{1}{2}$P (*i*), ∞P (*n*), $2\breve{P}2$ (*s*), $\infty\breve{P}2$ (*d*) 120° 10′, and $2\bar{P}\infty$ (*m*) 132° (fig. 427); also columnar and fibrous. Cl. imperfect; brittle. H. = 3·5 to 4; G. = 3·1 to 3·2. Translucent; vitreous. Leek-green to greenish black, also indigo-blue, red, and brown. B.B. fuses easily, with arsenical odour, to a grey magnetic slag. Sol. in h. acid, to a brown solution. C.c.: 49·8 arsenic acid, 34·6 iron peroxide, and 15·6 water. St Austell in Cornwall, near Limoges in France, Schwarzenberg, Lölling in Carinthia, Brazil, and Siberia.

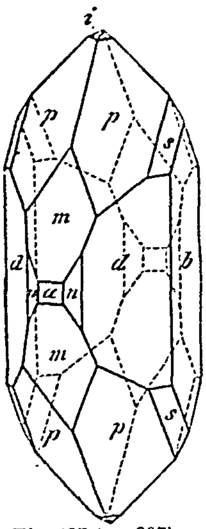

Fig. 427 (sp. 397).

398. STRENGITE, $\ddot{\bar{F}}e_2\dddot{\bar{P}}_2+4\dot{H}_2$.
Right prismatic. P with polar edges 101° 38′ and 115° 36′, middle edge 111° 30′. $\infty\breve{P}2$ (*d*) and $\infty\bar{P}\infty$ (*r*), P (*P*), 0P (*h*), $2\bar{P}\infty$ (*m*) 48° (fig. 428). Crystals generally *r*, *P*, *d*; *r* dominant. Cl. *r*. H. = 3 to 4; G. = 2·87. Cherry-red. Translucent. C.c.: protoxide of iron 43·18, phosphoric acid 37·42, water 19·4. Rock Bridge (Virginia).

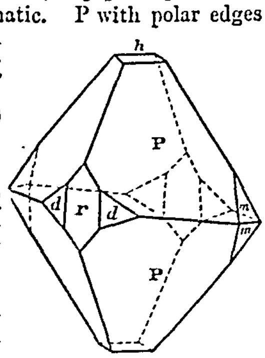

Fig. 428 (sp. 398).

399. DUFRENITE (*Kraurite*), $2\ddot{\bar{F}}e_2\dddot{\bar{P}}_2+3\dot{H}_2$.
Right prismatic. ∞P about 123°. Spherical or reniform. Cl. brachydiagonal; brittle. H. = 3 to 3·5; G. = 3·3 to 3·4. Translucent on the edges, or opaque; shining or dull. Dirty leek-green or blackish green; streak siskin-green. C.c.: 63 iron peroxide, 28 phosphoric acid, and 9 water. Westerwald, Hirschberg, and Limoges.

400 BERAUNITE, $5\ddot{\bar{F}}e_23\dddot{\bar{P}}_2+14\dot{H}_2$.
Occurs in small foliated and columnar aggregates. Cl. plane metallic pearly. H. = 2; G. = 2·878. Colour hyacinth-red to reddish brown; streak dirty-yellow. C.c.: 54·5 peroxide of iron, 28·65 phosphoric acid, and 16·55 water. Bohemia, Scheibenberg in Saxony.

401. ELEONORITE, $3\ddot{\bar{F}}e_22\dddot{\bar{P}}_2+8\dot{H}_2$.
Oblique prismatic, C 48° 33′. Twin face the orthopinacoid. Cl. $\infty P°\infty$. H. = 3 to 4. Dark hyacinth-red; streak yellow. Vitreous to pearly. C.c.: 51·94 peroxide of iron, 31·88 phosphoric acid, 16·37 water. Eleonore mine near Bieber.

402. CACOXENE, $2\ddot{\bar{F}}e_2\dddot{\bar{P}}_2+12\dot{H}_2$.
Radiated tufts, of a brownish-yellow colour. H. = 3 to 4; G. = 3·38. Sol. in h. acid. From the Hrbeck mine near Zbirow in Bohemia.

403. PHARMACOSIDERITE (*Cube Ore*), $4\ddot{\bar{F}}e_23\dddot{\bar{A}}s_2+15\dot{H}_2$.
Cubic and tetrahedral; usually $\infty O\infty$, with $\frac{O}{2}$, or ∞O. Brittle. H. = 2·5; G. = 2·9 to 3. Cl. $\infty O\infty$. Semitransparent to translucent; adamantine or resinous. Olive- to emerald-green, honey-yellow, and brown; streak straw-yellow. Pyro-electric. C.c.: 43 arsenic acid, 40 iron peroxide, and 17 water. Carharrack in Cornwall, Burdle Gill in Cumberland, Lobenstein in Reuss, Schwarzenberg in Saxony, North America, and the gold quartz of Australia.

404. CALAITE (*Turquoise*), $2(\ddot{\bar{A}}l_2)\dddot{\bar{P}}_2+5\dot{H}_2$.
Massive, reniform, or stalactitic; fracture conchoidal. H. = 6; G. = 2·6 to 2·8. Opaque or translucent on the edges; dull or waxy. Sky-blue, greenish blue, rarely green; streak greenish white. C.c.: 47 alumina, 32·5 phosphoric acid, and 20·5 water, but mixed with phosphate of iron and copper. Silesia, Lusatia, and Reuss. Oriental turquoise, in veins, at Meshed, near Herat; in pebbles in Khorasan, Bokhara, and Syrian desert. Takes a fine polish, and is valued as an ornamental stone, but is destroyed by oil, and deteriorated by soap.

405. WAVELLITE (*Lasionite*), $3\ddot{\bar{A}}l_22\dddot{\bar{P}}_2+12\dot{H}_2$.
Right prismatic. ∞P 126° 25; $\bar{P}\infty$ 106° 46′. Crystals $\infty P\infty$ (*P*), ∞P (*d*), $\bar{P}\infty$ (*o*) (fig. 429); but generally small, acicular, and in radiated-hemispherical and stellate-fibrous masses. Cl. along ∞P and $\bar{P}\infty$, perfect. H. = 3·5 to 4; G. = 2·3 to 2·5. Translucent; vitreous. Colourless, but generally yellowish or greyish, sometimes green or blue. C.c.: 38 alumina, 35·3 phosphoric acid, and 26·7 water; but generally traces of fluoric acid (2 per cent.). Shiant Islands and Glencoe in Scotland, Barnstaple, St Austell, near Clonmel and Portrush, Beraun in Bohemia, Amberg in Bavaria; also in New Hampshire and Tennessee. *Cæruleolactin*, from Nassau, has two equivalents less of water.

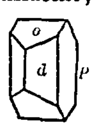

Fig. 429.

406. VARISCITE, $\ddot{\bar{A}}l_2\dddot{\bar{P}}_2+4\dot{H}_2$.
Right prismatic; reniform; conchoidal fracture. H. = 4 to 5; G. = 2·34 to 2·38. Apple- and emerald-green; streak white. C.c.: 32·4 alumina, 44·85 phosphoric acid, 22·74 water. Messbach in Reuss, Montgomery county in Arkansas.
Zepharovichite from Bohemia contains one equivalent more water; *Evansite* from Hungary two equivalents more.

407. FISCHERITE, $2\ddot{\bar{A}}l_2\dddot{\bar{P}}_2+8\dot{H}_2$.
Right prismatic. ∞P 118° 32′; generally in crystalline crusts. H. = 5; G. = 2·46. Grass- and olive-green. Vitreous lustre. C.c.: alumina 42, phosphoric acid 29, water 29. Nijni-Tagilsk.

408. PEGANITE, $2\ddot{\bar{A}}l_2\dddot{\bar{P}}_2+6\dot{H}_2$.
Right prismatic. ∞P 127°. In thin reniform crusts, of fibrous structure. H. = 3 to 4; G. = 2·49 to 2·54. Grass- and emerald-green. Vitreous or greasy lustre. C.c.: alumina 45, phosphoric acid 31·3, water 23·7. Striegis in Saxony.

409. HOPEITE, $\dot{Z}n_3\dddot{\bar{P}}+4\dot{H}_2$.
Right prismatic. $\infty\breve{P}2$ 82° 20′; P with polar edges 106° 36′ and 140°. Cl. macrodiagonal, perfect. H. = 2·5 to 3; G. = 2·76 to 2·85. Vitreous or pearly. Greyish white. C.c.: oxide of zinc 35·21, phosphoric acid 31·1, water 15·8. Altenberg.

410. ADAMITE, $4\dot{Z}n\dddot{\bar{A}}s_2+\dot{H}_2$.
Right prismatic. ∞P 91° 52′. Cl. macrodomic. H. = 3·5; G. = 4·34. Lustre vitreous. Colour honey-yellow to violet; streak white. Transparent. C.c.: oxide of zinc 56·6, arsenic acid 40·2, water 3·2. Cape Garonne in France, Chañarcillo in Chili.

411. LIBETHENITE $4\dot{C}u\dddot{\bar{P}}_2+6\dot{H}_2$.
Right prismatic. ∞P (*u*) 92° 20′, $\breve{P}\infty$ (*o*) 109° 52′, and P (fig. 430). H. = 4; G. = 3·6 to 3·8. Translucent on the edges; resinous. Leek-, olive-, or blackish-green; streak olive-green. C.c.: 66 copper protoxide, 30 phosphoric acid, and 4 water. Gunnislake (Devon), Libethen (Hungary), Nijni-Tagilsk.

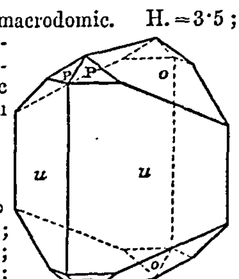

Fig. 430 (sp. 411).

412. Olivenite, $4\dot{C}u\,(\dddot{A}s_2\dddot{P}_2)+\dot{H}_2$.

Right prismatic. $\infty(P)$ (*r*) 92° 30′, $\breve{P}\infty$ (*l*) 110° 50′, $\infty\bar{P}\infty$ (*n*) (fig. 431); also spherical and reniform, and columnar or fibrous. Cl. (*r*) and (*l*), imperfect. H. = 3; G. = 4·1 to 4·6. Pellucid in all degrees; vitreous, resinous, or silky. Leek-, olive-, or blackish-green, also yellow or brown; streak olive-green or brown. B.B. in the forceps fuses easily to a dark brown adamantine bead, covered with radiating crystals; on charcoal detonates, emits arsenical vapours, and is reduced. Sol. in acids and ammonia. C.c.: 56·5 copper protoxide, 39·5 arsenic acid, and 4 water; but also 1 to 6 phosphoric acid. Carharrack, Tin Croft, Gwennap, and St Day in Cornwall; Alston Moor, Thuringia, Tyrol, Siberia, Chili.

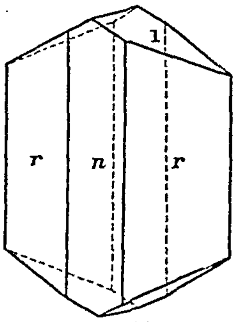

Fig. 431.

413. Veszelyite, $9\dot{C}u$, $6\dot{Z}n$, $\dddot{P}_2$, $\dddot{A}s_2+18\dot{H}_2$.

Oblique prismatic, C 103° 50′. H. = 3·5 to 4; G. = 3·53. Greenish blue. C.c.: copper 37·34, 25·20 zinc oxide, 10·41 arsenic acid, 9·01 phosphoric acid, 17·05 water. Moravicza (Banat).

414. Descloizite, $2\dot{P}b\dddot{V}_2+\dot{H}_2$.

Right prismatic. ∞P 116° 25′. H. = 3·5; G. = 5·86 to 6·1. Olive-brown to black. C.c.: 56·48 oxide of lead, 16·6 oxide of zinc, 1·16 oxide of manganese, 22·74 vanadic acid. Sierra de Cordoba in the Argentine Republic.

415. Volborthite, $4(\dot{C}u,\ \dot{C}a)\ \dddot{V}_2+\dot{H}_2$.

Hexagonal; small tabular crystals, 0P, ∞P, single or in groups. Generally massive. H. = 3; G. = 3·45 to 3·89. Olive-green; streak almost yellow. B.B. on charcoal fuses easily and forms a graphite-like slag, containing grains of copper. Sol. in n. acid, and with water gives a brick-red precipitate. C.c.: 37 to 38 vanadic acid, 39·4 to 46 copper oxide, 18·5 to 13 lime, 3·6 to 5 water. Sissersk (Urals), Nijni-Tagilsk, and Friedrichroda in Thuringia

416. Tagilite, $4\dot{C}u\dddot{P}_2+3\dot{H}_2$.

Oblique prismatic; but botryoidal and radiating-fibrous, or earthy. H. = 3; G. = 4. Emerald-green. C.c.: 61·8 copper protoxide, 27·7 phosphoric acid, and 10·5 water. Nijni-Tagilsk, and near Hirschberg.

417. Euchroite, $4\dot{C}u\dddot{A}s_2+7\dot{H}_2$.

Right prismatic. ∞P (*M*) 117° 20′, $\bar{P}\infty$ (*n*) 80° 52′, with $\infty\breve{P}2$ (*l*) and 0P (*P*) (fig. 432). Brittle. H. = 3·5 to 4; G. = 3·35 to 3·45. Translucent; vitreous. Emerald- or leek-green; streak verdigris-green. B.B. in forceps fuses to a greenish brown crystallized mass. Easily sol. in n. acid. C.c.: 47 copper protoxide, 34 arsenic acid, and 19 water. Libethen in Hungary.

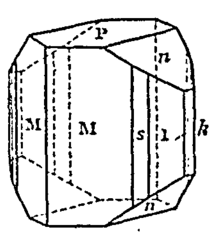

Fig. 432 (sp. 417).

418. Erinite, $5\dot{C}u\dddot{A}s_2+2\dot{H}_2$.

Reniform and foliated; conchoidal fracture. H. = 4·5 to 5; G. = 4 to 4·1. Translucent on the edges; dull resinous. Emerald- or grass-green; streak similar. C.c.: 59·9 copper protoxide, 34·7 arsenic acid, and 5·4 water. Cornwall. *Cornwallite* has 3 or 5 of water.

419. Dihyrite, $5\dot{C}u\dddot{P}_2+2\dot{H}_2$.

G. = 4·4. Oxide of copper 69, phosphoric acid 24·7, water 6·25. Rheinbreitenbach and Nijni-Tagilsk.

420. Mottramite, $5(\dot{C}u,\ \dot{P}b)\dddot{V}_2+2\dot{H}_2$.

Black crystalline crusts; streak yellow. H. = 3; G. = 5·9. C.c.: oxide of copper 20·4, oxide of lead 7·2, vanadic acid 18·7, water 3·7. Mottram in Cheshire.

421. Ehlite $5\dot{C}u\dddot{P}_2+3\dot{H}_2$.

Right prismatic; botryoidal, radiating, foliated. H. = 1·5 to 2; G. = 3·8 to 4·27. Translucent on the edges; pearly on the cleavage. Verdigris-green; streak paler. C.c.: 67 copper protoxide, 24 phosphoric acid, and 9 water. Ehl on the Rhine, Nijni-Tagilsk, Libethen.

422. Tyrolite, $5\dot{C}u\dddot{A}s_2+9\dot{H}_2$.

Right prismatic. Cl. basal, perfect; reniform. Radiate-foliaceous. H. = 1·5 to 2; G. = 3. Lustre pearly on cleavage face. Colour apple-green and verdigris-green to sky-blue; streak paler. Subtranslucent. C.c.: oxide of copper 50·3, arsenic acid 29·2, water 20·5. Tyrol, Hesse, Thuringia.

423. Phosphorochalcite (*Lunnite*), $6\dot{C}u\dddot{P}_2+3\dot{H}_2$.

Oblique prismatic. Crystals ∞P^c2 (*f*) 38° 56′, P (*P*) 117° 49′, with 0P (*a*) and $\infty P^c\infty$ (*c*) (fig. 433); usually small and indistinct; more common in spherical or reniform and radiated-fibrous masses. H. = 5; G. = 4·1 to 4·3. Translucent throughout or on the edges; adamantine to resinous. Blackish-, emerald-, or verdigris-green. C.c.: 70·8 copper protoxide, 21·2 phosphoric acid, and 8 water. Cornwall, Rheinbreitenbach, Nijni-Tagilsk.

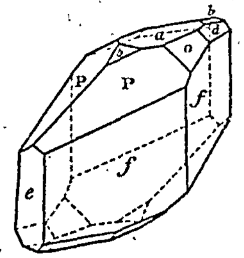

Fig. 433 (sp. 423).

424. Clinoclase, $6\dot{C}u\dddot{A}s_2+3\dot{H}_2$.

Oblique prismatic, C 80° 30′. 0P (*P*), ∞P (*m*) 56°, $\frac{4}{3}P^c\infty$ (*a*) 99° 30′, (*r*) 123° 48′ (figs. 434, 435); and hemispherical. Cl. basal, perfect. H. = 2·5 to 3; G. = 4·2 to 4·4. Translucent; vitreous; pearly on cl. Dark verdigris-green to sky-blue; streak blue. C.c.: 62·6 copper protoxide, 30·3 arsenic acid, 7·1 water. Cornwall, Tavistock, Erzgebirge.

425. Mixite.

Oblique prismatic or anorthic (?). Radiating, centrally granular. ∞P 125°. H. = 3 to 4; G. = 2·66. Emerald-green to blue-green; streak paler. C.c.: 43·21 copper oxide, 13·1 bismuth oxide, 30·45 arsenic acid, 11·1 water. Geistergang, Joachimsthal.

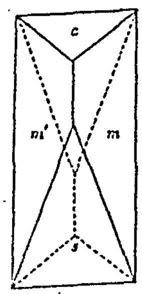

Fig. 434 (sp. 424).

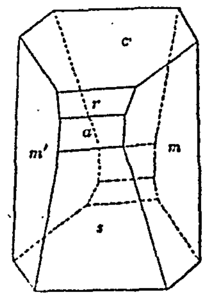

Fig. 435 (sp. 424).

426. Rhagite, $5\dot{B}i_22\dddot{A}s_2+8\dot{H}_2$.

Grape-like groups of minute crystals. Colour yellowish green; streak white. Lustre wax-like; brittle. H. = 5; G. = 6·82. C.c.: bismuth oxide 79·5, arsenic acid 15·6, water 4·9. Neustädtel near Schneeberg.

427. Trögerite, $3\dot{U}\dddot{A}s_2+12\dot{H}_2$.

Oblique prismatic, C 80°. Crystals thin tabular. Cl. clinodiagonal, perfect. Lustre pearly. G. = 3·3. Lemon-yellow. C.c.: 65·95 oxide of uranium, 17·56 arsenic acid, 16·49 water. In closed tube gives off water, and becomes golden brown, but again yellow on cooling. Neustädtel.

428. Struvite, $(N\dot{H}_4,\ 2\dot{M}g)\ \dddot{P}_2+12\dot{H}_2$.

Right prismatic. $\bar{P}\infty$ (*a*) 63° 7′, $\breve{P}\infty$ (*c*) 95°, $4\bar{P}\infty$ (*b*) 30° 32′, $\infty\breve{P}\infty$ (*n*), $\frac{1}{4}\bar{P}\infty$ (*m*) 123°, 0P (*o*) (fig. 436). Cl. brachydiagonal, perfect. H. = 1·5 to 2; G. = 1·66 to 1·75. Transparent or opaque; vitreous. Colourless, but yellow or brown. C.c.: 29·9 phosphoric acid, 16·3 magnesia, 10·6 ammonia, and 44 water. Under St Nicholas church at Hamburg, and in guano from South America.

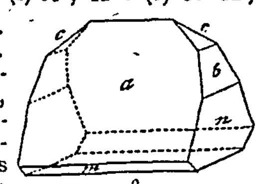

Fig. 436.

429. Arseniosiderite, $3\dot{C}a\dddot{A}s_2+3\dddot{F}e_2\dddot{A}s_2+6\dot{H}_2$.

Spherical and fibrous; friable. H. = 1·2; G. = 3·52 to 3·88. Opaque; silky. Golden yellowish brown; streak yellowish brown. C.c.: peroxide of iron 39·4, lime 13·8, arsenic acid 37·9, water 8·9. Romanèche near Macon.

430. Chalcosiderite.

Anorthic. Light green crystals. G. = 3·11. C.c.: 42·8 peroxide of iron, 8·1 oxide of copper, 4·45 alumina, 30·54 phosphoric acid, 15 water. Cornwall.

431. Lazulite, $\dddot{A}l_2\dddot{P}_2+(\dot{M}g,\ \dot{F}e)_3\dddot{P}_2+2\dot{H}_2$.

Oblique prismatic, C 88° 2′. ∞P 91° 30′, P (*e*) 99° 40′, −P (*p*) 100° 20′. Crystals often tabular through distortion; twins on 0P, and $\infty P^c\infty$; also massive; fracture splintery. Cl. ∞P. H. = 5 to 6; G. = 3 to 3·1. Translucent; vitreous. Indigo- and smalt-blue to greenish; streak white. In closed tube yields water, and loses colour. Soluble in acids after ignition. C.c.: 31·7 alumina, 10 magnesia, 6 protoxide of iron, 44 phosphoric acid, and 6 water. Salzburg, Styria, Brazil, Georgia, Lincoln in North Carolina.

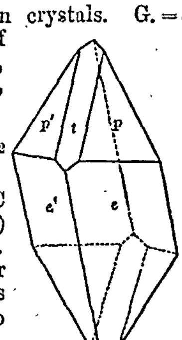

Fig. 437 (sp. 431).

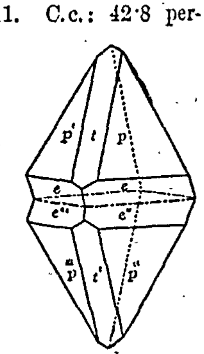

Fig. 438 (sp. 431).

432. Childrenite, $2(\dot{F}e, \dot{M}n)_4\dddot{\bar{P}} + \dddot{Al}\dddot{\bar{P}} + 15\dot{H}$. $\bar{P} = P_2, \dot{H} = H_2$, &c.

Right prismatic. Polar edges 101° 43′, 130° 10′, middle 98° 44′; usual form $\breve{P}$, $2\breve{P}\infty$, $\infty\bar{P}\infty$ (*c*, *a*, P, fig. 439). H. = 4·5 to 5; G. = 3·18 to 3·3. Translucent; vitreous. Yellowish white to wine- or ochre-yellow, brown, or almost black. C.c.: 30·7 iron protoxide, 9 manganese protoxide, 14·5 alumina, 29 phosphoric acid, and 17 water. Tavistock, Crinnis and Callington (Cornwall).

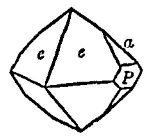

Fig. 439.

433. Eosphorite $(\dot{F}e, \dot{M}n)_2\dddot{Al}, \dddot{\bar{P}} + 4\dot{H}$.

Right prismatic. P (*p*) 133° 32′ and 118° 56′; ∞P (*i*) 104° 19′; $\infty\bar{P}\infty$ (*a*), $\infty\breve{P}\infty$ (*b*), $\infty\breve{P}2$ (*g*), $\frac{4}{3}\breve{P}\frac{4}{3}$ (*q*), $2\breve{P}2$ (*s*) (polar edges 130° 26′ and 98° 42′) (fig. 440). Cl. macrodiagonal. H. = 5; G. = 3·13. Pale red. Vitreous. C.c.: 22 alumina, 7·4 protoxide of iron, 23·5 oxide of manganese, 31·5 phosphoric acid, 15·6 water. Fairfield (Connecticut).

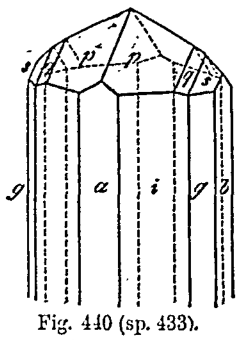

Fig. 440 (sp. 433).

434. Liroconite, $\dot{C}u_8\dddot{\bar{A}}s + \dddot{Al}\dddot{\bar{A}}s + 24\dot{H}$.

Oblique prismatic, C 88° 33′. ∞P (*d*) 61° 31′, $P^c\infty$ (*o*) 74° 21′ (fig. 349). H. = 2 to 2·5; G. = 2·8 to 3. Translucent; vitreous or resinous. Azure-blue to verdigris-green; streak paler. C.c.: 36·6 protoxide of copper, 11·9 alumina, 26·6 arsenic acid, 24·9 water. Redruth, Herrengrund in Hungary.

435. Chalcophyllite, $\dot{C}u_6\dddot{\bar{A}}s + 12\dot{H}$.

Hexagonal rhombohedral; R 69° 48′ (fig. 441). Cl. basal, perfect; sectile. H. = 2; G. = 2·4 to 2·6. Transparent; vitreous to adamantine. Pearly on 0R (*o*). Emerald- to grass- and verdigris-green; streak pale green. Soluble in acids and ammonia. C.c.: protoxide of copper 49·6, arsenic acid 18, water 32·4. Redruth in Cornwall, Saida in Saxony, Moldawa in the Banat.

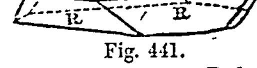

Fig. 441.

436. Uranite, $(\dot{C}a, \dddot{\bar{U}}_2)\dddot{\bar{P}} + 8\dot{H}$.

Right prismatic. ∞P 90° 43′; P middle edge 127° 32′. 0P : P 116·14; 0P : $2\bar{P}\infty$ 109° 6′; 0P : $2\breve{P}\infty$ 109° 19′ (figs. 442, 443). Crystals flat. Cl. basal, perfect; sectile. H. = 1 to 2; G. = 3 to 3·2. Translucent; pearly on 0P. Sulphur-yellow to siskin-green; streak yellow. C.c.: 15·5 phosphoric acid, 62·6 uranium peroxide, 6·1 lime, and 15·3 water. Cornwall, Autun and Limoges in France, Johann-Georgenstadt and Eibenstock in Saxony, Chesterfield in Massachusetts.

Fig. 442.

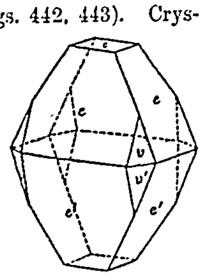

Fig. 443.

437. Uranospinite, $(\dot{C}a, \dddot{\bar{U}}_2)\dddot{\bar{A}}s + 8\dot{H}$.

Right prismatic; quadrangular, scale-like crystals. Cl. basal, perfect. H. = 2·3; G. = 3·45. Siskin-green. C.c.: lime 5·47, sesquioxide of uranium 59·18, arsenic acid 19·37, water 16·29. Neustädtel.

438. Uranocircite, $(\dot{B}a, \dddot{\bar{U}}_2)\dddot{\bar{P}} + 8\dot{H}$.

Yellowish green crystals, isomorphous with 437. Cl. basal. G. = 3·53. C.c.: sesquioxide of uranium 56·86, baryta 14·57, phosphoric acid 15·1, water 14. Falkenstein in Voigtland.

439. Chalcolite, $(\dot{C}u, \dddot{\bar{U}}_2)\dddot{\bar{P}} + 8\dot{H}$.

Pyramidal. P middle edge 142° 8′; P∞ 128° 14′. Crystals 0P, P, ∞P∞, P∞. Cl. basal, perfect; pearly lustre; brittle. H. = 2 to 2·5; G. = 3·5 to 3·6. Grass- to emerald- or verdigris-green; streak apple-green. C.c.: 15·2 phosphoric acid, 61 uranium peroxide, 8·5 copper protoxide, and 15·3 water. Redruth and St Austell, Johann-Georgenstadt, Eibenstock, Schneeberg Bodenmais, Baltimore.

440. Zeunerite, $(\dot{C}u, \dddot{\bar{U}}_2)\dddot{\bar{A}}s + 8\dot{H}$.

Pyramidal. P middle edge 142° 6′. 0P : P 109° 57′. Crystals tabular. Cl. basal. H. = 2·5; G. = 3·53. Grass-green. Lustre pearly. C.c.: 7·7 oxide of copper, 55·95 sesquioxide of uranium, 14 water. Huel Gorland in Cornwall, Neustädtel, Joachimsthal, Zinnwald, Wittichen.

441. Walpurgite, $5\dddot{\bar{B}}i\dddot{\bar{A}}s + 3\dddot{\bar{U}}\dddot{\bar{A}}s + 10\dot{H}$.

Anorthic; in scaly crystals. Wax-yellow to pomegranate-red. Adamantine to greasy. H. = 3·5; G. = 5·76. C.c.: sesquioxide of bismuth 60·4, sesquioxide of uranium 20·4, arsenic acid 13, water 4·5. Neustädtel.

442. Plombgomme, $\dot{P}b_3\dddot{\bar{P}} + 6\dddot{Al}\dot{H}_3$.

Reniform or stalactitic; fracture conchoidal and splintery. H. = 4 to 4·5; G. = 6·3 to 6·4. Translucent; resinous. Yellowish or greenish white to reddish brown. C.c.: 38 protoxide of lead, 35 alumina, 8 phosphoric acid, and 19 water; but with 2 chloride of lead. Poullauouen, Nuissière (near Beaujeu), Georgia.

Compounds of Phosphates, Vanadiates, and Arseniates with Haloid Salts.

443. Apatite, $3\dot{C}a\dddot{\bar{P}} + Ca(Cl, F)$.

Hexagonal and pyramidal-hemihedric. P 80° 26′. The most common forms are ∞P (M); ∞P2 (*n*); 0P (*m*); P (*x*); the base 0P seldom wanting (figs. 92, 95, 96, 97, 98). The crystals are short-prismatic or thick-tabular; also granular, fibrous, or compact; fracture conchoidal or splintery; brittle. H. = 5; G. = 3·1 to 3·25. Transparent to opaque; vitreous to resinous. Colourless and white, but generally light green, grey, blue, violet, or red. C.c.: phosphate of lime (89 to 92·3), with chloride (to 11) or fluoride (to 7·7) of calcium, or both. Disseminated in granite, gneiss, mica and hornblende slates, primary limestones, and trap rocks; also in beds and veins. Sutherland, Ross, and Aberdeen, in granite and limestone; Cumberland, Devonshire, and Cornwall; in tin-mines in Saxony; Bohemia, St Gotthard, Tyrol; Kragerö in Norway, New York, Canada.

444. Pyromorphite, $3\dot{P}b_3\dddot{\bar{P}} + PbCl$.

Hexagonal; P 80° 44′. Crystals ∞P, 0P, with ∞P2, or P (*M*, *P*, *x*, fig. 444), occasionally thicker in the middle, or spindle-shaped; also reniform or botryoidal; fracture conchoidal or uneven. H. = 3·5 to 4; G. = 6·9 to 7. Translucent; resinous or vitreous. Colourless, but generally grass-, pistachio-, olive-, or siskin-green, and clove- or hair-brown, and scarlet (Leadhills). C.c.: 89·7 phosphate and 10·3 chloride of lead, but with 0 to 9 arseniate of lead, 0 to 11 phosphate of lime, and 0 to 1 fluoride of calcium. Elgin, Wanlockhead, also Cornwall, Derbyshire, Yorkshire, Durham, Cumberland, Wicklow; Przibram, Mies, and Bleistadt in Bohemia; Berezoff, Phœnixville in Pennsylvania, and Mexico.

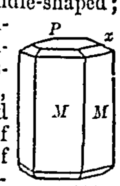

Fig. 444.

445. Vanadinite, $3\dot{P}b_3\dddot{\bar{V}} + PbCl$.

Hexagonal; P 78° 46′. Forms ∞P, 0P (*o*), P (*z*), 2P, $\frac{1}{2}$P ($b\frac{1}{2}$), ∞P2, ∞P$\frac{3}{2}$, 2P2 (fig. 445). Transparent to opaque; resinous. Honey-yellow to greyish brown; streak white. H. = 3; G. = 6·8 to 7·2. C.c.: oxide of lead 70·83, vanadic acid 19·35, lead 7·2, chlorine 2·62. Wanlockhead, Windischkappel in Carinthia, Haldenwirthshaus in the Black Forest, Bolet in West-Gotland, Berezovsk, Zimapan in Mexico, Cordoba in the Argentine Republic.

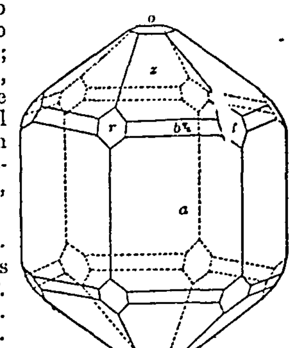

Fig. 445 (sp. 445).

446. Mimetesite, $3\dot{P}b_3\dddot{\bar{A}}s + PbCl$.

Hexagonal; P 81° 48′. Crystals ∞P, 0P, P (figs. 91, 444), or P, 0P. Cl. P; fracture conchoidal or uneven. H. = 3·5 to 4; G. = 7·19 to 7·25. Translucent. Colourless, but usually honey- or wax-yellow, yellowish green or grey. C.c.: 90·7 arseniate and 9·3 chloride of lead; but part of the arsenic occasionally replaced by phosphoric acid. Leadhills, Huel Alfred and Huel Unity in Cornwall, Roughten Gill and Dry Gill in Cumberland, Beeralston in Devonshire, Johann-Georgenstadt, Zinnwald, Badenweiler, St Prix in France, Nertchinsk, and Zacatecas in Mexico.

447. Wagnerite, $\dot{M}g_3\dddot{\bar{P}} + MgF$.

Oblique prismatic, C 63° 25′. ∞P 57° 35′. Cl. prismatic, and orthodiagonal imperfect; fracture conchoidal or splintery. H. = 5 to 5·5; G. = 3 to 3·2. Translucent or transparent; resinous. Wine-yellow and white. C.c.: 43·3 phosphoric acid, 11·4 fluorine, 37·6 magnesia, and 7·7 magnesium; but with 3 to 4·5 iron protoxide and 1 to 4 lime. Werfen in Salzburg.

448. Triplite, $(\dot{F}e, \dot{M}n)_3\dddot{\bar{P}} + RF$.

Oblique prismatic; only granular. Cl. in two directions at right angles; fracture conchoidal. H. = 5 to 5·5; G. = 3·6 to 3·8. Translucent or opaque; resinous. Chestnut- or blackish-brown; streak yellowish grey. C.c.: iron and manganese protoxides, with 33 phosphoric acid, and 7 or 8 fluorine. Limoges, Schlaggenwald.

449. Zwieselite, $(\dot{F}e, \dot{M}n)_3\dddot{\ddot{P}} + FeF$.

Right prismatic; but only massive. Cl. basal, perfect. H. = 4·5 to 5; G. = 3·95 to 4. Brown; streak yellow. C.c.: like triplite. Zwiesel in Bavaria.

450. Amblygonite, $\dddot{A}l_5\dddot{\ddot{P}}_3 + (\dot{L}i, \dot{N}a)_5\dddot{\ddot{P}}_3 + AlF_3 + (Li, Na)F$.

Anorthic; crystals rare; coarse granular. Cl. 0P, pearly, meeting two others at 105° and 87° 40′. Fracture uneven and splintery. H. = 6; G. = 3 to 3·1. Translucent; vitreous. Greyish or greenish white to pale mountain-green. C.c.: 47·9 phosphoric acid, 34·5 alumina, 6·9 lithia, 6 soda, and 8·3 fluorine. Penig, Arendal, Montebras (Creuse, France), also Hebron and Paris in Maine. *Montebrasite* has no soda.

451. Durangite, $(\dddot{R}_2)\,\dddot{\ddot{A}}s + 2NaF$.

Oblique prismatic; crystals like keilhauite (sp. 669). ∞P 110° 10′; P 112° 10′. Cl. prismatic. H. = 5; G. = 3·95 to 4. Bright orange-red; streak cream-yellow. Vitreous. C.c.: alumina 17·2, iron protoxide 9·2, arsenic acid 53, soda 13·1, fluorine 7·7. Durango (Mexico).

452. Herderite.

Right prismatic. P polar edges 77° 20′ and 141° 16′; ∞P̆ 115° 53′. Fracture conchoidal. H. = 5; G. = 2·9 to 3. Translucent; vitreous, inclining to resinous. Yellowish or greenish white. Ehrenfriedersdorf in Saxony. An anhydrous phosphate of alumina with lime and fluorine.

Phosphates with Sulphates and Borates.

453. Svanbergite.

Rhombohedral; R 90° 35′. H. = 4·5; G. = 2·57. Vitreous to adamantine. Honey-yellow, reddish brown, and rose-red; streak reddish. Subtransparent. C.c.: 37·8 alumina, 6 lime, 17·3 sulphuric acid, 12·8 soda, 17·8 phosphoric acid, 6·8 water. Horrsjöberg in Wermland.

454. Diadochite, $\dddot{F}e_3\dddot{\ddot{P}}_2 + 2\dddot{F}e\dddot{S}_2 + 32\dot{H}$.

Reniform and stalactitic; fracture conchoidal. H. = 3; G. = 1·9 to 2. Resinous; vitreous. Yellow or yellowish brown; streak white. C.c.: 36·7 iron protoxide, 14·8 phosphoric acid, 15·2 sulphuric acid, and 30·3 water. Gräfenthal and Saalfeld.

455. Pitticite, $\dddot{F}e_2\dddot{S}_3 + 2\dddot{F}e\dddot{\ddot{A}}s + 24\dot{H}$.

Reniform and stalactitic; brittle; fracture conchoidal. H. = 2·3; G. = 2·3 to 2·5. Translucent throughout, or on the edges; resinous to vitreous. Yellowish, reddish, or blackish brown, sometimes in spots or stripes; streak light yellow or white. C.c.: 35 iron peroxide, 26 arsenic acid, 14 sulphuric acid, and 24 water. In many old mines, as Freiberg and Schneeberg.

456. Beudantite.

Rhombohedral; R 91° 18′. H. = 3·5; G. = 4. Vitreous. Olive-green; streak greenish yellow. C.c.: oxide of iron 40·69, oxide of lead 24·05, sulphuric acid 13·76, phosphoric acid 8·97, water 9·77. Dernbach in Nassau, Cork in Ireland.

457. Lüneburgite $(2\dot{M}g, \dot{H})\,\dddot{\ddot{P}} + \dot{M}g\dddot{B} + 7\dot{H}$.

Concretions of fibrous structure. C.c.: 25·2 magnesia, 29·83 phosphoric acid, 14·74 boracic acid, 30·23 water. Lüneburg.

ARSENITES.

458. Ecdemite, $\dot{P}b_3\dddot{A}s_2 + 2PbCl_2$.

Pyramidal. Cl. 0P. H. = 2·5 to 3; G. = 7·14. Pale green. Vitreous on cleavage; resinous on fracture. C.c.: oxide of lead 59·67, lead 22·2, arsenious acid 10·59, chlorine 7·58. Långban in Wermland.

459. Trippkeite, $\dot{C}u\dddot{A}s$.

Pyramidal; P 111° 56′. Blue-green. Lustrous. Copiapo in Chili.

SILICATES.

Andalusite Group.

460. Andalusite, $\dddot{A}l\ddot{S}i$.

Right prismatic. ∞P (*m*) 90° 50′, P̄∞ (*r*) 109° 4′, P̆∞ (*s*) 109° 51′.

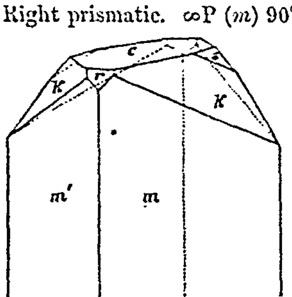

Fig. 446.

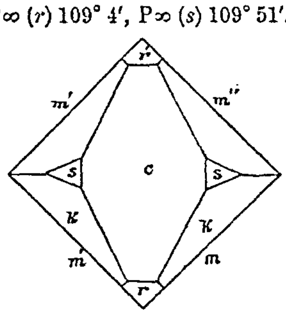

Fig. 447.

Also columnar. Cl. *m*; fracture splintery. H. = 7 to 7·5; G. = 3·1 to 3·2. Pellucid; vitreous. Grey, green, red, or blue. B.B. infusible. Not affected by acids. C.c.: alumina 63·1, silica 36·9. Clashnaree (figs. 446 to 449) and Clova in Aberdeenshire, Marnoch and Botriphnie in Banffshire, Killiney Bay in Wicklow, Andalusia, Tyrol, Penig, Massachusetts, Litchfield in Connecticut.

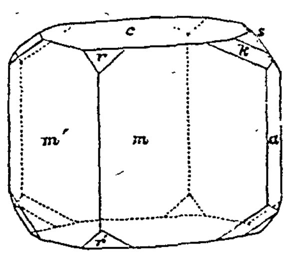

Fig. 448.

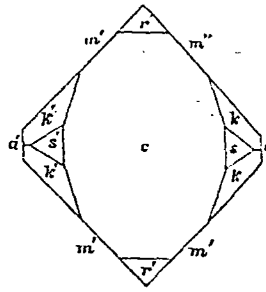

Fig. 449.

Chiastolite. H. = 5 to 5·5; G. = 3. Pale grey, yellow, green, and red. A compound structure, formed of four double wedge-shaped crystals, arranged in contact with the angles of a square conoidal crystal placed in their centre, and imbedded in a paste of clay slate. The section of the compound structure forms a tesselated cross, the appearance of which varies with the portion of the crystal which is cut. Portsoy (fig. 450) and Boharm in Banffshire, Wicklow, Keswick and Skiddaw, Brittany, Pyrenees, Maine, New Hampshire, Nova Scotia, Canada.

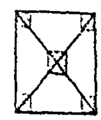

Fig. 450.

461. Cyanite (*Disthene*), $\dddot{A}l\ddot{S}i$.

Anorthic; generally broad-prismatic lengthened crystals, formed by two faces (*m*, *t*). *m* : *t* 106° 15′; *m* : *i* 145° 41′; *p* : *m* 93° 15′ (fig. 451). Hemitropes common, united by *m*. Also radiated. Cl. *m*, perfect; brittle. H. = 7, on cl. planes 5; G. = 3·5 to 3·7. Pellucid; vitreous. Cl. pearly. Colourless, and red, yellow, green, grey, and blue. B.B. infusible. Not affected by acids. C.c. same as andalusite. Hillswick in Shetland, Mount Battock, Tarfside (fig. 451), Botriphnie (Banffshire), Tyrol, St Gotthard, Bohemia, Pontivy in France.

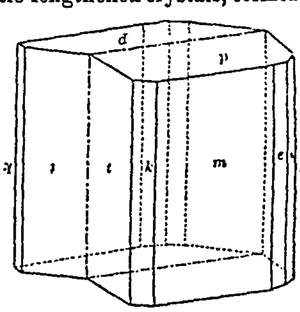

Fig. 451.

462. Sillimanite, $\dddot{A}l\ddot{S}i$.

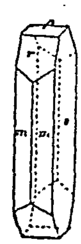
Right prismatic; ∞P 111°. Crystals fibrous, columnar, and radiating. Cl. macrodiagonal. H. = 7; G. = 3·2 to 3·26. Translucent; resinous; on cl. vitreous. Greyish, greenish, clove, or hair-brown. C.c. and chemical characters like cyanite. Tvedestrand, Norway; Chester and Norwich, Connecticut. Al_2O_3,SiO_2 is thus trimorphous. *Monrolite*, *Xenolite*, *Bucholzite*, *Fibrolite*, and *Bamlite* are varieties.

463. Topaz, $5\dddot{A}l\ddot{S}i + AlF_3 + SiF_2$.

Right prismatic. ∞P (*M*) 124° 17′, 2P̆∞ (*n*) 92° 42′, ∞P̆2 (*l*) 93° 14′, P (*o*). Crystals always prismatic (fig. 122), often hemimorphic. Cl. basal, perfect; fracture conchoidal. H. = 8; G. = 3·4 to 3·6. Transparent; vitreous. Colourless, honey-yellow, amber, pink, asparagus-green, blue. Becomes electric by heat or friction, and the yellow colours become pink. B.B. infusible. Not affected by h. acid; by digestion in s. acid gives traces of fluorine. The formula requires 33·2 silica, 56·7 alumina, 17·5 fluorine. Part of the oxygen must be replaced by fluorine, as the total of the above is 107·4. Ben-a-bourd and Arran, Scotland; Mourne Mountains, Ireland; St Michael's Mount, Cornwall; Siberia, Saxony, Bohemia, Connecticut, Australia, Ceylon, Brazil, Peru. The finest topazes are the blue from Scotland and Siberia, the pink, the yellow from Brazil, and the colourless from Peru. The last-named when cut may be distinguished at once from diamond by their electricity. *Pyrophysalite* is a massive opaque cleavable variety from Falun. *Pycnite* is a columnar straw-yellow to reddish white variety from Zinnwald in Saxony and Durango in Mexico.

464. Staurolite, $(\dddot{A}l, \dddot{F}e)\,\ddot{S}i + (\dot{F}e, \dot{M}g)\,\ddot{S}i$.

Right prismatic. ∞P (*m*) 128° 42′, P̆∞ (*r*) 70° 46′, ∞P̆∞ (*o*), 0P̆ (*p*) (fig. 452). Twins common, as figs. 140, 144, 187, 453. Cl. brachydiagonal, perfect; fracture conchoidal to splintery. H. = 7; G. = 3·5 to 3·8. Transparent to opaque; vitreous to resinous. Reddish brown; streak white. B.B. infusible. Not affected by h. acid, partially by s. acid.



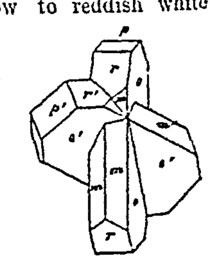


Fig. 452. (Sp. 464.) Fig. 453.

C.c.: silica 30, alumina 48·5, with 5·5 iron peroxide, 12·5 iron protoxide, 3·5 magnesia; often impure. Bixeter Voe and Unst in Shetland, Boharm and Marnoch in Banffshire, St Gotthard, Greiner in Tyrol, Finistère, Urals, and North America. *Xantholite* is a yellow variety from Urquhart (Inverness).

465. Sapphirite, $4\dot{M}g$, $5\dddot{A}l$, $2\dddot{S}i$.

Oblique prismatic; granular. H. = 7 to 8; G. = 3·4 to 3·5. Vitreous; pale blue or green; translucent; dichroic. C.c.: alumina 63·2, magnesia 19·3, silica 14·9. Fiskenaes in Greenland.

Tourmaline Group.

466. Tourmaline, $\dot{R}_3\dddot{S}i + \dddot{R}\dddot{S}i$.

Rhombohedral; R 133 10′. Crystals of 0R (k'), $-\frac{1}{2}$R; usually long prismatic, and striated (fig. 45, and 249 to 252). Generally hemimorphic; also radiating and fibrous; fracture conchoidal to uneven. H. = 6·5 to 7·5; G. = 3 to 3·3. Black varieties opaque, others transparent; vitreous. Generally black; but colourless, yellow, brown, blue, green, and rose-red; streak white. Different colours often disposed in layers parallel to the axis; and portions of one crystal differing also in colour along the axis. By friction acquires positive electricity; and becomes electrically polar when heated. Powder insol. in h. acid; imperfectly in s. acid. C.c. complex, but all with water and fluorine, some with boracic acid. Coarse black columnar varieties, called *Schorl*, very common in granite and gneiss. Black occur at Portsoy in Banff, Clova, Cabrach, and Rubislaw in Aberdeenshire, Bovey in Devonshire, St Just in Cornwall, in Greenland, Arendal, Tyrol, and North America; blue or *Indicolite* at Utö in Sweden; green at Glen Skiag in Cromarty. Crystals ruby-red within, surrounded by green or red at one extremity and green at the other, also blue and pink, at Albany, Paris, and Hebron in Maine. Currant-red or *Rubellite* in India and Ceylon, also in Siberia and Brazil.

467. Datholite, $\dot{C}a\dddot{B} + \dot{C}a\dddot{S}i_2 + \dot{H}$.

Oblique prismatic, C 89° 51′. ∞P (g) 115° 22′, ∞P°2 (f) 76° 38′. P (P) 120°, −P°∞ (a) 45° 8′, ∞P°∞ (s), 2P°∞ (o) (fig. 454); or rhombic with $b:f$ 90°, $b:a$ 135°, $b:c$ 141° 9′, and $f:g$ 160° 39′. Fracture uneven, or conchoidal. H. = 5 to 5·5; G. = 2·9 to 3. Transparent or translucent; vitreous. Colourless and tinted greenish, yellowish, or pink. In closed tube yields water. B.B. intumesces and melts easily to a clear glass, colouring the flame green; the powder gelatinizes in h. acid. C.c.: 38·1 silica, 21·6 boracic acid, 34·7 lime, and 5·6 water. Bishopton in Renfrew, Glen Farg in Perthshire (fig. 455), Salisbury Crags and Corstorphine Hill near Edinburgh, Arendal, Utö, Andreasberg, Seisser Alp, Connecticut, and New Jersey. Figs. 238, 239 are pseudomorphs of quartz after datholite termed *Haytorite*.

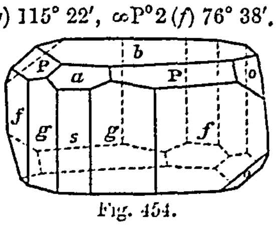

Fig. 454.

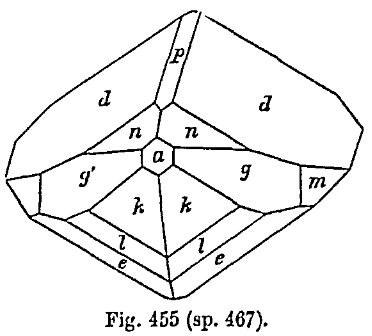

Fig. 455 (sp. 467).

468. Euclase, $2\dddot{G}l\dddot{S}i + \dddot{A}l\dot{H}$.

Oblique prismatic, C 79° 44′. ∞P°2 (s) 115°; 3P°3 (f) 105° 49′. Crystals specially of ∞P°2, ∞P°∞ (T), 3P°3. Cl. clinodiagonal, perfect; very brittle and fragile; fracture conchoidal.

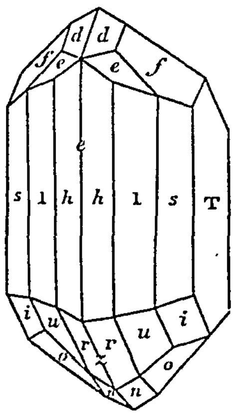

Fig. 456.

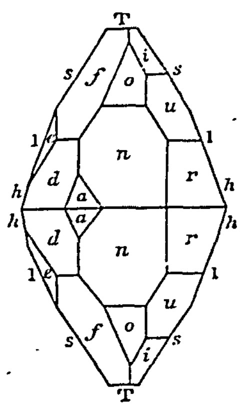

Fig. 457.

H. = 7·5; G. = 3 to 3·1. Transparent; splendent; vitreous. Mountain-green, passing into blue, yellow, or colourless. B.B. intumesces, becomes white, and melts in thin splinters to a white enamel. Not affected by acids. C.c.: 42 silica, 35 alumina, 18 glucina, 6 water. Peru and Brazil, and Southern Urals. Cannot be used as a gem on account of its brittleness; whence its name.

469. Homilite.

Oblique prismatic, C 89° 21′. H. = 5·5; G. = 3·28. Black and brownish black. Vitreous. C.c.: 27·28 lime, 16·25 protoxide of iron, 31·87 silica, 18·1 boracic acid. Stokö and Brevig (Norway).

470. Botryolite.

Fine fibrous, botryoidal, or reniform. Snow-white to hair-brown. Chemical and physical characters like datholite, but 10·64 of water,—being 2 equivalents. Arendal.

471. Gadolinite, $(\dot{Y}, \dot{C}e, \dot{F}e)_2\dddot{S}i$.

Oblique prismatic, C 89° 28′. ∞P 116°; P 120° 56′ (fig. 458). Fracture conchoidal, or splintery. H. = 6·5 to 7; G. = 4 to 4·4. Translucent on the edges; vitreous to resinous. Black; streak greenish grey. B.B. the conchoidal (vitreous) varieties incandesce; gelatinizes in h. acid. C.c.: 36 to 51 yttria, 10 to 15 iron protoxide, 5 to 17 protoxide of cerium with lanthanum, 0 to 12 glucina, and 25 to 29 silica. Hitterö in Norway, Ytterby, Broddbo and Finbo near Falun.

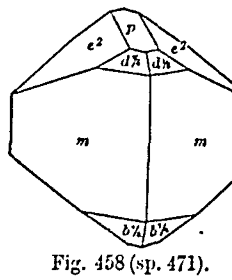

Fig. 458 (sp. 471).

Epidote Group.

472. Zoisite, $4\dot{C}a$, $3\dddot{A}l$, $6\dddot{S}i + \dot{H}$.

Right prismatic. ∞P 116° 26′; ∞P̆2 145° 24′; ∞P̄3 156° 40′; P̄∞ 122° 4′; 2P̆∞ 111 6′ (fig. 459). Cl. brachydiagonal, perfect. H. = 6; G. = 3·2 to 3·4. White, brownish grey, and dark green. B.B. intumesces, and forms a white or yellow porous mass; and on the edges fuses to a clear glass. C.c.: 29·8 alumina, 24·35 lime, 2·8 oxide of iron, 40·3 silica, and 2·1 water. Glen Urquhart, Dalnain, and Allt Gonolan, Inverness; Sterzing in Tyrol, the Sau Alp in Carinthia, the Urals, and Connecticut. *Thulite*, peachblossom-red, from Souland in Thelemark (Norway), is similar.

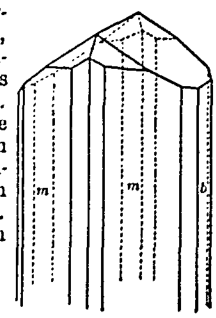

Fig. 459 (sp. 472).

473. Epidote, $4\dot{C}a$, $3\dddot{A}l$, $6\dddot{S}i + \dot{H}$.

Oblique prismatic, C 89° 27′. ∞P°∞ (M), ∞P 2 (o) 63° 1′, P°∞ (T) 64° 36′, −P (n) 70° 25′, −P̄∞ (r) 63° 42′, P (z) 70°. Crystals complex, with many partial forms. Hemitropes united by T; also columnar and granular. Cl. M, perfect; also T, forming 115° 24′; fracture conchoidal to splintery. H. = 6 to 7; G. = 3·2 to 3·5. Pellucid; vitreous. Green to yellowish grey. B.B. fuses and swells to a dark brown slag; after fusion soluble with gelatinization in h. acid. C.c.: 27·4 alumina, 8·5 iron peroxide, 23·9 lime, 38·3 silica, 1·9 water. Shetland, Glenelg in Inverness, Tilquilly in Aberdeen, in gneiss; in amygdaloid in Mull and Skye; in granite at Cassencary in Kirkcudbright; Arendal, Dauphiné, Greenland, the Urals, North America. *Withamite* from Glencoe is a red, strongly dichroic variety. *Piedmontite* or *Manganese Epidote*, brownish violet, from St Marcel, has 20 per cent. of manganese peroxide.

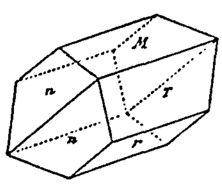

Fig. 460.

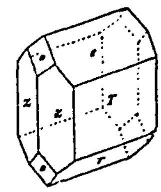

Fig. 461.

474. Allanite (*Orthite, Cerine*), $\dot{R}_3\dddot{S}i_2 + \dddot{R}\dddot{S}i$.

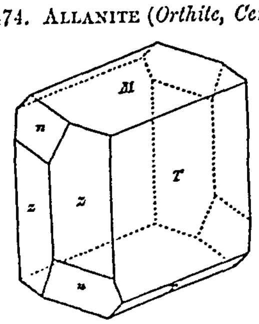

Fig. 462.

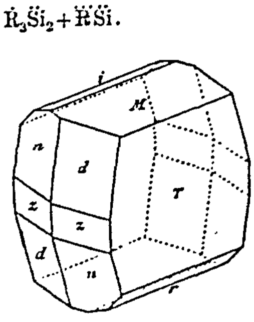

Fig. 463.

Oblique prismatic, C 65°. ∞P (z) 70° 48′, P (n) 71° 27′, −P (d)

96° 40′, 0P (*M*), $\bar{P}\infty$ (*r*), $\infty P\infty$ (*T*). *M* : *T* 115°, *T* : *n* 111° 21′, *T* : *d* 130° 18′. Often massive or granular; fracture conchoidal. H. = 6; G. = 3·4 to 3·8. Translucent on edges; vitreous to resinous. Black to brown or greenish; streak brownish grey. B.B. froths and melts to a brown glass. Gelatinous with h. acid. C.c.: 12 to 18 alumina with peroxide of iron, 13 to 26 oxide of cerium and lanthanum, 2 to 12 yttria, 4 to 20 protoxide of iron, 30 of silica. Small crystals common in the syenitic granites of Scotland; as at Lairg, Boat of Garten (fig. 463), Aboyne, and Criffel. In limestone at Urquhart (fig. 462), Greenland, Hitterö and Snarum, Thuringia, Pennsylvania, New Jersey. *Orthite* (massive) at Finbo, Kragerö, and Falun. *Cerine* (granular) at Riddarhyttan. *Pyrorthite* has carbonaceous matter. *Bodenite* is a variety.

475. IDOCRASE, $3(\dot{Ca}, \dot{Mg})_3\dddot{Si} + 2\overline{Al}\dddot{Si}$.

Pyramidal; P (*c*) 74° 27′ (figs. 464 to 466). Crystals ∞P (*d*),

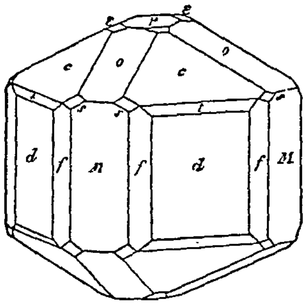

Fig. 464.

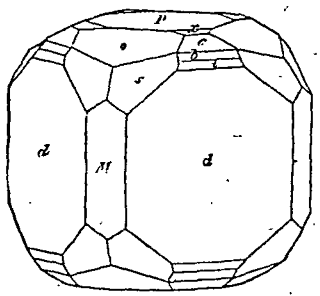

Fig. 465.

$\infty P\infty$ (*M*), P (*c*), 0P (*p*), $P\infty$ (*o*) 56° 29′, $\infty P2$ (*f*). Prismatic, striated; also granular; fracture uneven. H. = 6·5; G. = 3·35 to 4. Pellucid; vitreous to resinous. Brown, green, yellow; streak white. B.B. fuses easily, with intumescence, to a green or brown glass. Partially sol. in h. acid; after ignition totally, gelatinizing. C.c.: alumina 16, peroxide of iron 7, lime 34, silica 38. Glen Gairn and Crathie, Aberdeenshire, in limestone; Broadford, Skye; Wicklow and Donegal, Ireland; Egg, Norway; Mussa, Piedmont; Vesuvius; Wilui river, near Lake Baikal (fig. 463). *Cyprine* from Thelemark is azure-blue, from copper.

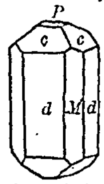

Fig. 466.

OLIVINE GROUP.

476. FORSTERITE, $\dot{Mg}_2\dddot{Si}$.

Right prismatic. Like olivine (sp. 478). H. = 6 to 7; G. = 3·2 to 3·3. Vitreous; transparent. White, wax-yellow, greenish; streak white. C.c.: magnesia 57·1, silica 42·86. Vesuvius. *Boltonite*, red, is from Massachusetts.

477. FAYALITE, $\dot{Fe}_2\dddot{Si}$.

Right prismatic; *n* : *n′* 49° 36′ (fig. 467). Massive. Cl. rectangular. Black, greenish, or brownish. Metallic to resinous; fracture conchoidal; magnetic. H. = 6·5; G. = 4 to 4·1. C.c.: protoxide of iron 70·5, silica 29·5. Mourne Mountains, Ireland; Fayal, Azores.

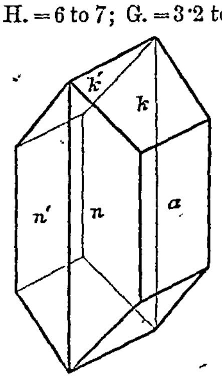

Fig. 467 (sp. 477).

478. CHRYSOLITE (*Olivine*, *Peridote*), $(\dot{Fe}, \dot{Mg})_2\dddot{Si}$.

Right prismatic. P (*e*) 85° 16′ and 139° 54′; middle 108° 30′. ∞P (*n*) 130° 2′, $\bar{P}\infty$ (*d*) 76° 54′, $2\breve{P}\infty$ (*k*) 80° 53′, $\infty\bar{P}\infty$ (*M*) (fig. 468). Also massive. Cl. brachydiagonal, perfect; fracture conchoidal. H. = 6·5 to 7; G. = 3·3 to 3·5. Transparent; vitreous. Olive-green, yellow, brown, and colourless. B.B. infusible. Soluble, with gelatinizing, in acids. C.c.: 47 magnesia, 12 protoxide of iron, 40 silica. Talisker in Skye, Haalival in Rum, Elie in Fife, Unkel on the Rhine, Vesuvius, Esneh in Egypt, Brazil. *Hyalosiderite*, brown and yellow, with metallic lustre and 30 per cent. protoxide of iron, is from the Kaiserstuhl in the Breisgau.

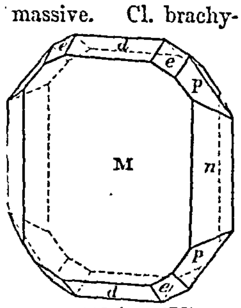

Fig. 468 (sp. 478).

479. TEPHROITE, $\dot{Mn}_2\dddot{Si}$.

Right prismatic; granular, with rectangular cleavages. Ash-grey, rose-red. Adamantine; translucent. H. = 5·5 to 6; G. = 4 to 4·1. C.c.: protoxide of manganese 70·2, silica 29·8. Franklin and Sparta in New Jersey.

480. KNEBELLITE, $\dot{Fe}_2\dddot{Si} + \dot{Mn}_2\dddot{Si}$.

Massive. Grey, brown, green, black. Glistening; brittle. H. = 6·5; G. = 3·71. C.c.: protoxide of iron 35·5, protoxide of manganese 35, silica 29·5. Ilmenau, Dannemora in Sweden.

481. MONTICELLITE, $\dot{Ca}_2\dddot{Si} + \dot{Mg}_2\dddot{Si}$.

Right prismatic. P (*f*) 110° 43′ and 97° 55′, ∞P (*s*) 98° 7′, $\infty\breve{P}2$ (*n*) 133° 6′, $\breve{P}\infty$ (*k*) 81° 57′, $\frac{1}{2}\breve{P}\infty$ (*h*) 120° 8′, $\breve{P}2$ (*c*) 141° 47′ and 82°, $\infty\breve{P}\infty$ (*b*) (fig. 469). Vitreous. Grey, yellowish and greenish, and white; streak white. Translucent. H. = 5 to 5·5; G. = 3 to 3·25. C.c.: lime 35, magnesia 21·9, protoxide of iron 5·6, silica 37·5. Sol. in h. acid, gelatinizing. Somma (Milan).

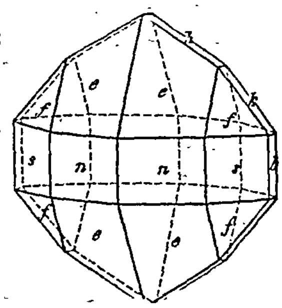

Fig. 469 (sp. 481).

482. CHONDRODITE (*Humite*), $\dot{Mg}_5\dddot{Si}_2$.

Right prismatic. P middle edge 156° 38′, polar edges 131° 34′ and 54° 28′ (figs. 470 to 472). Crystals monoclinic in habit, often granular-massive. H. = 6·5; G. = 3·15 to 3·25. Translucent; vitreous to resinous. Yellow, red, brown, green, and black; streak white. B.B. infusible. Decomposed by acids. C.c.:

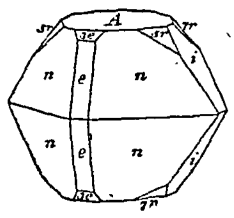

Fig. 470.

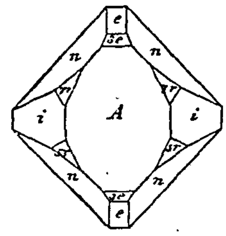

Fig. 471.

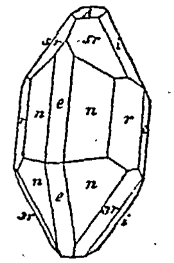

Fig. 472.

silicate of magnesia, with 2 to 3 of fluorine. From limestone on Loch Ness (?); Pargas, Finland; Gallsjö and Aker, Sweden; New York; Sparta, New Jersey. *Humite*, from Somma.

483. LIEVRITE, $3(\dot{Fe}, \dot{Ca})_2\dddot{Si} + \overline{Fe}\dddot{Si} + \dot{H}$.

Right prismatic. P (*o*) polar edges 139° 30′ and 117° 27′; ∞P 112° 38′, $\bar{P}\infty$ (*d*) 112° 49′, $\infty P2$ (*s*) 106° 15′. Crystals (fig. 124) are long-prismatic and vertically striated; also radiated, columnar, or fibrous; brittle. H. = 5·5 to 6; G. = 3·9 to 4·2. Opaque; resinous or imperfect metallic. Brownish or greenish black; streak black. B.B. fuses easily to a black magnetic globule. Sol. in h. acid, forming a yellow jelly. C.c.: 29·3 silica, 19·6 iron peroxide, 35·2 iron protoxide, 13·7 lime, and 2·2 water. Rio in Elba, Fossum, Kupferberg, Rhode Island, and Greenland.

484. CERITE $(\dot{Ce}, \dot{R})_2\dddot{Si} + \dot{H}$.

Hexagonal; 0P; ∞P; in low six-sided prisms. Generally fine-granular; fracture uneven, splintery; brittle. H. = 5·5; G. = 4·9 to 5. Translucent on the edges; dull, adamantine, or resinous. Clove-brown, cherry-red, or pearl-grey. Sol. in h. acid, leaving gelatinous silica. C.c.: 20·5 silica, 73·5 protoxide of cerium (with didymium and lanthanum), and 6 water. Bastnaes near Riddarhyttan.

485. GALMEI, $\dot{Zn}_2\dddot{Si} + \dot{H}$.

Right prismatic, and hemimorphic; $2\breve{P}2$ (*P*) with polar edges 101° 35′ and 132° 26′, ∞P (*d*) 103° 50′, $\bar{P}\infty$ (*o*) 117° 14′, $\breve{P}\infty$ (*l*) 128° 55′ (fig. 46); common form $\infty\breve{P}\infty$ (*s*), ∞P, $\bar{P}\infty$. Also columnar, fibrous, granular, and earthy. Cl. prismatic along ∞P, very perfect; along $\bar{P}\infty$ perfect. H. = 5; G. = 3·3 to 3·5. Transparent to translucent; vitreous and pearly. Colourless or white, but often light grey, also yellow, green, brown, and blue; becomes electric by heat. B.B. decrepitates slightly, but is infusible; with cobalt solution blue and partly green; readily soluble in acids, and gelatinizes. C.c.: 25 silica, 67·5 zinc oxide, and 7·5 water. Wanlockhead, Mendip Hills, Matlock, Raibl and Bleiberg in Carinthia, Aix-la-Chapelle, Iserlohn, Nertchinsk, Pennsylvania, Virginia. Used as an ore of zinc.

WILLEMITE GROUP.

486. WILLEMITE, $\dot{Zn}_2\dddot{Si}$.

Rhombohedral; R 116° 1′. Cl. basal, and prismatic, ∞R; brittle. H. = 5·5; G. = 3·9 to 4·2. White, yellow, brown, and red. Vitreous lustre. C.c.: oxide of zinc 73, silica 27. Altenberg, Liége, Greenland, New Jersey.

487. TROOSTITE, $\dot{Z}n\ddot{S}i + \dot{M}n\ddot{S}i$.

Rhombohedral; R 116°. Cl. prismatic, ∞P2; brittle. H. = 5·5; G. = 4·1. Asparagus-green, grey, and reddish brown. Vitreous. C.c.: oxide of zinc 58, oxide of manganese 13, silica 28. New Jersey.

488. CENTROLITE ($\dot{P}b\dot{M}n$) $\ddot{S}i$.

Right prismatic; ∞P 115° 18′. Form ∞P, P, ∞P̆∞. H. = 5; G. = 6·2. Red-brown. Cl. prismatic; splendent on P. Southern Chili.

489. PHENACITE, $Gl_2\ddot{S}i$.

Hexagonal and tetartohedral; R (p) 116° 36′ (fig. 473). Crystals R, ∞P2, ⅔P2. Twins with parallel axes, and intersecting. Cl. R, and ∞P2; fracture conchoidal. H. = 7·5 to 8; G. = 2·97. Transparent or translucent; vitreous. Colourless, and wine-yellow or brown when fresh, but colour soon lost on exposure. B.B. infusible; not affected by acids. C.c.: glucina 45·8, silica 54·2. Framont in Alsace, Takovaya in Urals, Miask, Durango in Mexico.

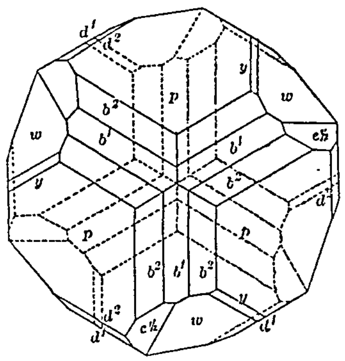

Fig. 473 (sp. 489).

490. DIOPTASE, $\dot{C}u\ddot{S}i + \dot{H}$.

Hexagonal and rhombohedral; R 125° 54′, −2R (r) 95° 28′, ∞P2, −2R$\frac{7}{4}$ (s) (fig. 474). Cl. R, perfect; brittle. H. = 5; G. = 3·2 to 3·3. Transparent or translucent; vitreous. Emerald-green, rarely verdigris-green or blackish green; streak green. C.c.: 38·7 silica, 50 copper protoxide, and 11·3 water. Altyn-Tübeh in the Kirghiz Steppe, Muroshnaya, Copiapo.

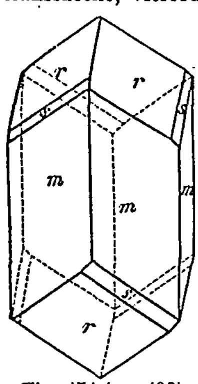

Fig. 474 (sp. 490).

491. CHRYSOCOLLA, $\dot{C}u\ddot{S}i + 2\dot{H}$.

Botryoidal or investing; brittle; fracture conchoidal. H. = 2 to 3; G. = 2 to 2·3. Translucent; resinous. Verdigris- to emerald-green or azure-blue; streak greenish white. C.c.: 34·83 silica, 44·94 copper protoxide, and 20·23 water. Leadhills, Lackentyre in Kirkcudbright, Cornwall, Saxony, Hungary, Spain, Urals, Australia, Chili.

492. BOGOSLOVSKITE (*Kupferblau*).

Massive; fracture conchoidal; brittle. H. = 4 to 5; G. = 2·56. Sky- to ultramarine-blue; streak smalt-blue, and shining. A silicate of copper, with 45·5 per cent. copper oxide. Schapbach Valley in Baden, Bogoslovsk in the Urals. *Demidowite* may be the same.

GARNET GROUP.

493. GARNET, $\dot{R}_3\ddot{S}i_2 + \ddot{\bar{R}}\ddot{S}i$.

Cubic; most common forms ∞O and 2O2 (figs. 33, 40, 60, 475). Also granular. Cl. dodecahedral; fracture conchoidal, or splintery. H. = 6·5 to 7·5; G. = 3·5 to 4·3. Pellucid; vitreous or resinous. Rarely colourless or white; generally red, brown, black, green, or yellow. B.B. in general fuses to a glass, black or grey in those containing much iron, green or brown in the others, and often magnetic; imperfectly soluble in h. acid. C.c. exceedingly variable, but generally forming two series, according as R_2O_3 is chiefly alumina or chiefly iron peroxide; and these are again divided according as RO is more especially lime, iron protoxide, magnesia, or a similar base. The more important varieties are—

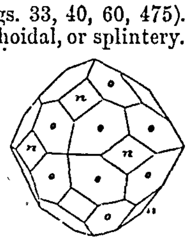

Fig. 475.

(1) *Lime-Alumina Garnet*, $\dot{C}a_3\ddot{S}i_2 + \ddot{\bar{A}}l\ddot{S}i$, with 40 silica, 23 alumina, and 37 lime. To this subdivision belong—

(*a*) *Water Garnet.*—Colourless to white. Craig Mohr, Aberdeen; Thelemark in Norway.

(*b*) *Grossular.*—Olive- to gooseberry-green. Craig Mohr; Wilui river; America.

(*c*) *Cinnamon Stone.*—Hyacinth-red to orange-yellow. Glen Gairn (Aberdeen), Allt Gonolan and Ord Ban (Inverness), Ceylon, Wermland. *Romanzowite*, from Kimito (Finland), is the same. This variety when polished is often sold as *Hyacinth*.

(*d*) *Common Lime Garnet.*—Here one half of the alumina is replaced by iron peroxide. Colours red, brown, yellow. Piedmont, Vesuvius, the Urals.

(2) *Magnesia-Alumina Garnet*; RO chiefly magnesia. Arendal.

(3) *Manganese-Alumina Garnet*; RO = MnO; reddish-brown. Spessart (Bavaria), Sweden.

(4) *Magnesia-Iron-Lime-Alumina Garnet, Pyrope.*—Colour port-wine to purplish red. Elie in Fife, Zöblitz in Saxony, Bohemia.

(5) *Iron-Alumina Garnet, Almandine, Noble Garnet.*—Columbine-red, inclining to violet, blood-red, and reddish brown. Common in mica-slate, gneiss, and granite. Shetland, Ross, Inverness, Aberdeen, Falun, Arendal, Tyrol, the Urals, North America, Pegu, and Ceylon.

(6) *Lime-Chrome-Alumina Garnet*, $\dot{C}a_3\ddot{S}i_2 + (\ddot{\bar{C}}r, \ddot{\bar{A}}l)\ddot{S}i$, *Uwarowite.* Emerald-green; with 22 per cent. chrome oxide. Bissersk and Kyshtimsk in the Urals, India, and California.

(7) *Lime and Iron Garnet*, $\dot{C}a_3\ddot{S}i_2 + \ddot{\bar{F}}e, \ddot{S}i$. This includes—

(*a*) *Common Iron-Garnet, Rothoffite, Allochroite.*—Subtranslucent or opaque. Green, brown, yellow, or black; with white, grey, or yellow streak. Sweden and Arendal.

(*b*) *Melanite.*—Black; opaque; in thin splinters translucent; streak grey; slightly magnetic. Albano near Frascati, Vesuvius, France, Lappmark.

(*c*) *Colophonite.*—Yellowish-brown to pitch-black, also yellow or red; resinous; streak white. G. = 3·43. Arendal.

The red varieties, when cut *en cabochon*, are termed *Carbuncles.*

494. AXINITE, $(\ddot{\bar{A}}l, \ddot{B})\ddot{S}i + 2(\dot{C}a, \dot{F}e)\ddot{S}i$.

Anorthic. Crystals unsymmetrical. *u* : *P* 135° 31′; *u* : *r* 115° 38′, *P* : *r* 134° 45′ (figs. 136, 137). Cl. distinct along planes truncating the sharp edges between *P* and *u* and *P* and *r*. H. = 6·5 to 7; G. = 3·2 to 3·3. Pellucid; vitreous. Clove-brown, inclining to smoke-grey or plum-blue; but often cinnamon-brown in one direction, dark violet-blue in a second, and pale olive-green in a third (*trichroism*). B.B. colours flame green; intumesces, and fuses easily to a dark green glass, becoming black in the ox. flame; not sol. in h. acid till after ignition, when it gelatinizes. C.c.: 45·9 silica, 5·9 boracic acid, 17·5 alumina, 9·3 iron (with manganese) protoxide, and 21·4 lime. Botallack and other mines in Cornwall, Bourg d'Oisans in Dauphiné, Kongsberg, Arendal, Nordmark in Sweden, Pyrenees, St Gotthard, Tyrol, Thum in Saxony, Urals, and North America.

495. DANBURITE $(\dot{C}a, \ddot{B})\, 2\ddot{S}i$.

Right prismatic. ∞P (*I*) 122° 52′, ∞P̆2 (*e*) 94° 52′, P̄∞ (*d*) 97° 7′, 4P̆∞ (*w*) 54° 58′, 0P (*c*), P (*o*), 2P̆2 (*r*), ∞P̄∞ (*a*), ∞P̆4 (*n*).

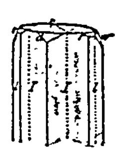

Fig. 476.

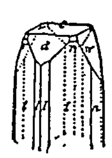

Fig. 477.

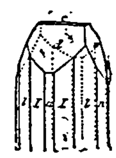

Fig. 478.

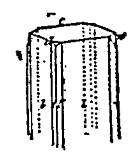

Fig. 479.

Cl. basal; fracture uneven to subconchoidal; vitreous to greasy lustre. H. = 7 to 7·5; G. = 2·986 to 3·021. Pale yellow to reddish brown. Translucent; brittle. C.c.: 22·76 lime, 28·46 boracic acid, 48·76 silica. Danbury in Connecticut, Russell in New York.

HELVINE GROUP.

496. HELVINE, $\dot{M}nS + 3\dot{R}_2\ddot{S}i$.

Cubic and tetrahedral. $\frac{O}{2}$ or $\frac{O}{2} - \frac{O}{2}$ (fig. 64 and with 66). Imbedded or attached. Cl. octahedral. H. = 6 to 6·5; G. = 3·1 to 3·3. Translucent on the edges; resinous. Wax-yellow, siskin-green, or yellowish brown. B.B. in the red. flame fuses with intumescence to a yellow obscure pearl; sol. in h. acid, evolving sulphuretted hydrogen, and gelatinizes. C.c.: 34 silica, 10 glucina, 8 iron protoxide, 43 manganese protoxide, and 5 sulphur. Schwarzenberg in Saxony, and near Modum in Norway.

497. DANALITE, $3\dot{R}_2\ddot{S}i + ZnS$.

Cubic. In octahedra, with striated dodecahedral planes. H. = 5·5 to 6; G. = 3·43. Vitreous to resinous. Flesh-red to grey; streak lighter. Translucent; brittle. C.c.: protoxide of iron 29, of manganese 6·5, of zinc 19, silica 31·5, sulphur 5·5. Rockport in Massachusetts.

498. EULYTINE, $\ddot{B}i_2\ddot{S}i_3$.

Cubic and tetrahedral. $\frac{2O2}{2}$ and $-\frac{2O2}{2}$. The crystals (fig. 66) small, and often with curved faces; fracture conchoidal. H. = 4·5 to 5; G. = 5·9 to 6·1. Transparent and translucent; adamantine. Clove-brown, yellow, grey, or white; streak white or grey. C.c.: 16·2 silica and 83·8 bismuth peroxide. Schneeberg and Bräunsdorf near Freiberg.

Scapolite Group.

499. Sarcolite, $8\dot{C}a$, $3\dddot{A}l$, $\dot{N}a$, $9\dddot{S}i$.

Pyramidal. P 102° 54′; ∞P∞; 0P; P, and other faces as in fig. 480, many of the faces being alternately hemihedral. H. = 5·5 to 6; G. = 2·93. Vitreous. Grey to rose-red. Translucent; very brittle. C.c.: alumina 21·5, lime 32·4, soda 3·3, silica 40·5. B.B. fuses to a white enamel; gelatinizes with acids. Somma.

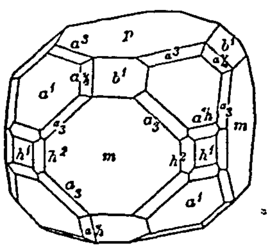

Fig. 480 (sp. 499).

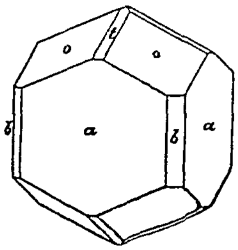

Fig. 481 (sp. 500).

500. Meionite, $6(\dot{C}a, \dot{N}a)$, $4\dddot{A}l$, $9\dddot{S}i$.

Pyramidal. P (*o*) 63° 42′; P∞ (*t*); ∞P (*a*); ∞P (*b*) (fig. 481). Cl. macrodiagonal. H. = 5·5 to 6; G. = 2·6 to 2·74. Vitreous. Colourless or white. Transparent. Much cracked. C.c.: 31·9 alumina, 26·2 lime, 41·9 silica. Gelatinizes in acids. Somma.

501. Mizzonite, $6(\dot{C}a, \dot{N}a)$, $4\dddot{A}l$, $15\dddot{S}i$.

Pyramidal; P 64° 4′ (fig. 482). Similar to meionite. C.c.: alumina 23·8, lime 8·8, soda 9·8, silica 54·7. Insoluble in h. acid. Somma.

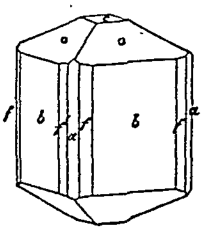

Fig. 482 (sp. 501).

502. Scapolite, $3(\dot{C}a, \dot{N}a)\dddot{S}i + \dddot{A}l_2\dddot{S}i_3$.

Pyramidal. P 63° 42′; ∞P∞; P; ∞P; also massive. Cl. ∞P∞, perfect; and ∞P. H. = 5 to 5·5; G. = 2·6 to 2·8. Transparent or translucent; vitreous, pearly, or resinous. Colourless, but also pale grey, green, yellow, or red. B.B. melts with effervescence to a vesicular glass; in the closed tube may show traces of fluorine; with solution of cobalt becomes blue. Sol. in h. acid. C.c.: 49 silica, 28 alumina (with iron peroxide), and 23 lime (with soda). Tiree (Scotland), Arendal, Tunaberg, Pargas, Massachusetts, and New York. Known by its rectangular cleavage, resinous lustre on fractured surfaces, and action B.B. *Dipyre*, P 64° 4′, is a variety.

503. Mellilite (*Humboldtilite*), $2(\dot{C}a, \dot{M}g)\dddot{S}i_2 + (\dddot{A}l, \dddot{F}e)\dddot{S}i$.

Pyramidal. P 65° 30′; 0P; ∞P∞. Cl. basal, perfect. H. = 5 to 5·5; G. = 2·91 to 2·95. Translucent on edges; vitreous to resinous. Honey-yellow, orange-brown, and yellowish white. C.c.: 32 lime, 7 magnesia, 9 alumina, 7 iron peroxide, 40 silica. Capo di Bove, and Vesuvius.

504. Gehlenite, $(\dot{C}a, \dot{F}e)_3\dddot{S}i + (\dddot{A}l, \dddot{F}e)\dddot{S}i$.

Pyramidal. P. 59°; 0P; ∞P∞; ∞P3; 2P. Cl. basal. H. = 5·5 to 6; G. = 2·9 to 3·1. Translucent on edges. Dull resinous. Mountain-, leek-, or olive-green, and liver-brown. C.c.: 22 alumina, 5 iron peroxide, 35 lime, 4 magnesia, 31·4 silica. Monzoni in the Fassa Valley.

Nepheline Group.

505. Leucite, $\dddot{A}l$, $\dddot{S}i_3 + \dot{K}\dddot{S}i$.

Pyramidal. Combination of the ditetragonal pyramid (*i*) with the tetragonal pyramid (*o*), and 2P∞ (*u*) with ∞P (*m*). Hemitropes united

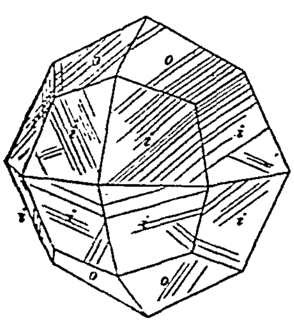

Fig. 483.

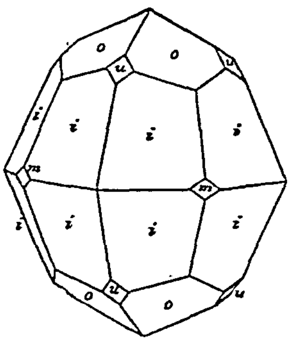

Fig. 484.

by (*u*). Fracture conchoidal. H. = 5·5 to 6; G. = 2·4 to 2·5. Transparent to translucent on the edges; vitreous, inclining to resinous. Colourless, but greyish, yellowish, or reddish white; streak white. B.B. infusible; with cobalt solution becomes blue. Sol. in h. acid, without gelatinizing. C.c.: 54·9 silica, 23·6 alumina, and 21·5 potash. Abundant in the lavas of Vesuvius, the tufas near Rome, and the peperino of Albano; also at the Kaiserstuhl, and near Lake Laach. Readily distinguished from analcime by its infusibility, and by never showing faces of the cube.

506. Nepheline (*Elæolite*), $\dddot{A}l\dddot{S}i + 4(\dot{N}a, \dot{K})\dddot{S}i$.

Hexagonal. P 88° 10′. ∞P, 0P, P common; also fig. 485. Crystals imbedded, or in druses; also massive-granular; fracture conchoidal, or uneven. H. = 5·5 to 6; G. = 2·58 to 2·64. Transparent or translucent; vitreous and resinous. Colourless or white (nepheline); or opaque, dull resinous, and green, red, or brown (elæolite). B.B. melts difficultly (nepheline), or easily with slight effervescence (elæolite), into a vesicular glass. Sol. and gelatinizes in h. acid. C.c.: 41·2 silica, 35·3 alumina, 17 soda, 6·5 potash. Nepheline at Monte Somma, Capo di Bove, Katzenbuckel in the Odenwald, Aussig, and Lusatia. Elæolite in the zircon syenite at Laurvig, Fredriksvärn, Brevig, and Miask.

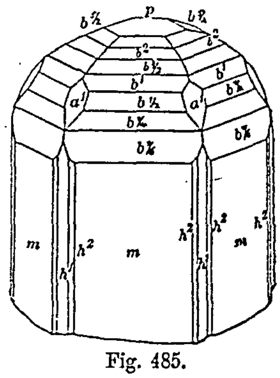

Fig. 485.

Davine, with ½P 51° 46′, seems only a variety; as also *Cancrinite*, bright blue, and with some carbonate of lime.

507. Microsommite, $\dot{K}\dddot{S}i + \dddot{A}l\dddot{S}i + NaCl$.

Hexagonal. ∞P; 0P; ∞P2; ∞P$\frac{3}{2}$. Cl. ∞P. H. = 6; G. = 2·42 to 2·53. Colourless to yellow; lustre silky. Somma and Vesuvius.

508. Sodalite, $3(\dddot{A}l\dddot{S}i + \dot{N}a\dddot{S}i) + NaCl$.

Cubic; ∞O, and fig. 486; generally distorted; also massive and granular. Cl. ∞O; fracture conchoidal or uneven. H. = 5·5; G. = 2·13 to 2·29. Translucent; vitreous. White, grey, and rarely green or blue. C.c.: 37 silica, 31·8 alumina, 19·2 soda, 4·7 sodium, and 7·3 chlorine. Greenland, Vesuvius, Ilmen Hills, Fredriksvärn, and Litchfield in Maine.

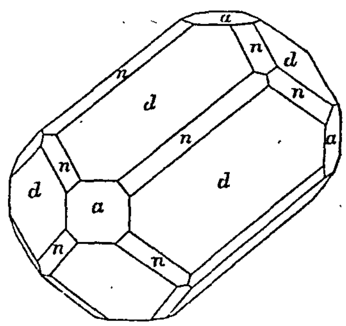

Fig. 486 (sp. 508).

509. Nosean, $3(\dddot{A}l\dddot{S}i + \dot{N}a\dddot{S}i) + \dot{N}a\dddot{S}$.

Cubic; and granular. H. = 5·5; G. = 2·28 to 2·40. Translucent; vitreous to resinous. Ash or yellowish grey, sometimes blue, brown, or black. C.c.: 36 silica, 31 alumina, 25 soda, and 8 sulphuric acid. Lake Laach, and Rieden near Andernach, on the Rhine. Occurs in phonolites, in minute crystals.

510. Hauyne, $2(\dddot{A}l\dddot{S}i + \dot{N}a\dddot{S}i) + \dot{C}a\dddot{S}$.

Cubic; chiefly ∞O; also fig. 487; but more common in grains. Cl. ∞O. H. = 5 to 5·5; G. = 2·4 to 2·5. Semitransparent or translucent; vitreous or resinous. Azure- or sky-blue; streak bluish white. C.c.: 34·2 silica, 28·5 alumina, 11·5 soda, 4·3 potash, 10·4 lime, and 11·1 sulphuric acid. Vesuvius, Mount Vultur near Melfi, the Campagna of Rome, and Niedermendig near Andernach.

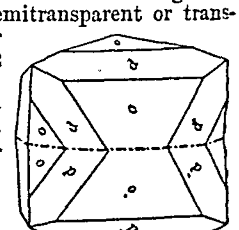

Fig. 487 (sp. 510).

511. Lapis-Lazuli.

Cubic; O∞; generally massive, granular. H. = 5·5; G. = 2·38 to 2·42. Translucent on edges; dull resinous or vitreous. Ultramarine, or azure-blue; streak light blue. B.B. fuses readily to a white porous glass. In h. acid the powder is dissolved and gelatinizes, evolving sulphuretted hydrogen. C.c.: 45·50 silica, 5·89 sulphuric acid, 31·76 alumina, 9·09 soda, 3·52 lime, 0·86 iron, 0·42 chlorine, 0·95 sulphur, 0·12 water. Near Lake Baikal, China, Tibet, Tartary, Monte Somma, and Chili. It is used for ornamental purposes, and in the preparation of ultramarine. The colour both in it and hauyne seems due to some compound of sulphur with sodium and iron.

Mica Group.

512. Biotite (*Magnesia-Mica*), $\dddot{A}l_2\dddot{S}i_3 + (\dot{M}g, \dot{K}, \dot{F}e)_2\dddot{S}i_3$.

Oblique prismatic, C 89° 59′. 0P (*c*), 98° 41′ P (*m*), −½P (*o*), ∞P^c∞ (*b*), P̆∞ (*r*), −$\frac{2}{3}$P^{c}3 (*z*). Cl. basal, perfect; sectile; thin plates elastic. H. = 2·5 to 3; G. = 2·85 to 2·9. Transparent, but often only

in very thin plates. Generally uniaxal, sometimes with divergence = 56°. Metallic, pearly. Usually dark green, brown, or black; streak greenish grey or white. B.B. difficultly fusible to a grey or black glass. Completely sol. in concentrated s. acid, leaving white

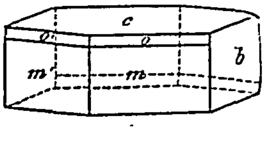

Fig. 488.

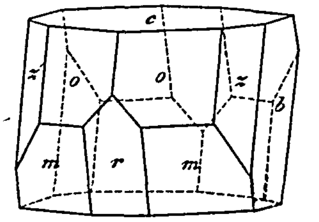

Fig. 489.

pearly plates of silica. C.c.: 39 silica, 17 alumina, 10 iron protoxide, 20 magnesia, 9 potash. Hillswick, Shetland, in gneiss; Sutherland, Ross, Inverness, in limestone; Skye and Fife in trap; Pargas, Bodenmais, Greenland, New York. *Rubellan* is a decomposed variety.

513. Haughtonite, $(\dddot{\mathrm{A}}\mathrm{l},\dddot{\mathrm{F}}\mathrm{e})\ddot{\mathrm{S}}\mathrm{i}+(\dot{\mathrm{F}}\mathrm{e},\dot{\mathrm{K}})_2\ddot{\mathrm{S}}\mathrm{i}$.

Oblique prismatic. Cl. basal, perfect. H. = 3; G. = 3·1. Vitreous to adamantine. Chocolate-brown to black. Weathers pale green and ochry. Difficultly soluble in acids. B.B. fused with difficulty to a highly magnetic bead. C.c.: silica 36, alumina 18, ferric oxide 4·5, ferrous oxide 18, magnesia 9, potash 8, water 3. Common in the granites of Scotland. Black Forest, Harzburg, Tyrberger.

514. Lepidomelane, $(\dddot{\mathrm{A}}\mathrm{l},\dddot{\mathrm{F}}\mathrm{e})\ddot{\mathrm{S}}\mathrm{i}+(\dot{\mathrm{F}}\mathrm{e},\dot{\mathrm{K}})\ddot{\mathrm{S}}\mathrm{i}$.

Oblique prismatic. Cl. basal, perfect; brittle. H. = 3; G. = 2·97. Vitreous; transparent to opaque. Rich brown to raven-black. B.B. fuses easily to a black feebly-magnetic bead. Sol. in h. acid, leaving pearly scales of silica. C.c.: 37 silica, 17 alumina, 24 iron peroxide, 3 protoxide of iron, 8 potash, 10 magnesia, 4 water. Rarely in gneiss, Scotland; common in granite, Ireland; and Persberg, Sweden.

515. Anomite, $12\dot{\mathrm{M}}\mathrm{g}$, $3\dddot{\mathrm{A}}\mathrm{l}$, $2\dot{\mathrm{K}}$, $\dot{\mathrm{H}}$, $12\ddot{\mathrm{S}}\mathrm{i}$.

Oblique prismatic. $c:m$ 98° 42′. Form c, m, o, b (see fig. 488); divergence of optic axes 12° to 13°. Monroe (New York), Lake Baikal.

516. Phlogopite, $(\frac{3}{5}\dot{\mathrm{R}}_3+\frac{1}{5}\dddot{\mathrm{R}})\ddot{\mathrm{S}}\mathrm{i}_3$.

Oblique prismatic. 0P (c), P (m), $-\frac{1}{2}$P (o), ∞P∞ (b). $c:m$ 98° 30′ to 99°. Cl. basal, perfect. H. = 2·5 to 3; G. = 2·75 to 2·97. Pearly to submetallic. Yellowish brown with copper-like reflexion; also green, white, and colourless. Transparent. Divergence of optic axes 3° to 20°. C.c.: 14 alumina, 2 protoxide of iron, 28 magnesia, 8·6 potash, 2·57 fluorine, 41 silica. B.B. whitens, and fuses on edges. Decomposed by s. acid, leaving the silica in scales. Pargas (Finland), Fassa Valley, New York, Canada, Ceylon. Characteristic of serpentine and of dolomitic limestones.

517. Zinnwaldite.

Oblique prismatic. Forms as in figs. 490, 491; also $2\bar{\mathrm{P}}\infty$ (H) and $3\mathrm{P}^c3$ (x). $m:c$ 98° to 99°. Divergence of optic axes 65°. G. = 2·82 to 3·2. C.c. similar to muscovite (sp. 519), but with 4 to

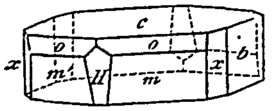

Fig. 490.

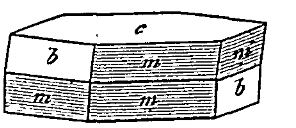

Fig. 491.

8 fluorine, 2 to 5 lithia, and traces of rubidium, cæsium, and thallium. Altenberg and Zinnwald, St Just and Trewavas in Cornwall. *Cryophyllite* from Cape Ann in Massachusetts is similar.

518. Lepidolite.

Oblique prismatic. Forms like muscovite. Divergence of optic axes 50° to 77°. Cl. basal, perfect. H. = 2·5 to 4; G. = 2·84 to 3. Often massive; scaly granular, coarse or fine. Lustre pearly. Colour rose-red, violet, lilac, yellow, greyish white. Contains 5 to 6 per cent. lithia, with rubidium, cæsium, and thallium, also fluorine. B.B. colours flame red. Mourne Mountains, Rozena (Moravia), Utö (Sweden), Ekaterinburg, Maine.

519. Muscovite (*Muscovy-Glass*), $3\dddot{\mathrm{A}}\mathrm{l}\ddot{\mathrm{S}}\mathrm{i}+\dot{\mathrm{K}}\ddot{\mathrm{S}}\mathrm{i}$.

Right prismatic, with monoclinic habit. 0P (c); ∞P (M); $\infty\mathrm{P}^c\infty$ (b); P (m); $2\mathrm{P}^c\infty$ (y). ∞P nearly 120°. Twin-face c. Cl. basal, perfect; elastic. Angle of optic divergence from 44° to 77°. Metallic, pearly. Colourless, and tinged of various shades to black. B.B. fuses to an opaque enamel. Not affected by acids. C.c.: 36·6 alumina, 11·8 potash, 45·1 silica, 4·5 water, with traces of fluorine. Shetland, Loch Glass in Sutherland, Glen Skiag (crystals 15 inches in length) and Struay Bridge in Ross, Aberdeen, Cornwall, St Gotthard, Norway, Sweden, Siberia. Crystals over a yard in diameter in China, where it is used for windows. *Fuchite*, bright green, has 6 per cent. of chrome oxide. *Margarodite* contains 4 to 6 water. *Gilbertite*, Cornwall, may be different.

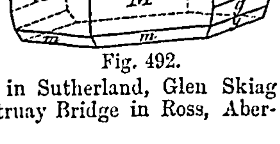

Fig. 492.

520. Paragonite (*Soda-Mica*), $3\dddot{\mathrm{A}}\mathrm{l}_2\ddot{\mathrm{S}}\mathrm{i}_3+(\dot{\mathrm{N}}\mathrm{a},\dot{\mathrm{H}})\ddot{\mathrm{S}}\mathrm{i}$.

Massive; foliated. Lustre pearly. H. = 2·5 to 3; G. = 2·78 to 2·9. Yellowish, greyish, and greenish. C.c.: 40·1 alumina, 6·1 soda, 47·75 silica, 4·6 water. Monte Campione, St Gotthard.

521. Sandbergerite (*Baryta-Mica*).

White minute scaled aggregates. G. = 2·894. C.c.: 30·2 alumina, 4·9 magnesia, 5·9 baryta, 7·6 potash, 42·6 silica, 4·43 water. Pfitsch Valley in Tyrol, and the Swiss Alps.

522. Margarite (*Lime-Mica*).

Right prismatic. Cl. basal perfect. H. = 3·5 to 4·5; G. = 2·99 to 3·1. Lustre of cl. pearly. Lateral planes, vitreous. Snow-white, reddish white, and pearl-grey. Laminæ brittle. Optic axial angle 109° to 129°. C.c.: 51·2 alumina, 11·6 lime, 2·6 soda, 30·1 silica, and 4·5 water. Greiner in Tyrol, Naxos, Asia Minor, Greece, Pennsylvania, North Carolina. *Diphanite* is similar.

523. Euphyllite $(\frac{1}{5}\dot{\mathrm{R}}_3+\frac{4}{5}\dddot{\mathrm{R}})_2\ddot{\mathrm{S}}\mathrm{i}_3+\frac{4}{5}\dot{\mathrm{H}}$.

Like muscovite, but laminæ not easily separable. H. = 3·5 to 4·5; G. = 2·83 to 3. Lustre of cl. pearly to adamantine. White to colourless. Transparent to opaque. Laminæ brittle. Optic axial angle 71½°. C.c.: alumina 42·3, lime 1·5, potash 3·2, soda 5·9, silica 41·6, water 5·5. Unionville in Pennsylvania.

524. Clintonite, $(\frac{3}{4}\dot{\mathrm{R}}_3+\frac{7}{4}\dddot{\mathrm{A}}\mathrm{l})_2\ddot{\mathrm{S}}\mathrm{i}+\frac{1}{2}\dot{\mathrm{H}}$.

Oblique prismatic; in hexagonal tables, or massive foliated. Cl. basal, perfect. H. = 5 to 5·5; G. = 3·15. Translucent; pearly to metallic on the cleavage. Angle of the optic axes 3° to 13°. Reddish brown to yellow. C.c.: 39·7 alumina, 21·1 magnesia, 13·1 lime, 19·2 silica, 2 protoxide of iron, 4·9 water. Amity and Warwick in New York. *Brandisite* is similar.

525. Xanthophyllite.

Oblique prismatic, C about 90°. Crystalline aggregates. Radiate lamellar. H. = 4·5 to 6; G. = 3·1. Lustre pearly. Colour yellowish to copper-red. Angle of optic axes 0° to 20°. C.c.: alumina 43·6, lime 13, magnesia 17·5, silica 16·9, water 5·1. Zlatoust.

526. Chloritoid, $\dot{\mathrm{F}}\mathrm{e}\ddot{\mathrm{S}}\mathrm{i}+\dddot{\mathrm{A}}\mathrm{l}\dot{\mathrm{H}}$.

Right prismatic; in foliated crystals; brittle. Cl. basal. Lustre greasy to pearly. H. = 5·5 to 6; G. = 3·52 to 3·56. Dark green; streak greenish white. C.c.: 40 alumina, 27 protoxide of iron, 25 silica, 7 water. *B.B. infusible, but becomes magnetic.* Decomposed by s. acid. Hillswick in Shetland, Pregratten in Tyrol, Ekaterinburg, Canada.

527. Masonite.

Broad plates. H. = 6·5; G. = 3·53. Grey-green. Streak grey. Pearly to vitreous. C.c.: 26·4 alumina, 19 peroxide of iron, 16·7 protoxide of iron, 32·68 silica, 4·5 water. Middletown in Rhode Island.

528. Ottrelite, $\dddot{\mathrm{A}}\mathrm{l}_2\ddot{\mathrm{S}}\mathrm{i}_3+3(\dot{\mathrm{F}}\mathrm{e},\dot{\mathrm{M}}\mathrm{n})\ddot{\mathrm{S}}\mathrm{i}+3\dot{\mathrm{H}}$.

Thin hexagonal tables. Cl. parallel to the prismatic faces. H. = 5·5; G. = 4·4. Translucent; vitreous. Greenish or blackish grey. C.c.: 24·3 alumina, 16·8 protoxide of iron, 11·1 protoxide of manganese, 43·4 silica, 5·65 water. Ottrez in the Ardennes (Luxemburg), Aste in the Pyrenees, Ebnat in Bavaria, Newport (Rhode Island), Vardhos (Greece).

529. Pyrosmalite, $7\dot{\mathrm{R}}\ddot{\mathrm{S}}\mathrm{i}+\mathrm{RCl}_2+5\dot{\mathrm{H}}$.

Hexagonal. P 101° 34′; crystals ∞P, 0P; tabular; also granular. Cl. basal, perfect; brittle. H. = 4 to 4·5; G. = 3 to 3·2. Translucent to opaque; resinous, or metallic-pearly. Liver-brown to olive-green. C.c.: 35·5 silica, 27·5 iron protoxide, 21·5 manganese protoxide, 8 chloride of iron or manganese, and 7·5 water. Nordmark in Sweden.

530. Astrophyllite, $(\dot{\mathrm{R}}_3,\dddot{\mathrm{R}})_2\ddot{\mathrm{S}}\mathrm{i}_3$.

Right prismatic, with oblique habit. In long tabular prisms, and in stellate groups. Cl. basal, perfect. H. = 3·5; G. = 3·33. Submetallic to pearly. Tombac-brown to gold-yellow. Pellucid. Axial divergence 118° to 124°. C.c.: peroxide of iron 9·3, protoxide 23·6, protoxide of manganese 10, soda 3·9, potash 5·9, titanic acid 7·90, silica 39·2. Brevig, El Paso in Colorado.

Chlorite Group.

531. Chlorite, $2\dot{\mathrm{R}}\ddot{\mathrm{S}}\mathrm{i}+\dot{\mathrm{R}}_2\dddot{\mathrm{A}}\mathrm{l}+3\dot{\mathrm{H}}$.

Hexagonal. P 106° 50′; crystals tabular of 0P, ∞P or 0P, P (fig. 493); often in comb-like or other groups; generally foliated and scaly. H. = 1 to 1·5; G. = 2·78 to 2·96. Leek-green to blackish green; streak greenish grey. C.c.: 21 alumina, 20 protoxide of iron, magnesia 18, silica 24, water 11. Tarfside, Bute, and Jura in Scotland. Cornwall, Cumberland, Wales, Fassa Valley, Urals, America.

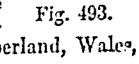

Fig. 493.

532. Pennine, $4\dot{M}g\ddot{S}i+\dot{M}g_3\ddot{A}l+5\dot{H}$.

Hexagonal, rhombohedral; R 65° 28′. Crystals chiefly very acute rhombohedrons, with or without the base. Lustre resinous. H. = 2 to 3; G. = 2·6 to 2·77. Streak greenish white. B.B. exfoliates, becomes white, and fuses on the edges to a white enamel. Completely sol. in warm s. acid. C.c.: 33·6 silica, 14·4 alumina, 39·4 magnesia, and 12·6 water; but with 5 to 6 iron protoxide replacing magnesia. Scalpa in Harris, Glen Lochy in Perthshire, Zermatt in Valais, Tyrol, Ala di Stura in Piedmont, Mauléon in the Pyrenees. *Leuchtenbergite* is the same. *Kämmererite*, with 5 to 8 chromium sesquioxide, is violet-blue or green; Unst, Siberia, Pennsylvania. *Rhodochrome* and *Tabergite* are also varieties.

533. Clinochlore (*Ripidolite*), $3\dot{M}g\ddot{S}i+\dot{M}g_3\ddot{A}l+4\dot{H}$.

Oblique prismatic, C. 76° 4′. ∞P 121° 28′. 0P : P 113° 59′; 0P : ∞P 192° 8′. Crystals −2P, P, 4P∞, 0P (*n*, *m*, *t*, P, fig. 494). Twins common; lustre vitreous or resinous. H. = 2 to 3; G. = 2·6 to 2·8. B.B. becomes white, and fuses on thin edges to a greyish yellow enamel. C.c.: 30·3 silica, 17·3 alumina, 40·3 magnesia, and 12·1 water. Edentian and Blair Athole in Scotland, Traversella in Piedmont, Akhmatovsk in Urals, West Chester in Pennsylvania. *Corundophyllite*, *Epichlorite*, and *Kotschubeyite* are varieties.

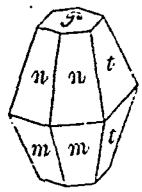

Fig. 494.

534. Pyrosclerite, $(\frac{2}{3}\dot{R}, \frac{1}{3}\ddot{R})_3\ddot{S}i_3+3\dot{H}$.

Right prismatic. Cl. basal, perfect; fracture uneven; brittle; sectile. H. = 3; G. = 2·7 to 2·8. Pearly; translucent. Apple-, emerald-, and grey-green. C.c.: alumina 13·4, chrome oxide 1·4, protoxide of iron 3·5, magnesia 31·6, silica 37, water 11. Porto-Ferraio in Elba, China.

535. Chonicrite.

Massive; crystalline-granular and globular-radiated. H. = 2·5 to 3; G. = 2·91. Weak silky. White, with yellowish spots; greenish blue. C.c.: 17·1 alumina, 22·6 magnesia, 12·6 lime, 35·7 silica, 9 water. B.B. fuses easily, with intumescence, to a grey glass. Decomposed by h. acid, with separation of silica. Colmonell (Ayrshire), Porto-Ferraio.

536. Pycnotrop.

Large grained aggregates. Cl. along two rectangular faces; fracture hackly, splintery. Greyish white to brown-red. Vitreous to greasy. H. = 2 to 2·3; G. = 2·6 to 2·7. C.c.: alumina 29·3, magnesia 12·6, potash 4·4, silica 45, water 7·8. Waldheim in Saxony.

537. Thuringite, $(\frac{1}{2}\dot{R}, \dot{H}_3+\frac{1}{2}(\ddot{A}l, \ddot{F}e))_4\ddot{S}i_3+4\dot{H}$.

Massive; scaly. H. = 2 to 2·5; G. = 3·2. Pearly. Olive-green to pistachio-green; streak paler. Very tough. Powder greasy. C.c.: alumina 16, peroxide of iron 14, protoxide of iron 33, silica 23, water 11. Schmiedefeld in Thuringia, Harper's Ferry on the Potomac, Hot Springs in Arkansas.

538. Delessite, $(\dot{F}e\frac{1}{4}, \dot{M}g\frac{3}{4})_2\ddot{S}i_2+(\ddot{A}l\frac{11}{15}, \ddot{F}e\frac{9}{15})\ddot{S}i+3\dot{H}+2\dot{M}g\dot{H}$.

Massive; scaly. H. = 2 to 2·5; G. = 2·6 to 2·89. Olive-green to dark green, passing to dark brick-red; streak light green. C.c.: alumina 16·3, protoxide of iron 12·6, magnesia 21, silica 31·5, water 15·8. Common in igneous rocks of Old Red Sandstone and Coal-measure age in Scotland. Oberstein, Zwickau, Lagrève near Mielin.

539. Cronstedtite, $\ddot{F}e\ddot{S}i+(\dot{F}e, \dot{M}g)_3\ddot{S}i+3\dot{H}$.

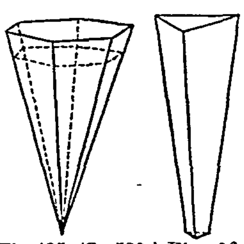

Fig. 495. (Sp. 539.) Fig. 496.

Rhombohedral; radiated columnar. In tapering hexagons, and hemihedral (figs. 495, 496). Cl. basal, perfect; elastic. H. = 2·5; G. = 3·3 to 3·5. Vitreous. Coal-black and brownish black; streak dark olive-green. C.c.: protoxide of iron 39, peroxide of iron 29, silica 22, water 11. Huel Maudlin in Cornwall, Przibram, Brazil (*Sideroschisolite*).

Talc and Serpentine Group.

540. Talc, $\dot{M}g_3\ddot{S}i_4+\dot{H}$.

Right prismatic (?); rarely found in six-sided or rhombic tables; generally massive, granular, or scaly. Rarely fibrous. Cl. basal, perfect; soft, sectile, and flexible in thin plates. H. = 1; G. = 2·6 to 2·8. Transparent in thin plates, and optically binaxal; pearly or resinous. Colourless, but generally greenish or yellowish white to apple- or olive-green. Feels very greasy. B.B. emits a bright light, exfoliates, and hardens (H. = 6), but is infusible; with cobalt solution becomes red. Not sol. in h. or s. acid before or after ignition. C.c.: 63·5 silica, 31·7 magnesia, and 4·8 water. Unst in Shetland, green; Cairnie in Aberdeenshire, brown; Greiner in Tyrol, Sala and Falun, the Pyrenees. Used as crayons, also for forming crucibles and for porcelain.

Steatite.—Massive. Grey, red, yellow, or green. Shetland, Sutherland, Portsoy, and near Kirkcaldy, Scotland; the Lizard Point, Cornwall; Briançon, Wunsiedel. Savage nations cut the steatite into culinary utensils.

Potstone is a mixture of talc, chlorite, and other minerals.

541. Picrophyll, $3\dot{R}\ddot{S}i+2\dot{H}$.

Right prismatic. H. = 2·5; G. = 3·75. Dark green. Foliated, shining. C.c.: magnesia 30·1, protoxide of iron 6·9, silica 49·8, water 9·8. Sala in Sweden.

542. Picrosmine, $2\dot{M}g\ddot{S}i+\dot{H}$.

Right prismatic, but massive. Cl. ∞P̆∞ perfect, less so in other directions; sectile. H. = 2·5 to 3; G. = 2·5 to 2·7. Translucent or opaque; vitreous, but pearly on ∞P̆∞. Greenish white, grey, or blackish green; streak colourless. Yields a bitter odour when breathed on; hence the name. C.c.: 55·8 silica, 36·1 magnesia, and 8·1 water. Presnitz in Bohemia, and Greiner in Tyrol.

543. Monradite, $4(\frac{4}{5}\dot{M}g, \frac{1}{5}\dot{F}e)\ddot{S}i+\dot{H}$.

Massive, foliated, translucent, and yellowish-grey. H. = 6; G. = 3·27. C.c.: silica 55·2, magnesia 31·9, protoxide of iron 8·8, water 4·1. B.B. infusible. Bergen in Norway.

544. Meerschaum, $2\dot{M}g_2\ddot{S}i_3+4\dot{H}$.

Fracture earthy; sectile. H. = 2 to 2·5; G. = 0·8 to 1 (when moist nearly 2). Opaque, dull. Yellowish and greyish white; streak slightly shining. Feels rather greasy, and adheres strongly to the tongue. C.c.: 54·2 silica, 24·7 magnesia, and from 9 to 21·7 water. Negropont, Anatolia, near Madrid and Toledo, Moravia, Wermland.

545. Aphrodite, $4\dot{M}g\ddot{S}i+\dot{H}$.

Soft and earthy. G. = 2·21. Milk-white; opaque. C.c.: 52·9 silica, 35·3 magnesia, 11·9 water. Långbau (Sweden), Elba.

546. Spadaite, $\dot{M}g_5\ddot{S}i_6+4\dot{H}$.

Massive; fracture splintery; sectile. H. = 2·5. Translucent; resinous. Red, with white streak. C.c.: 57 silica, 31·6 magnesia, 11·4 water. Capo di Bove near Rome.

547. Gymnite.

Massive. H. = 2 to 3; G. = 1·9 to 2·2. Translucent; resinous. Dull orange-yellow. C.c.: 41 silica, 37 magnesia, 22 water. Tyrol, Passau, Texas, Barehills near Baltimore. *Nickel Gymnite* has 29 of nickel oxide, replacing the water. Unst, Texas, Pennsylvania.

548. Saponite, $(\dot{F}e\dot{C}a\dot{M}g)_6\ddot{S}i_6+(\ddot{A}l_3\ddot{F}e)\ddot{S}i+13\dot{H}$.

Massive; sectile, and very soft. H. = 1·5; G. = 2·2 to 2·3. White, orange-yellow, pale green, and reddish brown. Feels greasy; does not adhere to the tongue; falls to pieces in water. C.c.: silica 40·8, alumina 7·5, ferric oxide 3·9, magnesia 20·6, water 22·7. Occurs in all the above colours in the later igneous rocks of Scotland, commonly. Lizard Point and St Clear in Cornwall, and Dalecarlia in Sweden. *Pimelite* has 2·8 oxide of nickel.

549. Serpentine, $2\dot{M}g\ddot{S}i+\dot{M}g\dot{H}_3$.

Crystallization uncertain; pseudomorphic after olivine, &c.; generally massive, and granular or fibrous; fracture flat-conchoidal, uneven, or splintery; sectile, and slightly brittle. H. = 3 to 3·5; G. = 2·5 to 2·7. Translucent to opaque; dull resinous. Green, grey, yellow, red, or brown; often in spots, stripes, or veins; streak white, shining. Feels greasy, and does not adhere to the tongue. In the closed tube yields water, and becomes black. C.c.: 43·5 silica, 43·5 magnesia, and 13 water; but with 1 to 8 iron protoxide, and also carbonic acid, bitumen, and chrome oxide.

Varieties are—(1) *Noble Serpentine*, brighter coloured, $16H_2O$, and more translucent; (2) *Picrolite*, or fibrous (H. = 3·5 to 4·5); (3) *Common*, or compact; (4) *Chrysotile* (*Baltimorite*, *Metaxite*), in fine asbestiform fibres, easily separated, with a metallic or silky lustre (G. = 2·219).

Common in Shetland, Urquhart, Portsoy, Ballantrae; Lizard Point in Cornwall; Norway, Sweden, North America. Chrysotile at Colafirth and Fetlar, Shetland, Portsoy, Towanreiff, in Scotland; Reichenstein in Silesia, the Vosges Mountains, and North America. Serpentine is often a product of decomposition, or pseudomorph of various minerals, as augite, hornblende, olivine, spinel, enstatite, garnet, &c. It forms whole rocks and mountains, and is manufactured into various ornamental articles.

550. Marmolite, $3\dot{M}g\ddot{S}i+2\dot{M}g\dot{H}_2$.

Oblique prismatic; often foliated. H. = 2·5 to 3; G. = 2·41 to 2·47. Lustre pearly. Greenish white, bluish white, and asparagus-green. C.c.: silica 42·1, magnesia 38·5, water 17·5. In veins in serpentine of Urquhart and Portsoy (Scotland) Cornwall, Finland, Hoboken.

551. Antigorite.

Thin flat laminæ. H. = 2·5; G. = 2·6. Translucent. Green with brown spots; streak white. C.c.: silica 40·8, magnesia 36·3, protoxide of iron 5·8, water 12·4. Antigorio in Piedmont.

552. HYDROPHITE, $(\dot{M}g, \dot{F}e)_4\ddot{S}i_3 + 4\dot{H}$.

Massive and fibrous. H. = 3 to 4; G. = 2·65. Mountain-green to blue-black; streak paler. C.c.: silica 36·2, magnesia 21·1, protoxide of iron 22·7, water 16. Taberg in Sweden, New York.

553. VILLARSITE, $2\dot{M}g_2\ddot{S}i + \dot{H}$.

Right prismatic; crystals P, 0P, meeting at 136° 32′, often twins in triple combination; also granular. H. = 3; G. = 2·9 to 3. Translucent. Greenish to greyish yellow. C.c.: silica 39·6, magnesia 47·4, protoxide of iron 3·6, water 5·8. Totaig, Ross-shire; Traversella, Piedmont; Forez, France.

554. PYRALLOLITE.

Oblique prismatic, C 72° 56′; columnar and granular. Cl. basic and hemidomatic, meeting at 94° 36′; fracture splintery; brittle. H. = 3·5 to 4; G. = 2·6. Translucent on edges; resinous. Greenish to yellow-grey. C.c.: silicate of magnesia and water. Storgard in Finland.

555. DERMATINE, $(\dot{M}g, \dot{F}e)\ddot{S}i + 2\dot{H}$.

Reniform; stalactitic; fracture conchoidal; brittle. H. = 2·5; G. = 2·1. Resinous. Blackish green; streak yellow. Does not adhere to tongue. C.c.: silica 38, magnesia 22, protoxide of iron 12, water 23. Waldheim in Saxony.

556. CHLOROPHÆITE, $\dot{R}\ddot{S}i + \ddot{R}_2\ddot{S}i_3 + 4\dot{H}$.

Massive, rarely reniform. Coating or filling up geodes in amygdaloidal cavities. H. = 1·5; G. = 2·02 to 2·3. Sectile; fracture conchoidal. On first exposure transparent and olive-green to orange-yellow, but soon changes to black and opaque, splitting in so doing. Vitreous to shining. B.B. melts to a black glass. C.c.: silica 36·2, alumina 8·9, peroxide of iron 13·8, protoxide of iron 2·4, lime 3·8, magnesia 10, water 21·8. Rum and Canna in the Hebrides, Giant's Causeway. The original mineral from Rum has 22·8 iron peroxide and no alumina.

557. FORCHHAMMERITE, $\dot{F}e\ddot{S}i + 6\dot{H}$.

Granular massive. Subresinous to dull. Dark green. H. = 2; G. = 1·8. C.c.: silica 32·8, protoxide of iron 21·6, magnesia 3·4, water 42·2. Faroes.

558. KIRWANITE.

Fills druses in amygdaloids with divergent sheaf-like crystals. H. = 2; G. = 2·9. Opaque. Olive-green to dark green. C.c.: silica 40·5, alumina 11·1, protoxide of iron 23·9, lime 19·8, water 4·4. Loch Baa in Mull; Mourne Mountains in Ireland.

559. GLAUCONITE.

Round grains. Dull resinous. Light green. C.c.: silicate of protoxide of iron and potash. Ashgrove near Elgin; greensand of England, France, Germany, and America.

560. CELADONITE, $3\dot{R}\ddot{S}i_2 + \ddot{R}_2\ddot{S}i_3 + 5\dot{H}$.

Massive, forming crusts, as of agates. Earthy, sectile. H. = 1 to 2; G. = 2·6 to 2·8. Opaque, shining. Bright green. Feels greasy. C.c.: silica 54, alumina 3·8, ferric oxide 11·9, ferrous oxide 5·4, magnesia 6·8, potash 7·9, water 10. Orkney, Rum, and Fifeshire in Scotland. Giant's Causeway, Verona, Faroes, Iceland, Cyprus, Bohemia.

561. STILPNOMELANE, $2(\dot{F}e, \dot{M}g)\ddot{S}i + \ddot{A}l\ddot{S}i + 2\dot{H}$.

Massive or radiating-foliated. One cl. perfect; brittle. H. = 3 to 4; G. = 3 to 3·4. Opaque; vitreous to pearly. Greenish black. C.c.: 45·3 silica, 6·9 alumina, 38·3 iron protoxide (with 2 to 3 magnesia), and 9·5 water. Zuckmantel in Silesia and Weilburg in Nassau.

562. CHAMOISITE.

Oolitic and massive. H. = 3; G. = 3 to 3·4. Greenish grey to black; streak paler. C.c.: silica 14·3, alumina 7·8, protoxide of iron 60·5, water 17·4. Chamoison (or Chamoson) in Valais, the Vosges. *Berthierine* has 75 protoxide of iron and 5 of water; Moselle.

AUGITE AND HORNBLENDE GROUP.[1]

Hornblende and augite rather represent groups of mineral substances than single species. They are best distinguished when imperfectly formed, by the cleavage and angles of the prisms.

563. ENSTATITE (*Chladnite*), $\dot{M}g\ddot{S}i$.

Right prismatic. ∞P 92° to 93°; crystals ∞P̄∞ (*a*), ∞P̆∞ (*b*), ∞P (*m*), ½P̆∞ (*k*), ⅔P̄∞ (*q*), ⅙P̆∞ (*ψ*), ⅔P (*τ*) (fig. 497). Usually imbedded, or indistinct granular masses. Cl. macrodiagonal very perfect, prismatic ∞P distinct, brachydiagonal imperfect. H. = 5·5; G. = 3·1 to 3·3. Translucent throughout, or only on the edges; vitreous or pearly on the more perfect cleavage-planes. Colourless, greyish or greenish white, yellowish, or brown. Not affected by acids. B.B. almost infusible.

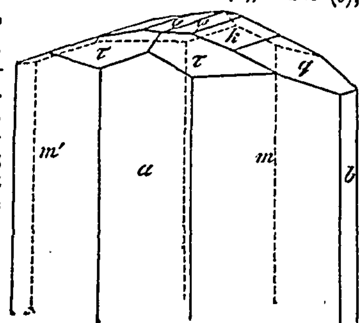

Fig. 497.

C.c.: 60 silica and 40 magnesia, but with 6 to 8 iron protoxide, 1 to 2 alumina, and 1 or 2 water. In olivine and serpentine rocks in Moravia, the Harz (Baste), and the Pyrenees.

564. BRONZITE (*Schiller Spar, Bastite*), $(\dot{M}g, \dot{F}e)\ddot{S}i$.

Right prismatic. ∞P 94°; only granular and foliated. Cl. brachydiagonal perfect, prismatic less so; fracture uneven, splintery. H. = 4 to 5; G. = 3 to 3·5. Translucent on thin edges; metallic pearly. Green, inclining to yellow or brown. Imperfectly sol. in h. acid, wholly in s. acid. B.B. becomes magnetic, and fuses in very thin splinters. C.c.: 43 silica, 26 magnesia, 2·7 lime, 7·4 iron protoxide, 3·3 iron peroxide, 2·4 chrome oxide, 1·7 alumina, and 12·4 water. *Bastite* is possibly altered enstatite. Belhelvie and Black Dog in Aberdeenshire, Baste, Tyrol, Baireuth, Styria.

565. PAULITE (*Hypersthene*), $(\dot{F}e, \dot{M}g)\ddot{S}i$.

Right prismatic. ∞P (*m*) 93° 30′, P̆2 (*c*), 2P̆2 (*i*), ⅔P̆⅔ (*u*), ∞P̆2 (*n*), ¼P̆∞ (*h*), ∞P̄∞ (*a*), ∞P̆∞ (*b*), ½P̆∞ (*k*), 2P̄∞ (*d*). Granular or disseminated. Cl. brachydiagonal very perfect, prismatic ∞P distinct, macrodiagonal very imperfect. H. = 6; G. = 3·3 to 3·4. Opaque or translucent on thin edges; vitreous or resinous, but metallic pearly on the cleavage planes, of which one is copper-coloured to violet or silvery. Pitch-black and greyish black; streak greenish grey or pinchbeck-brown, inclining to copper-red. Not affected by acids. B.B. melts more or

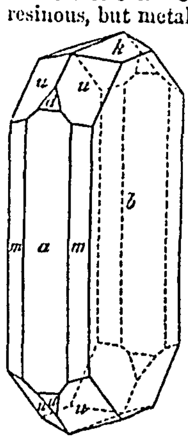

Fig. 498.

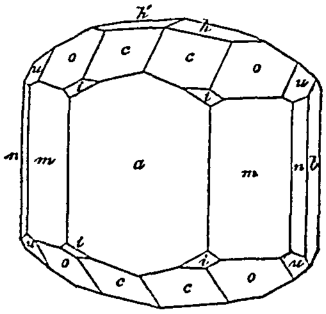

Fig. 499.

less easily to a greenish black glass, often magnetic. C.c.: generally 46 to 58 silica, 0 to 4 alumina, 11 to 26 magnesia, 1 to 5 lime, 13 to 34 iron protoxide, 0 to 6 manganese protoxide. Portsoy and Craig Buroch in Banffshire, Barra Hill in Aberdeenshire, Paul's Island, Labrador, and Greenland. Crystals occur in sanadine bombs at Lake Laach (*Amblystegite*), and in meteorites of Breitenbach. Hypersthene rock in Norway, Elfdal in Sweden, Cornwall (?), the Harz, and Canada. Chemically enstatite and paulite pass into one another; the essential difference is that the axial dispersion is uniformly $\rho < \nu$ in the former, and the opposite in the latter.

566. WOLLASTONITE (*Tabular Spar*), $\dot{C}a\ddot{S}i$.

Oblique prismatic, C 84° 30′. ∞P 87° 18′, 0P (*u* or *h′*), ∞P̄∞ (*c* or *p*), ∞P⅔ (*z*) 110° 7′, ∞P°2 (*x* or *e′*) 51°, −P̄∞ (*v*) 44° 27′, ½P̄∞ (*a*) 69° 56′ (fig. 500). Rarely crystallized, mostly broad prismatic or laminar. Frequently fibrous. Cl. along 0P and ∞P°∞ perfect, but planes uneven or rough; meet at 95° 23′. H. = 4·5 to 5; G. = 2·8 to 2·9. Translucent; vitreous or pearly on cleavage. White, inclining to grey, yellow, red, or brown; streak white.

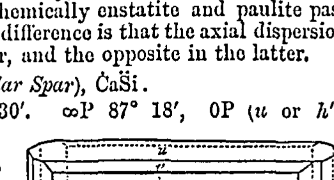

Fig. 500.

[1] Hornblende and augite agree so closely in crystalline forms and chemical composition that it has sometimes been proposed to unite them in one species. They, however, differ too widely to justify their union. Hornblende is more fusible, and ranges lower in specific gravity (hornblende from 2·931 to 3·415, augite 3·195 to 3·525). Though both possess a cleavage parallel to their vertical prisms, yet these differ in angular dimensions:—hornblende 124° 12′, augite 87° 6′. They also occur in distinct geognostic positions:—hornblende in rocks containing quartz or free silica, and mostly with minerals that are neutral compounds of silica, as orthoclase and albite; augite in rocks that do not contain free silica, and mostly with minerals that are not neutral silicates, as labradorite, olivine, and leucite. Hence there are two distinct series of massive or igneous rocks:—the hornblende series, including granite, syenite, diorite, diorite-porphyry, and red porphyry; and the augite series or hypersthene rock, gabbro, dolerite, nepheline rock, augite-porphyry, and leucite-porphyry.

Phosphoresces with heat or friction; gelatinizes in h. acid. B.B. difficultly fusible to a semitransparent glass. C.c.: 51·7 silica and 48·3 lime, but with 0 to 2 magnesia and 0 to 2 iron protoxide. Glen Gairn, Crathie, &c., in Aberdeenshire, Urquhart in Inverness, Skye, Banat, Finland, Sweden, Vesuvius (fig. 501), North America, Ceylon, Capo di Bove.

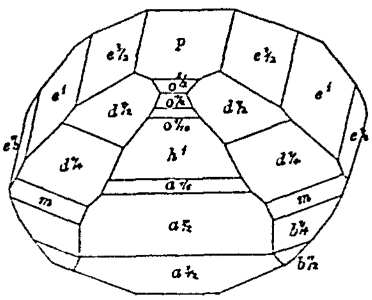

Fig. 501 (sp. 566).

567. Augite (*Pyroxene*), $\dot{R}\dddot{Si}=(\dot{C}a, \dot{M}g, \dot{F}e)\dddot{Si}$.

Oblique prismatic, C 74°11′. ∞P 87° 6′; P (*s* : *s*) 120° 48′; − P (*u*) 131° 30′; 2P (*o*) 95° 48′; 0P; 3P; ∞P°∞. In fig. 130 ∞P (*M*), ∞P°∞ (*r*), ∞P^c∞ (*l*), P(*s*); also various twins and hemitropes of same form (figs. 191, 502, 503). Almost always prismatic, imbedded, or attached; also granular, columnar, and scaly. Cl. prismatic along ∞P (with

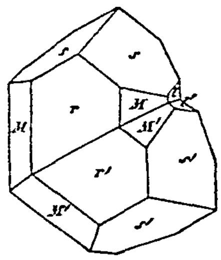

Fig. 502.

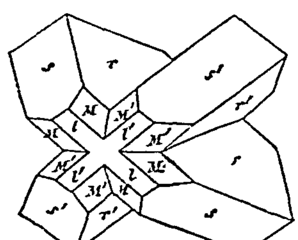

Fig. 503.

angles of 87° 6′ and 92° 54′), generally rather imperfect; orthodiagonal and clinodiagonal imperfect. H. = 5 to 6; G. = 3 to 3·5. Pellucid in all degrees; vitreous; in some pearly on ∞P°∞. Colourless, and white, but usually grey, green, or black. B.B. generally fusible; imperfectly soluble in acids. C.c. generally as follows:—

	Silica.	Lime.	Magnesia.	Iron.
(*a*) Magnesia augite	56·22	25·54	18·24	...
(*b*) Magnesia-iron augite	52·72	23·81	8·50	14·97
(*c*) Iron augite	49·06	22·29	...	28·65

Analysis gives 47 to 56 silica, 20 to 25 lime, 5 to 15 magnesia, 1 to 20 iron protoxide, with 0 to 3 manganese protoxide and 0 to 8 alumina. The alumina, chiefly found in very dark green or black augites, may in some replace either silica or part of the silicate.

The more important varieties are—

Diopside.—Greyish or greenish white, to pearl-grey or leek-green; streak white. Crystallized or broad columnar, or concentric lamellar. Transparent to translucent on the edges. Not affected by acids. B.B. fuses to a whitish semitransparent glass. C.c.: generally lime 26 and magnesia 18·5, with 55·5 silica. Mussa Alp (*Mussite*) and Ala (*Alalite*) in Piedmont, Schwarzenstein in Tyrol, Scandinavia, Finland, Urals, and North America.

Malacolite, Sahlite.—White, green, rarely yellow, brown, or red; streak white. Translucent, or only on the edges; vitreous, inclining to pearly. Seldom crystallized, mostly columnar

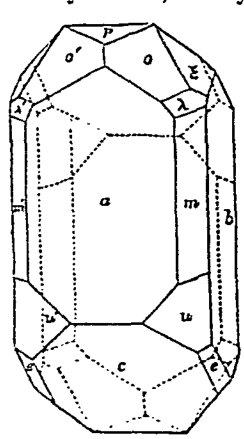

Fig. 504.

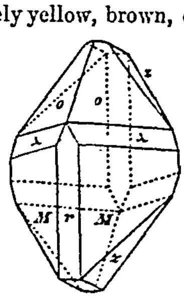

Fig. 505.

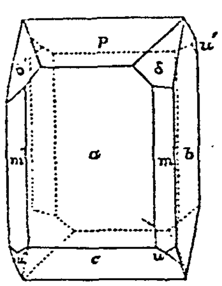

Fig. 506.

or lamellar. B.B. melts to a dark-coloured glass. Malacolite common in primary limestones in Scotland, as at Shinness, Ledbeg (fig. 505), and Glen Tilt. Fassa Valley (*Fassaite*), Piedmont, Arendal, Philipstadt in Sweden; Lake Baikal (*Baikalite*); near Lake Lherz in the Pyrenees (*Lherzolite*); Sala (or Sahla) in Sweden (*Sahlite*); Shinness (figs. 504, 506), Glenelg, Tiree, in Scotland; Tyrol; North America. *Coccolite* is a granular sahlite or augite.

Augite.—Leek-green, greenish black, or velvet-black, rarely brown; streak greenish grey. Vitreous to resinous; translucent or opaque. Only slightly affected by acids. B.B. fuses to a black, often magnetic glass. An essential component of many rocks, as basalt, dolerite, clinkstone, and augite porphyry; Germany, Auvergne, Vesuvius; St Kilda, Rum, Tiree, Dalnain, and Urquhart in Scotland. Augite crystals in basalt often contain very many microscopic crystals and glasses; also pores with fluid carbonic acid.

Hudsonite.—Cleavable lamellar, and jet-black, with green streak and bronzy tarnish, from the Hudson river; the most highly ferruginous variety.

Amianthus.—Some asbestiform minerals are augite, but the greater number hornblende.

Breislackite.—Fine yellowish or brown woolly crystals. Vesuvius, and Capo di Bove near Rome.

568. Diallage, $(\dot{C}a, \dot{M}g, \dot{F}e)\dddot{Si}$.

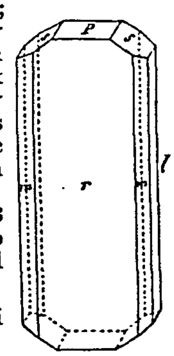
Like augite, and only a variety with very perfect cleavage in the clinodiagonal, which forms with a second cleavage an angle of 87°. Lustre metallic pearly; colour grey or pinchbeck-brown. H. = 4; G. = 3·23. B.B. melts easily to a greyish or greenish enamel. C.c.: 50 to 53 silica, 1 to 5 alumina, 15 to 23 magnesia, 11 to 20 lime, and 5 to 20 manganese protoxide. Constituent of the augite rock of the Cuchullins in Skye and of the gabbro of Unst and Ayrshire. Baste in the Harz, Silesia, the Alps, Apennines, and Urals. *Vanadine-Bronzite*, containing soda and vanadic acid, is similar. At Craig Buroch (Banffshire) diallage passes in paulite.

569. Jeffersonite.

Oblique prismatic. Cl. prismatic ∞P 87° 30′, and orthodiagonal. H. = 4·5; G. = 3·3 to 3·5. Dark olive-green, brown to black. Lustre greasy. A manganese and zinc augite, with 10·2 protoxide of manganese, and 10·15 oxide of zinc. Sparta in New Jersey.

570. Acmite, $2\ddot{F}e\dddot{Si}_3+3\dot{R}\dddot{Si}$.

Oblique prismatic. Crystals long often acute-pointed prisms. ∞P 87° 15′, ∞P̄∞ (*r*), P(*s*), 6P (*o*), − 6P^{c}3(*z*) (figs. 507, 508). Cl. like augite. H. = 6 to 6·5; G. = 3·4 to 3·6. Nearly opaque; vitreous. Brownish or greenish black; streak greenish grey. Imperfectly soluble in acids. B.B. fuses easily to a black magnetic glass. C.c.: 52 silica, 30 iron peroxide, 5 iron protoxide, and 13 soda, but with 1 to 3 manganese peroxide, and also 3 to 4 titanic acid. Eger and Porsgrund in Norway.



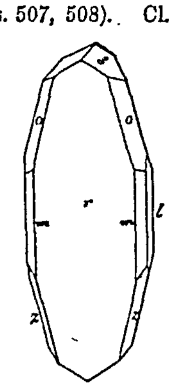


Fig. 507. (Sp. 570.) Fig. 508.

571. Ægerine, $\dot{R}_2\dddot{Si}_5+\ddot{R}\dddot{Si}+2\dot{N}a\dddot{Si}$.

Oblique prismatic; striated or reed-like prisms of 86° 30′ to 87° 45′. Cl. orthodiagonal perfect, less distinct clinodiagonal, and prismatic. H. = 5·5 to 6; G. = 3·4 to 3·5 or 3·6. Vitreous; translucent on edges, or opaque. Greenish black. B.B. fuses easily, colouring the flame yellow. Scarcely affected by acids. C.c.: 49 silica, 31·7 iron peroxide, 6·6 iron (and manganese) protoxide, and 12·7 soda, with a little magnesia and potash. Has the same relation to augite as arfvedsonite to hornblende. Near Brevig and Barkevig in Norway.

572. Spodumene, $4\ddot{Al}\dddot{Si}_3+3(\dot{L}i, \dot{N}a, \dot{K})\dddot{Si}$.

Oblique prismatic, C 69° 40′. ∞P 87° (fig. 509). Cl. prismatic ∞P and orthodiagonal, perfect; chiefly massive or foliated. H. = 6·5 to 7; G. = 3·1 to 3·2. Translucent; vitreous or pearly. Pale greenish grey or white to apple-green; streak white. B.B. intumesces slightly, tinging the flame momentarily purplish red, and fuses easily to a colourless glass. Not affected by acids. C.c.: 65 silica, 28·7 alumina, and 6·3 lithia. Killiney near Dublin, Utö in Sweden, Tyrol. *Killinite* (sp. 651), from Killiney, seems to be decomposed spodumene.

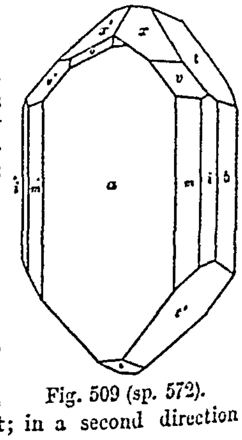

Fig. 509 (sp. 572).

573. Petalite (*Castor*), $4\ddot{Al}\dddot{Si}_6+3(\dot{L}i, \dot{N}a)\dddot{Si}_2$.

Oblique prismatic. Castor has C 67° 34′ and ∞P 86° 20′, in irregular rectangular prisms, petalite being massive and coarse granular. Cl. basal, distinct; in a second direction

(meeting at 141½°) less so. H. = 6·5 ; G. = 2·4 to 2·5. Greenish, greyish, or reddish white to pale red. Translucent; vitreous or pearly. B.B. melts easily into a porous obscure glass, colouring the flame red. Not affected by acids. C.c.: 78·3 silica, 17·4 alumina, 3·2 lithia, and 1·1 soda. Utö, Bolton in Massachusetts, York in Canada. *Castor* in Elba. *Milarite*, valley of Milar, Switzerland.

574. RHODONITE (*Manganese-Spar*), $\dot{M}n\ddot{S}i$.

Anorthic. $\infty\breve{P}\infty\,(a)$; $\infty\bar{P}\infty\,(b)$; $0P\,(c)$; $\infty P'\,(u)$; $\breve{P}'\infty\,(k)$; $\bar{P}\infty\,(s)$; $'\bar{P}'\infty\,(o)$; $m'\bar{P}'\infty\,(t)$: $a:b$ 111° 9′ ; $c:a$ 93° 28′ ; $n:a$ 106° 19′; but chiefly massive or granular. Cl. $\infty P\infty$ and $0P$, meeting at 87° 38′, perfect; brittle. H. = 5 to 5·5; G. = 3·5 to 3·7. Translucent; vitreous or partly pearly. Dark rose-red, bluish red, or reddish brown. Not affected by acids. B.B. fusible. C.c.: 45·8 silica and 54·2 manganese protoxide, with 3 to 5 lime and 0 to 6 iron protoxide. St Marcel, Långban, Ekaterinburg, the Harz, and New Jersey. *Bustamite*, pale greenish or reddish grey, with 14 lime, Mexico; *Fowlerite*, New Jersey, with 7 to 11 iron protoxide; and *Paisbergite*, Sweden, are varieties. *Hydropite*, *Photicite*, *Allagite*, and *Horn-Manganese* are mere mixtures.

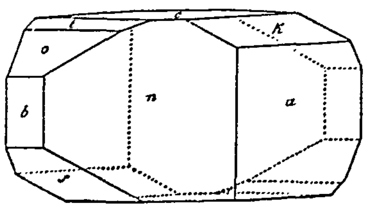

Fig. 510.

575. BABINGTONITE, $9(\dot{C}a, \dot{F}e, \dot{M}n)\ddot{S}i + \ddot{F}e\ddot{S}i_3$.

Anorthic. Crystals very low eight-sided prisms, small, attached. $g:h$ 90° 24′; $c:a$ 87° 27′; $a:b$ 112° 12′; $b:d$ 81° 8′; $c:d$ 150° 10′ (fig. 511). Cl. basal (c), very perfect; also along b. H. = 5·5 to 6; G. = 3·3 to 3·4. Thin laminæ translucent. Splendent vitreous; black. Not affected by acids. B.B. fuses easily with effervescence to a black magnetic bead. C.c.: 50·7 silica, 11 iron peroxide, 10·3 iron protoxide, 7·7 manganese protoxide, and 20·3 lime, in the Arendal specimens; one from Nassau gave about 17 of peroxide, with protoxides only 11. Tongue (Sutherland), Portsoy (Banffshire), Arendal, Nassau, and Gouverneur (New York).

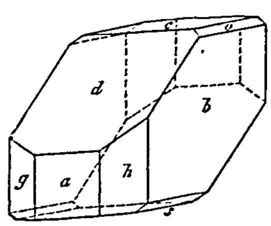

Fig. 511.

576. SZABOITE, $11\ddot{F}e\ddot{S}i_3 + 2\dot{C}a\ddot{S}i$.

Anorthic. $\infty P'\,(l)$; $\infty'P\,(m)$ 88° 40′; $\infty\breve{P}\infty\,(b)$; $\infty\bar{P}\infty\,(a)$; $P'\,(p)$; $'P\,(o)$; $2'\breve{P},\infty\,(y)$; $2\breve{P}'\infty\,(x)$ (fig. 512). H. = 6·5; G. = 3·5. Brownish red to reddish yellow. Pleochroic. C.c.: silica 52·4, peroxide of iron 44·7, lime 3·1. Slightly sol. in s. acid, more so in h. acid. Calvario on Etna, Mont Dore.

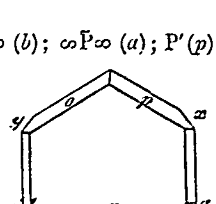

Fig. 512 (sp. 576).

577. ANTHOPHYLLITE, $3\dot{M}g\ddot{S}i + \dot{F}e\ddot{S}i$.

Right prismatic. ∞P 124° 30′. Cl. macrodiagonal, perfect. Clove-brown to purplish brown and leek-green. Translucent; radiating and foliated. Pearly on cl. plane. H. = 5·5; G. = 3·2. C.c.: silica 55·9, protoxide of iron 16·7, magnesia 27·8. B.B. very difficultly fusible. Hillswick, Shetland; Kongsberg and Modum, Norway; Greenland, and the United States.

578. HORNBLENDE.

Oblique prismatic (figs. 513 to 517; see also fig. 192). Distinct cleavage in several directions. H. = 4 to 6, but generally 5 (will scratch with knife); G. = 2·5 to 4·0, but mostly high. Mostly coloured. Lustre vitreous, in some silky or metallic pearly. Sol., but not very readily, in acids; more or less easily fusible. C.c.: anhydrous silicates and aluminates of lime, magnesia, iron protoxide; more sparingly of soda, yttria, and manganese protoxide. The chief species form by their decomposition highly fertile soils.

Amphibole.—Oblique prismatic, C 75° 10′. ∞P 124° 30′, P 148° 30′. The crystals short and thick, or long and thin prismatic; formed especially by $\infty P\,(m)$, $\infty P^c\infty\,(x)$, and bounded on the ends chiefly by $0P\,(p)$ and $P\,(r)$. Twins common, with the chief axis the twin axis. Very often radiated, fibrous, or columnar, or granular. Cl. prismatic along ∞P 124½°, very perfect; orthodiagonal and clinodiagonal very imperfect. H. = 5 to 6; G. = 2·9 to 3·4. Pellucid in all degrees; vitreous, but sometimes pearly or silky. Colourless or white, but usually some shade of grey, yellow, green, brown, or black. B.B. fuses, generally intumescing and boiling, to a grey, green, or black glass. Those containing most iron are most fusible, and are also partially sol. in h. acid, which scarcely affects the others. C.c. very variable; the silica is partly replaced by alumina, specially in the green or black varieties; RO is chiefly MgO, CaO, and FeO. Lime is the most

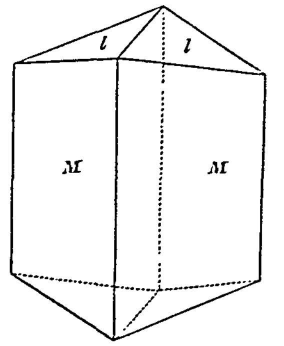

Fig. 513.

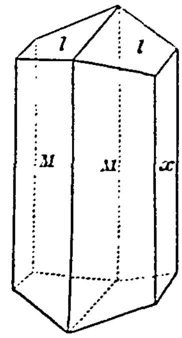

Fig. 514.

constant element, in most from 10 to 12; magnesia and iron protoxide replace each other, the one increasing as the other diminishes. With $4\ddot{S}i$ and $\dot{R} = 2\dot{M}g + 1\dot{C}a + 1\dot{F}e$, the average composition is 53·6 silica, 17·8 magnesia, 12·5 lime, and 16·1 iron protoxide; but

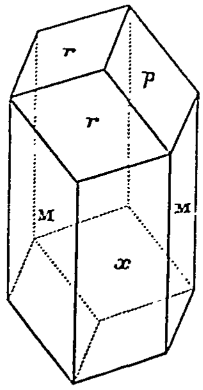

Fig. 515.

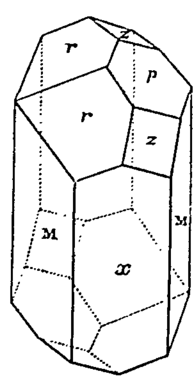

Fig. 516.

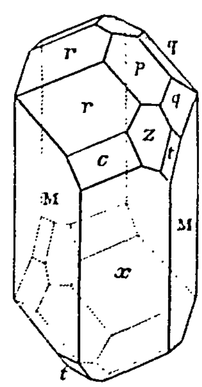

Fig. 517.

analyses give 40 to 60 silica, 0 to 17 alumina, 0 to 30 magnesia, 10 to 15 lime, 0 to 36 iron protoxide (or peroxide), and 0 to 4 manganese protoxide, 0 to 8 soda, 0 to 3 potash, and 0 to 1·5 fluorine with a little water.

The more important varieties are—

Amianthus, *Asbestos*, and *Byssolite*, $2\dot{M}g\ddot{S}i + \dot{C}a\ddot{S}i$. Fine fibrous. White, grey, or green. The fibres often easily separable, elastic, and flexible. Unst, Shinness, Portsoy, Savoy, Tyrol, Corsica.

Tremolite, *Grammatite*, $3\dot{M}g\ddot{S}i + \dot{C}a\ddot{S}i$, with 58·35 silica, 28·39 magnesia, and 13·26 lime. White, grey, green; in long prismatic crystals, often striated longitudinally. Pearly or silky; semi-transparent or translucent. B.B. fuses readily to a white or nearly colourless glass. Loch Shin (Sutherland), Glen Tilt, Glenelg, Tiree, Cornwall, Cumberland, Sweden, the Alps, Pyrenees, Silesia, Siberia, North America.

Nephrite, or *Jade*, is a tough, compact, fine-grained tremolite, with H. = 6 to 6·5; G. = 2·9 to 3·1. Fracture close splintery. Very tenacious. Translucent; dull to resinous. Leek-green to blackish green. Feels slightly greasy. Formerly made into ring-stones, amulets, idols, and war axes. New Zealand, China, Mexico, Peru, Balta (Shetland).

Actinolite, *Actinote*, or *Strahlstein* $(\dot{C}a, \dot{M}g, \dot{F}e)\ddot{S}i$. Colour green, inclining to black, grey, or brown. Translucent throughout, or only on the edges. Long prismatic crystals, or radiated-columnar masses. B.B. melts to a greenish or blackish enamel. Fethaland and Colafirth and Hillswick (Shetland), Oronsay, Ord Ban (Inverness), Sweden, Tyrol, North America.

Hornblende.—$6\dot{R}\ddot{S}i + \ddot{R}_2\ddot{S}i_3$. Green or black, seldomer brown or grey. G. = 3·1 to 3·3. B.B. fuses rather easily to a yellow, greenish, or black enamel. Three varieties are distinguished. (a) The noble or *Pargasite*, pale celadon- or olive-green, and strong pearly or vitreous lustre; at Pargas in Finland, Tyrie in Scotland. (b) Common hornblende, dark leek- or blackish-green, opaque; streak greenish grey. A constituent of many rocks, as in Norway, the Alps, and Scottish Highlands (Ballater, Ben Arihaar, Glenbucket, Colafirth). (c) Basaltic, foliated, with bright even cleavage, opaque, velvet-black; streak grey or brown. Generally contains alumina (9 to 15) and much (5 to 11) iron peroxide. In basalt and volcanic rocks. Etna, Vesuvius, Rhineland, Bohemia.

579. Arfvedsonite, $\dot{R}\ddot{S}i+\dot{F}e\ddot{S}i_3$.

Oblique prismatic. ∞P; $\infty P^6\infty$; P; $2P^6\infty$ 120° 24′; 0P. Cl. ∞P 124° 22′, perfect; also 0P. Massive. Black; opaque. Vitreous. H. = 6; G. = 3·44. C.c.: silica 43, alumina 4·5, peroxide of iron 3·8, protoxide 34, lime 5·7, soda 8·5. Streak dark blue-grey. Fusible in fine splinters in the flame of a candle. B.B. intumesces and melts easily to a black magnetic globule. Not sol. in acids. Kangerdluarsuk in Greenland, Frederiksvärn, Arendal, El Paso in Colorado.

580. Pilolite, $4\dot{M}g\ddot{S}i_2+\ddot{\ddot{A}}l\ddot{S}i_2+15\dot{H}$.

Felted or matted fibres more or less dense. Cream yellow to buff. Dull; extremely tough; absorbs water like a sponge. H. = 1 to 2·5; G. = ·63 to 1·34. Structure varies considerably, and has given rise to trivial names, as mountain paper, mountain leather, mountain flesh, rock cork, &c. *Mountain Paper* occurs in thin sheets at Boyne Castle near Banff; *Mountain Leather*, Burn of the Cairn (Cabrach), Tod Head (Kincardineshire), Leadhills, Strontian; *Rock Cork*, Portsoy and Boyne Castle, Saxony, and Sweden. C.c.: silica 51·6, alumina 8·6, ferrous oxide 2·88, magnesia 10·2, water 23·3.

581. Krokidolite, $3\dot{F}e\ddot{S}i+(\dot{N}a,\dot{M}g)\ddot{S}i_2+2\dot{H}$.

Delicate, easily separable, but tough fibres; elastic. H. = 4; G. = 3·2 to 3·3. Translucent; silky. Indigo-blue; streak lavender. B.B. fuses easily to a black magnetic glass. C.c.: silica 50·3, iron protoxide 35, magnesia 2·2, soda 6·7, water 5·8. Stavern in Norway, Greenland. A fibrous yellow mineral from Orange river, South Africa, has been referred here; its fibres are not separable, and its hardness is 7. *Abriachanite*, a very similar mineral, of blue colour, occurs near Inverness.

582. Glaucophane, $9\dot{R}\ddot{S}i+2\ddot{\ddot{A}}l\ddot{S}i_3$.

Oblique prismatic. Cl. prismatic, perfect; fracture conchoidal. H. = 5·5; G. = 3·1. Translucent; vitreous to pearly. Indigo-blue, grey, bluish black. B.B. becomes brown, fusing easily to olive-green glass. C.c.: silica 56·5, alumina 12·2, protoxide of iron 10·9, magnesia 8, soda 9·3. Island of Syra.

583. Hermannite, $\dot{M}n\ddot{S}i$.

Granular and arborescent. Rose-red. G. = 3·4. C.c.: protoxide of manganese 46·7, silica 48·9, lime 2, magnesia 2·4. Cummington in Massachusetts.

584. Grunerite, $\dot{F}e\ddot{S}i$.

Asbestiform. G. = 3·7. Brown; silky lustre. C.c.: protoxide of iron 51·55, silica 45·45. Mt. des Maures (Var).

585. Iolite (*Cordierite, Dichroite*), $\ddot{\ddot{A}}l\ddot{S}i_3+2(\dot{M}g,\dot{F}e)\ddot{S}i$.

Right prismatic. ∞P (*P*) 119° 10′, middle edge of P 95° 36′. Form ∞P (*T*), $\infty \breve{P}\infty$ (*l*), 0P (*m*); and this with $\infty \bar{P}\infty$ (*k*), $\infty \breve{P}3$ (*d*), $\breve{P}\infty$ (*n*), and $\frac{1}{2}P$ (*s*), (fig. 518); short, prismatic. Cl. $\infty \bar{P}\infty$ distinct, traces along $\breve{P}\infty$; fracture conchoidal or uneven. H. = 7 to 7·5; G. = 2·5 to 2·7. Transparent or translucent; vitreous, inclining to resinous. Colourless, but chiefly dark blue, or violet, green, brown, yellow, and grey. Often with distinct trichroism; on 0P blue, on $\infty \breve{P}\infty$ grey, and on $\infty \bar{P}\infty$ yellowish. B.B. fuses difficultly to a clear glass; slightly affected by acids. C.c.: 48 to 51 silica, 29 to 33 alumina, 8 to 13 magnesia, 1 to 12 iron protoxide. Cabo de Gata in Spain, Bodenmais (*Peliom*), Orijerfvi in Finland (*Steinheilite*), Norway, Sweden, Greenland, North America, and Siberia. Small rolled masses of an intense blue colour and transparent, found in Ceylon, are the *Sapphire d'Eau* or *Luchssapphir* of the jewellers.

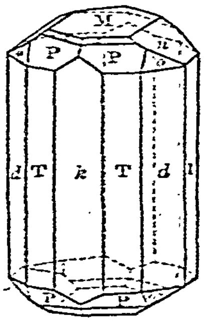

Fig. 518.

The following have been considered cordierite altered, or with 2 to 6 atoms water:—(*a*) *Bonsdorfite, Hydrous Iolite*, greenish brown or dark olive-green; near Åbo. (*b*) *Esmarkite, Chlorophyllite*, large prisms or foliated, green or brownish; near Cabrach (Aberdeen), Brevig in Norway, Unity in Maine, and Haddam in Connecticut. (*c*) *Fahlunite, Triclasite*, compact, greenish brown or black, foliated; H. = 2·5 to 3; G. = 2·5 to 2·8; Falun. (*d*) *Huronite*, granular; pearly, yellowish-green; H. = 3·3; G. = 2·86; infusible and insoluble; Lake Huron. (*e*) *Weissite*, kidney-shaped and ash-grey or brown; Falun and Lower Canada. (*f*) *Pyrargillite*, indistinct imbedded crystals, black passing into brown or red, dull resinous lustre; H. = 3·5; G. = 2·5; Helsingfors. (*g*) *Pinite*, crystallized, or massive and laminar, with imperfect cleavage; H. = 2 to 3; G. = 2·7 to 2·9, semitranslucent or opaque, dull or resinous, and dirty grey, green, or brown; B.B. fuses to a glass, sometimes clear, at other times dark-coloured; Auvergne, Schneeberg, Penig in Saxony, the Harz, Cornwall, Cabrach and Torry (Aberdeenshire), the United States, and Greenland (*Gieseckite*, sp. 650). *Oosite* from Geroldsau in Baden, snow-white, opaque, fragile, is similar. (*h*) *Gigantolite*; H. = 3·5; G. = 2·8 to 2·9; opaque, dull resinous, and greenish grey or brown; B.B. intumesces slightly, and fuses easily to a greenish slag; Tammela in Finland. (*i*) *Praseolite*, lamellar and green; Brevig in Norway.

586. Emerald (*Beryl*), $\ddot{\ddot{A}}l\ddot{S}i_3+3\dot{G}l\ddot{S}i$.

Hexagonal; P 59° 53′. Crystals of ∞P, 0P, and ∞P, $\infty P2$, 0P, P (*a, p, c, s*, fig. 519) are prismatic, generally with vertical striæ. Cl. basal, rather perfect; ∞P imperfect. H. = 7·5 to 8; G. = 2·6 to 2·8. Transparent or translucent; vitreous. Colourless or white, but generally green, sometimes very brilliant; also yellow and smalt-blue. B.B. melts with difficulty on the edges to an obscure vesicular glass. Not affected by acids. C.c.: 67·5 silica, 18·7 alumina, and 13·8 glucina, with 0·3 to 3 iron peroxide, and 0·3 to 3·5 chrome oxide in the rich green emerald. *Emerald*, bright green; G. = 2·710 to 2·759; occurs in Muso Valley near Bogota, also in Salzburg and the Urals. *Beryl*, or *Aquamarine*, colourless, or less brilliant; G. = 2·677 to 2·725; near Mursinsk and Nertchinsk in Siberia, Salzburg, and Brazil; in the United States, where at Grafton, between the Connecticut and Merrimack, crystals 4 to 6 feet long, and weighing 2000 to 3000 lb, occur; Mourne Mountains in Ireland; Mount Battock and Cairngorm in Scotland (fig. 98). *Common Beryl* at Falun in Sweden, Fossum in Norway, Limoges in France, Rabenstein in Bavaria, Nigg Bay and Pitfodels and Rubislaw near Aberdeen (*Davidsonite*), Struay Bridge (Ross). Emerald and beryl are much valued as precious stones. Known from quartz by face *p*. Forms shown in figs. 92, 95, 96, 97, 98, 276.

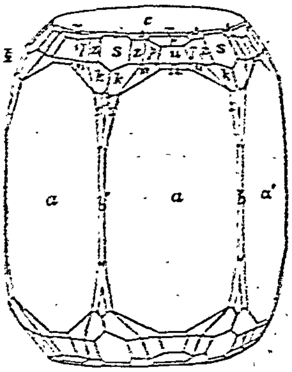

Fig. 519.

587. Leucophane, $6\dot{C}a\ddot{S}i+3\dot{G}l\ddot{S}i+2NaF$.

Right prismatic. ∞P 91°. Cl. basal perfect. H. = 3·5 to 4; G. = 2·97. Pellucid. Wine-yellow to olive-green. Vitreous. B.B. fuses to pale violet-blue bead. C.c.: silica 47, lime 23·4, glucina 10·7, soda 11·3, fluorine 6·6. Lamö in Norway.

588. Melinophane, $7(\dot{R}_3\ddot{S}i_2)+6NaF$.

Pyramidal. P 122° 23′. Mostly lamellar. H. = 5; G. = 3. Honey-yellow to citron-yellow. Brevig and Frederiksvärn.

Felspar Group.

Crystallization oblique prismatic or anorthic; very similar both in aspect and in angles. Cl. very distinct, especially the basal P; less so the clino- or brachydiagonal M. G. = 2·4 to 3·2, but mostly 2·5 to 2·8; H. = 6 or a little more. Slightly or not at all soluble in acids. B.B. fusible, but often with difficulty. Translucent; pure varieties transparent. Colourless, white, or shades of red; less commonly of green or yellow. C.c.: anhydrous silicates of alumina, and of an alkali or alkaline earth.

The felspars are very important constituents of the earth's crust, occurring in nearly all the igneous rocks, and in many of the stratified crystalline schists. In true strata they are found chiefly as fragments or decomposed, and in the latter state form a large part of wet soils and clays. By the older mineralogists and in popular language many species are conjoined under the common name of *felspar* which are now considered as distinct, each of them having not only its peculiar physical and chemical characters, but also geognostic position and associated groups of minerals. Thus orthoclase, and the other more siliceous felspars with potash, abound in granite and the plutonic rocks; the less siliceous, with soda and lime, characterize the volcanic rocks,—*e.g.*, labradorite the basaltic group, glassy felspar the trachytic. Orthoclase is associated with quartz, hornblende, and mica; glassy felspar either with hornblende and a black mica or with augite; labradorite with augite, very rarely with quartz or hornblende.

The felspars are best known from similar minerals by their hardness (they scarce scratch with a good knife), difficult fusibility, and unequal cleavages. The following marks may aid the student in distinguishing the more common species. In orthoclase the basal cleavage plane forms a right angle with the clinodiagonal cleavage planes *M* on both hands; in the triclinic or plagioclase felspars the angles are unequal. Orthoclase, albite, andesine, and oligoclase are insoluble in acids; labradorite and anorthite are more or less soluble. In granite, when decomposing, orthoclase often becomes reddish or dark-red; oligoclase dull green, and at length white.

Walterhausen considers that the felspars are mixtures of three true species, forming a series with the oxygen of the silica, alumina, and RO in the proportions $x:3:1$,—x ranging from 24 to 4. Tcher-

mak and most mineralogists now take a similar view, regarding orthoclase, albite, and anorthite alone as true species, of which the others are mixtures. Those consisting essentially of potash and soda only are mechanical mixtures of orthoclase and albite, the distinct lamellæ being visible by the microscope; those again that contain essentially lime and soda together are, sometimes at least, chemical, being isomorphous compounds of albite and anorthite in various proportions, and with corresponding transitions in crystallographic and physical properties. Notwithstanding this, these intermediates must be regarded as independent mineral species, inasmuch as they are severally typical of certain rocks, and have characteristic forms differing from each other in angular inclination.

589. ORTHOCLASE, $\dddot{Al}\ddot{Si}_3+\dot{K}\ddot{Si}_3$.

Oblique prismatic, C = 63° 57′. ∞P (T and l) 118° 47′; $P^{\circ}\infty$ (x) 65° 46′; $2P^{c}\infty$ (n) 90° 71′; $2P^{\circ}\infty$ (y) 35° 45′. The commonest and simplest forms are ∞P, $0P$, $P^{\circ}\infty$, and $\infty P^{c}\infty$ (M), ∞P, $0P$ (P), $2P^{\circ}\infty$ (figs. 520 to 527). When ∞P predominates the crystals

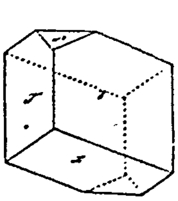

Fig. 520.

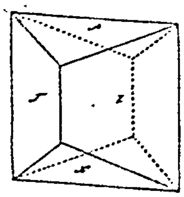

Fig. 521.

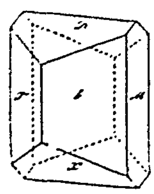

Fig. 522.

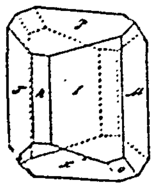

Fig. 523.

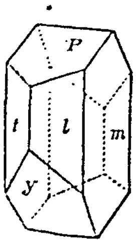

Fig. 524.

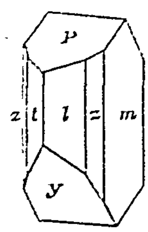

Fig. 525.

are short rhombic prisms; when $\infty P^{c}\infty$ predominates they are tabular; when ∞P and $\infty P^{c}\infty$ predominate they are short hexagonal prismatic, when $0P$ and $\infty P^{c}\infty$ they are rectangular prismatic, often much lengthened. Twins are very frequent, and occur according primarily to four laws. *First*, through revolution of one half or of a whole crystal, then forming interpenetrating twins round a vertical axis (fig. 195). In the case of this hemitropic revolution one of the external faces becomes a face of union. According as the right or the left half (or whole crystal) is conceived to be that which has been revolved the crystals are termed right and left, as in figs. 188, 189. *Second*, by revolution of one half around an axis normal to M; in such twins the composition is not evidenced externally except by sutures. *Third*,

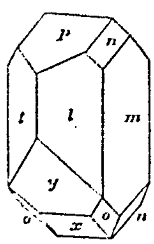

Fig. 526.

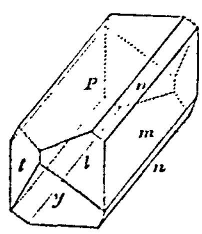

Fig. 527.

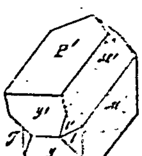

Fig. 528.

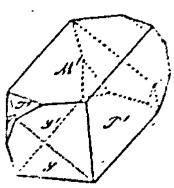

Fig. 529.

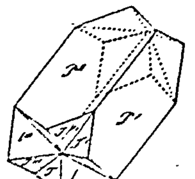

Fig. 530.

through revolution round an axis normal to P, forming orthorhombic prisms which show a herring-bone lineation, through the meeting of striæ commonly present upon the face M parallel to the intersection of its edge with the face T (fig. 528). *Fourth*, by revolution round an axis normal to $2P^{c}\infty$ (n); this also forms a prism the section of which is nearly square (fig. 529). Compound twins on this last type are formed of 3 to 4 and 8 crystals (fig. 530).

Occurs also massive, and coarse or fine granular. Cl. basal (P), very perfect; clinodiagonal (M), perfect (P : M = 90°); fracture conchoidal or splintery. H. = 6; G. = 2·53 to 2·58. Transparent to translucent on the edges; vitreous but pearly on cl.; and also opalescent, with bluish or changing colours. Occasionally colourless but generally red, yellow, grey, or green. B.B. fuses with difficulty to an opaque vesicular glass. Not affected by acids. C.c.: 64·6 silica, 18·5 alumina, and 16·9 potash, but generally 10 to 14 potash, 1 to 4 soda, 0 to 1·3 lime, 0 to 2 iron peroxide. Varieties are—

(1) *Adularia* and *Ice-spar*, transparent or translucent, splendent, and almost colourless. Some with bluish opalescence are named *Moonstone*; St Gotthard, Mont Blanc, Dauphiné, Arendal, Greenland, and Ceylon.

(2) *Common Felspar*, generally white or red, especially flesh-red, is a common constituent of many rocks. Crystals at Baveno on Lago Maggiore, Lomnitz in Silesia, Mourne Mountains and Wicklow in Ireland, Aberdeenshire (at Rubislaw 6 or 8 inches long) in Scotland, and at Carlsbad and Elnbogen in Bohemia. *Amazon Stone*, verdigris-green, from Sutherland, Lake Ilmen, and Colorado, and *Murchisonite*, golden or greyish yellow, from Arran and Dawlish, are varieties.

(3) The *Glassy Felspar* or *Sanidine* (C 64° 1′, ∞P 119° 16′) contains 3 to 12 potash and 3 to 10 soda. Crystals imbedded; vitreous, translucent, and often much cracked; Arran, Eigg, and other parts of Scotland, Drachenfels, Auvergne, and other countries.

Orthoclase occurs in granite, gneiss, and porphyry in many countries. It is commonly associated with quartz; sometimes, as in the *Graphic Granite* of Sutherland, Harris, and Portsoy, in letter-like combinations of the latter. It is very liable to decomposition, when it is converted especially into kaolin, used for manufacturing porcelain and stoneware. The adularia or moonstone and the green amazon stone are cut as ornamental stones. *Leelite*, from Biddean nam Bian in Argyllshire and Grythyttan in Sweden, is a somewhat siliceous horny-lustred flesh-coloured compact variety. *Petuntze* and *Hornstone* are similar but more impure. *Microcline* is a variety with angle distorted by interstitial penetration, by oligoclase (Sutherland), and by albite (Frederiksvärn, &c.).

590. ALBITE, $\dddot{Al}\ddot{Si}_3+\dot{Na}\ddot{Si}_3$.

Anorthic. $0P$ (P) : $\infty\breve{P}\infty$ (M) 86° 24′; $\infty P'$ (l) : $\infty'P$ (T) 122° 15′; but angles variable. Crystals, generally like those of orthoclase, are tabular or prismatic (fig. 197). Hemitropes common, especially united by a face of $\infty\breve{P}\infty$ (figs. 531, 532) the re-entering angle between the faces of $0P$ (P and P') 172° 48′ being very characteristic. Fig. 198 is another common hemitrope. Also massive, and in radiating plates. Cl. basal and brachydiagonal, almost equally perfect; fracture conchoidal or uneven. H. = 6 to 6·5; G. = 2·6 to 2·67. Rarely transparent; vitreous, pearly on the cl. Colourless, but generally white, grey, green, red, or yellow; streak white. B.B. difficultly fusible, tinging the flame yellow, to a white semiopaque glass. Not affected by acids. C.c.: 68·6 silica, 19·6 alumina with 0·1 to 1 iron peroxide, and 11·8 soda, with 0·3 to 4 lime, 0 to 2·5 potash. Hence albite and orthoclase both contain soda and potash, only in different proportions. Albite is most easily recognized by its frequent re-entering angles, its readier fusibility, and the obliquity (93° 36′) of its cl. planes, often marked with striæ. *Pericline* is a variety of which fig. 533 is a typical form.

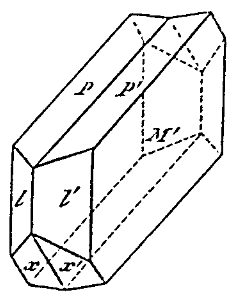

Fig. 531.

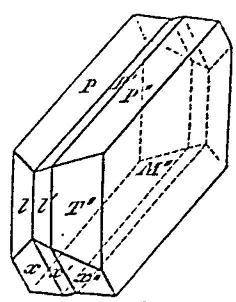

Fig. 532.

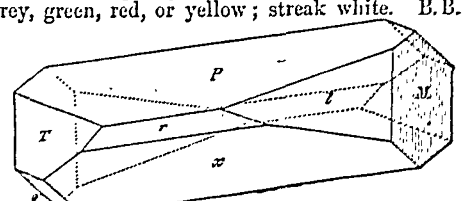

Fig. 533.

Albite is a constituent of many "greenstones," as at Corstorphine (Edinburgh), and of granite, syenite, gneiss, porphyry, and trachyte. Crystallized at Murdoch's Cairn, Aberdeenshire, being the colourless felspar of the red granites of Scotland. Dauphiné, St Gotthard, Tyrol, Salzburg, and Arendal.

Adinole is a compact variety similar in appearance to *Leelite*.

591. ANORTHITE, $\dddot{Al}\ddot{Si}+\dot{Ca}\ddot{Si}$.

Anorthic. $0P$ (P) : $\infty\breve{P}\infty$ (M) 85° 50′; $\infty P'$ (l) : $\infty'P$(T) 120° 30′. Hemitropes common on both M and P. Angle between P and P' 180° 24′. Cl. basal and brachydiagonal, perfect. H. = 6;

G. = 2·7 to 2·78. Transparent or translucent; vitreous. Colourless or white. B.B. fuses to a clear glass; soluble without gelatinizing in con. h. acid. C.c.: 43 silica, 36·9 alumina, 20·1 lime. sometimes

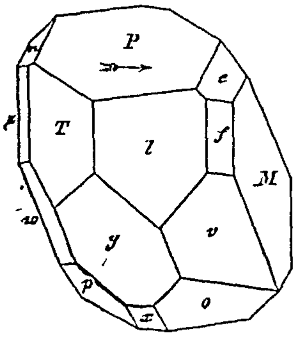

Fig. 534.

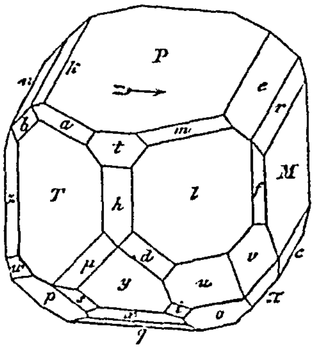

Fig. 535.

with magnesia and soda. Fetlar in Shetland; Lendalfoot in Ayrshire, in gabbro; Monte Somma, Iceland, Java. *Lepolite* and *Amphodelite* are varieties. In *Latrobite* the greater part of the lime is replaced by potash. Glen Gairn and Labrador. At both rose-red.

592. Oligoclase, $2\dddot{A}l\dddot{S}i_3+(\dot{N}a, \dot{C}a)_2\dddot{S}i_3$.

Anorthic. 0P : $\infty\breve{P}\infty$ 86° 10′; $\infty P'$: $\infty' P$ 120° 42′. Hemitropes face *m*, with *p* : *p′* 173° 4′; *l* : *l* 120° 20′; *y* : *y* 179° 9′; *x* : *x* 175° 59′. Cl. basal, perfect; brachydiagonal, less so. H. = 6; G. = 2·62 to 2·84. Vitreous, resinous on the cl. White, with a tinge of green, grey, or red. B.B. melts easier than orthoclase or albite to a clear glass; not affected by acids. C.c.: 63 silica, 23·4 alumina, 8·4 soda, and 4·2 lime; thus nearly = 3 albite and 1 anorthite. Distinguished from orthoclase by the marked striæ on the faces; less readily from albite, but more fusible and G. higher. The common associate of orthoclase in the Scotch grey granites, especially in vein granite, as at Rispond and Ben Loyal (figs. 536, 537) in Sutherland, and at

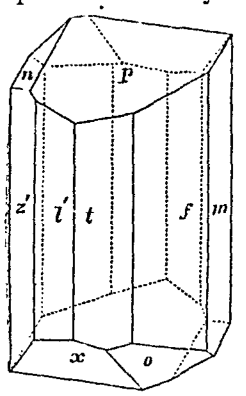

Fig. 536.

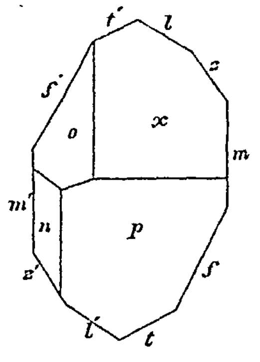

Fig. 537.

Rubislaw; Scandinavia, Urals, Harz, and North America. The *Sunstone*, from Foinaven in Sutherland, Norway, Lake Baikal, and Ceylon, with a play of colour due to imbedded crystals of rubinglimmer (göthite), belongs to this species.

593. Labradorite, $\dddot{A}l\dddot{S}i_3+(\dot{C}a, \dot{N}a)\dddot{S}i$.

Anorthic. 0P : $\infty\breve{P}\infty$ 86° 40′; 0P : $\infty' P$ 111°; 0P : $\infty P'$ 113° 34′; $\infty P'$: $\infty' P$ 121° 37′; $\infty\breve{P}\infty$: $\infty P'$ 120° 53′; $\infty\breve{P}\infty$: $\infty' P$ 117° 30′. Hemitropes of three types:—(1) according to the first law of orthoclase as in fig. 538; that is, vertical revolution and face of union $\infty\breve{P}\infty$; (2) revolution of one half with reunion on the face $\infty\breve{P}\infty$,

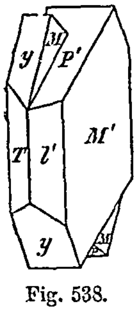

Fig. 538.

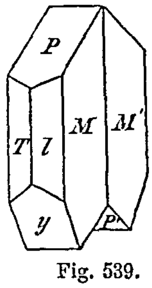

Fig. 539.

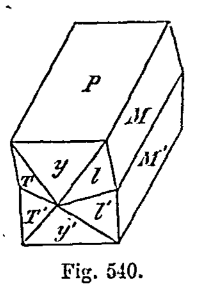

Fig. 540.

as in fig. 539; (3) with twin face P, as in fig. 540. Hemitropes of the last form also occur in which the lower half consists of a hemitrope formed according to the second method. Crystals imbedded in rocks consist generally of repeated twins affording an angle of 173° 20′. Cl. basal, perfect; brachydiagonal, less so; both usually striated on account of the above twinning. H. = 6; G. = 2·68 to 2·74. Translucent; vitreous, on the cl. resinous. Grey, passing into white, green, yellow, or red. The faces of $\infty\breve{P}\infty$ often exhibit very beautiful changing colours—blue, green, yellow, red, or brown—sometimes bands intersecting at certain angles. B.B. fuses more readily than orthoclase to a compact colourless glass. Sol. in h. acid. C.c.: 52·9 silica, 30·3 alumina, 12·3 lime, and 4·5 soda. It is thus = 1 albite and 3 anorthite. Common constituent of dolerite, gabbro, and hypersthene rocks. In Scotland, Labrador, Finland, Harz, Tyrol; also at Etna and Vesuvius.

594. Andesine, $\dddot{A}l\dddot{S}i_3+(\dot{N}a\dot{C}a)\dddot{S}i$.

Anorthic. Crystals similar to albite and anorthite. Twin face *M*. Crystals generally formed of repeated plates. G. = 2·67 to 2·7. Physical properties like albite; more easily fusible to a porous white glass; h. acid sometimes dissolves out alternate laminæ of crystals. C.c.: 59·7 silica, 25·6 alumina, 7·7 soda, and 7 lime, and thus nearly 1 of albite and 1 anorthite. Typical of the primary limestones and a granitic belt therein in Scotland, as at Shinness, Urquhart, Dalnain, &c. In the Andes, the Vosges, and Iceland.

595. Hyalophane, $\dddot{A}l\dddot{S}i_3$, $\dot{K}\dddot{S}i_3+\dddot{A}l\dddot{S}i$, $\dot{B}a\dddot{S}i$.

Oblique prismatic; resembles orthoclase; crystals and angles nearly the same. Cl. 0P, perfect. H. = 6 to 6·5; G. = 2·8 to 2·9. Transparent. Lustre vitreous. Colourless, white, and flesh-red. C.c.: silica 52·7, alumina 21, baryta 15·1, potash 7·8, soda 2·1. B.B. difficultly fusible to a blebby glass, not acted upon by acids. Binnen in Valais, Jacobsberg in Sweden.

596. Barsovite, $\dddot{A}l\dddot{S}i+\dot{C}a\dddot{S}i$.

Right prismatic, or oblique prismatic. H. = 5·5 to 6; G. = 2·58. Snow-white; translucent. Fracture granular. Pearly. C.c.: silica 42·2, alumina 36·4, lime 19·8. Gelatinizes in h. acid, difficultly fusible. A dimorphic form of anorthite. Barsovskoi in the Urals.

597. Saussurite.

A massive, granular, translucent, white or pale green felspathic mineral of the nature of anorthite mixed with labradorite. H. = 6 to 7; G. = 3·26 to 3·4. Probably a mixture. Occurs in loose blocks near Geneva, and in Corsica. In China and in India is carved under the name of Oriental jade (nephrite). Seems to be confounded also with zoizite, and perhaps with yu (prehnite). *Jadeite* is similar.

Zeolite Group.

These crystallize in all the systems except the anorthic, and themselves present great variety of development. Mostly hyaline and white; rarely red, grey, or yellow. Cl. generally distinct. All yield water in closed tube; all fusible B.B. most easily, and often intumescing; all sol. in acids, and mostly gelatinize or deposit silica. They are hydrated silicates of alkalies, or alkaline earths, mostly with silicates of alumina, but rarely contain magnesia. Some mineralogists regard the water as basic, in union with silica, and Kenngott gives the formula in that form, thus:—

Analcime, $(\dot{N}a\dddot{A}l)$ $2\dddot{S}i+2(\dot{H}, \dddot{S}i)$,

Natrolite, $(\dot{N}a\dddot{A}l)$ $2\dddot{S}i+2(\dot{H}, \dddot{S}i)$,

Stilbite, $\dot{C}a$, $\dddot{A}l+6(\dot{H}, \dddot{S}i)$,

and the others similar. They are generally found in amygdaloidal cavities or fissures of trap or plutonic rocks, apparently as deposits from water percolating into them, and are thus probably products of decomposing nepheline or felspars, or hydrated felspars themselves. They never form constituents of rocks. Natrolite, scolezite, thomsonite, and the connected varieties are marked by their needle-like radiating forms; stilbite and heulandite by their broad, foliated, pearly cleavage.

598. Pectolite, $4\dot{C}a\dddot{S}i+\dot{N}a\dddot{S}i_2+\dot{H}$.

Oblique prismatic, C 84° 37′. $\infty\bar{P}\infty$ (*c*); 0P (*u*) 95° 23′. Cl. *c* and *u*. Twin-face *c*; chiefly spheroidal and radiating fibrous. H. = 5; G. = 2·74 to 2·88. Translucent; crystals pearly; fibres silky. Pale green to yellowish white. Sol. in h. acid, leaving silica. C.c.: 54·2 silica, 33·7 lime, 9·4 soda, and 2·7 water. Ratho, Corstorphine, Castle Rock, and Arthur's Seat, Edinburgh; Kilsyth, Stirling; Knockdolian and Lendalfoot, Ayrshire; Skye; Montebaldo; Monzoni Valley in Tyrol.

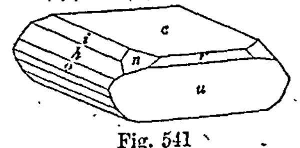

Fig. 541

599. Walkerite, $4\dot{C}a\dddot{S}i+\dot{M}g\dddot{S}i+\dot{N}a\dddot{S}i_2+2\dot{H}$.

Like pectolite, but columnar. H. = 4·5; G. = 2·7. Flesh-coloured. Lustre pearly to greasy. C.c.: silica 53·7, lime 28·6, magnesia 5·1, soda 7·9, water 4·6. Corstorphine Hill, Burntisland.

600. Xonotlite, $4\dot{C}a\dddot{S}i+\dot{H}$.

Massive. H. = 6; G. = 2·6 to 2·7. Pink, white, and grey. Tough;

fracture conchoidal and splintery. C.c.: silica 49·8, lime 43·5, protoxide of manganese 2·3, protoxide of iron 2·9, water 3·7. Killinichen and Torosay (Mull), Xonotla (Mexico).

601. TOBERMORITE, $3(\dot{C}a_4, \dot{H})\ddot{S}i_5 + 2\frac{1}{2}\dot{H}$.

Massive, fine granular; translucent; fracture hackly. H. = 5; G. = 2·4. Pale pink. C.c.: silica 49·8, lime 37·2, water 12·9. Tobermory (Mull), Dunvegan (Skye).

602. OKENITE, $\dot{C}a\dot{H}\ddot{S}i_2 + \dot{H}$.

Right prismatic. ∞P 122° 19′. Usually fine fibrous; radiating. H. = 5; G. = 2·28 to 2·36. Pellucid; slightly pearly. Yellowish to bluish white. In powder easily sol. in h. acid, leaving gelatinous flakes after ignition. C.c.: 56·6 silica, 28·4 lime, and 17 water; an apophyllite without the fluorine. Disco Island, Faroes, and Iceland.

603. APOPHYLLITE, $8(\dot{C}a\ddot{S}i + 2\dot{H}) + KF$.

Pyramidal. P 120° 56′. P, ∞P∞ (m), 0P (o), ∞P2 (r). Rarely lamellar. Cl. o, perfect. Brittle. H. = 4·5 to 5; G. = 2·3 to 3·4. Transparent; vitreous. On o pearly (*Ichthyophthalmite*). Colourless, rarely pink, green, red, brown, and yellow. B.B. exfoliates, intumesces, and melts to white enamel. Sol. in h. acid, leaving silica. C.c.: silica 50·3, lime 24·7, water 15·9;

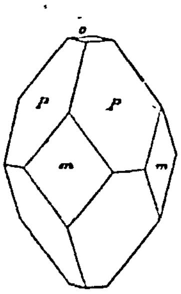

Fig. 542.

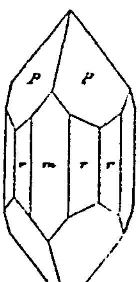

Fig. 543.

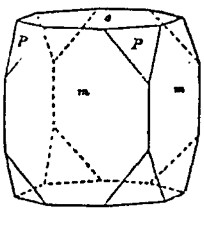

Fig. 544.

potassium 4·3, fluorine 2·1. Dunvegan and Storr, Skye (*fig. 544*); Chapel, Fife; Corstorphine (fig. 542) and Ratho, near Edinburgh; Kilsyth, Bowling, Kilpatrick; Port Rush, Ireland. In the form P (fig. 79), grass-green at Oxhaveer, Iceland (*Oxhaverite*); Utö, Sweden; Andreasberg and Faroes (pink); Faroes, and Poonah in India (green). Internal structure tesselated, being built up of wedge and lenticular forms with varying refractive indices, hence exhibiting a beautiful structure with polarized light.

604. GYROLITE, $(\frac{2}{3}\dot{C}a + \frac{1}{3}\dot{H})\ddot{S}i + \dot{H}$.

Lamellar, radiate, spherical, and investing. H. = 3 to 4. Pearly. Bluish white to cream-coloured. Transparent, rapidly becoming opaque. C.c.: silica 53·3, lime 32·9, water 13·8. Quiraing, Lyndale, and Storr, Skye; Loch Screden and Carsaig, Mull; Canna; Karartut, Niakornak, and Disco; Faroes; Nova Scotia.

605. ANALCIME, $\ddot{A}l\ddot{S}i_3 + \dot{N}a\ddot{S}i + 2\dot{H}$.

Cubic. ∞O∞; 2O2. Fracture uneven. H. = 5·5; G. = 2·1 to 2·28. Colourless, white, flesh-red, scarlet. Vitreous; transparent. B.B. melts without frothing to a clear vesicular glass. Decomposable with gelatinization in h. acid. C.c.: 54·5 silica, 23·3 alumina, 14·1 soda, 8·2 water. Walls, Orkney; Talisker, Skye; Sanda, and Hebrides generally. Transparent at Eigg, and Elie, Fife; scarlet at Bowdens, Kincardine; opaque white at Glen Farg, Salisbury Crags, and Dumbarton; Giant's Causeway, Seisser Alp in Tyrol, Cyclopean Islands (fig. 545), Faroes, Iceland, and Nova Scotia. *Eudnophite* is a variety. Pectolite (sp. 598) occurs pseudomorphous after analcime, in large crystals of a, n, at Ratho, Edinburghshire.

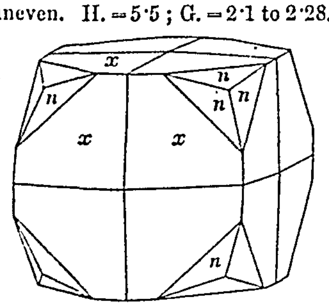

Fig. 545.

606. POLLUX, $3(\ddot{A}l\ddot{S}i_3 + (\dot{C}s\frac{2}{3}, \dot{N}a\frac{1}{3})\ddot{S}i) + 2\dot{H}$.

Cubic. ∞O∞; 2O2 (fig. 546). Also massive. Gum-like externally. Brittle, with traces of cleavage. Fracture conchoidal. H. = 5·5 to 6·5; G. = 2·86 to 2·9. Colourless. Vitreous. Sol. in h. acid. C.c.: silica 44, alumina 16, oxide of cæsium 34, soda 2·5, water 2·4. Elba. The only mineral which contains cæsium in quantity.

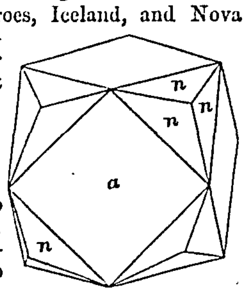

Fig. 546 (sp. 606).

607. FAUJASITE, $2\ddot{A}l\ddot{S}i_3 + (\dot{C}a\dot{N}a)_2\ddot{S}i_3 + 18\dot{H}$.

Cubic; in octahedrons with the icositetrahedron $\frac{6}{5}O\frac{6}{5}$. Fracture uneven; brittle. H. = 7; G. = 1·92. Transparent; vitreous to adamantine. White to brown. Sol. in h. acid. C.c.: 46·8 silica, 16 alumina, 4·4 lime, 4·8 soda, 28 water. Kaiserstuhl in Baden, Annerod near Giessen, Eisenach, Marburg.

608. CHABASITE (*Lime-Chabasite*), $\ddot{A}l\ddot{S}i_3 + \dot{C}a\ddot{S}i + 6\dot{H}$.

Rhombohedral; R 94° 46.′ $\frac{16}{15}R\frac{4}{5}$; $-\frac{1}{2}R$ (r); $-2R$ (e); ∞P2 (a). Twins very common (generally intersesting), on faces ∞P and

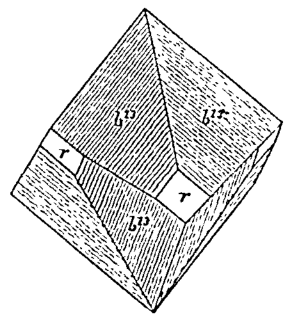

Fig. 547.

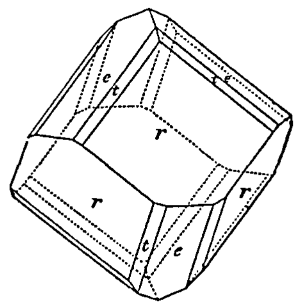

Fig. 548.

P̆∞. Primary rhombohedron is sometimes twinned with a crystal with faces r, e, s. Cl. r perfect. H. = 4 to 4·5; G. = 2 to 2·2. Transparent or translucent; vitreous. Colourless, and brownish,

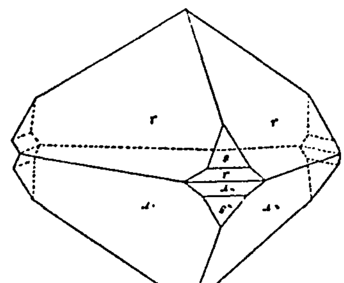

Fig. 549.

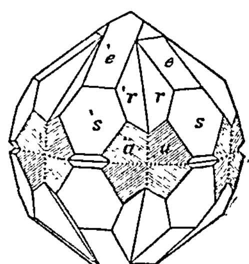

Fig. 550.

yellowish, brick-, and flesh-red. Sol. in h. acid, leaving silica. C.c.: silica 47·8, alumina 20·8, lime 10·7, water 21·3. Lyndale (figs. 547, 548, 549), Talisker (figs. 176, 550, sometimes flesh

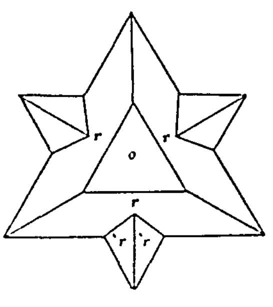

Fig. 551.

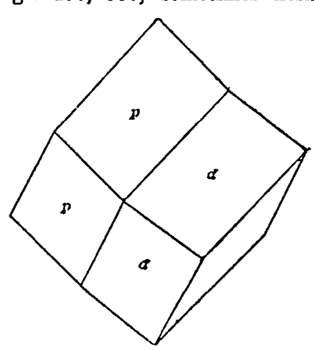

Fig. 552.

colour), and Storr, Skye (figs. 547, 548); Port Glasgow and Kilmalcolm (pink and brown); Giant's Causeway and Magee Island (red), Faroes, Iceland, Aussig, Andreasberg (fig. 551). *Haydenite* in twinned rhombohedra, with p : p 95° to 97° and p : d 170° reentering (fig. 552), from Fassa and Maryland, is similar. *Phacolite* is chabasite in twins of $\frac{4}{3}$P2, ∞P2, R, $-\frac{1}{2}$R at the Giant's Causeway (fig. 154). At Richmond in Victoria they occur as in fig. 553, $-2R$ (n), $-\frac{2}{3}R$ (r), $\frac{4}{3}$P2 (t), 0P (c); polar edge, $\frac{4}{3}$P2 145°. In this, half of the lime is replaced by soda.

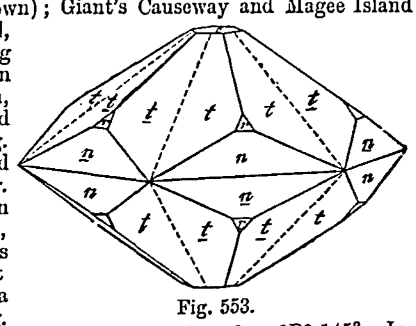

Fig. 553.

609. GMELINITE (*Soda-Chabasite*), $\ddot{A}l\ddot{S}i_3 + \dot{N}a\ddot{S}i + 6\dot{H}$.

Hexagonal. R 112° 26′; P 79° 54′. Combination P, 0P, ∞P

(figs. 554, 556). Faces of P striated parallel to the polar edge, those of the prism horizontally (fig. 555). Cl. ∞P distinct. Gelatinizes with h. acid. C.c.: 47·6 silica, 19·7 alumina, 12 soda, 20·7 water. Certain crystals seem to indicate twinning. Talisker in Skye (twins of fig. 555), Glenarm in Antrim (fig. 555), Vicenza, Pyrgo in Cyprus, Cape Blomidon in Nova Scotia.

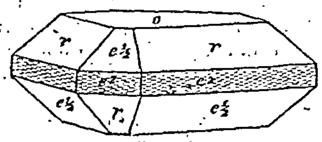

Fig. 554.

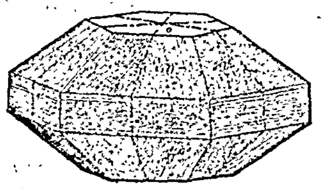

Fig. 555.

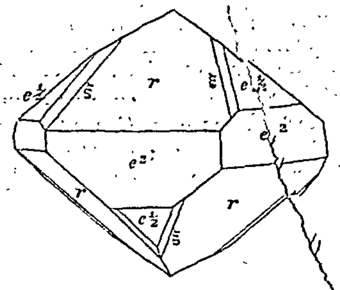

Fig. 556.

610. Levyne, $\dddot{A}l\ddot{S}i_2 + \dot{C}a\ddot{S}i + \dot{H}5$.

Rhombohedral; R (s) 79° 29′; $-\frac{1}{2}$R (r) 106° 3′; 0R (o). Forms intersecting twins as in fig. 557. H. = 4; G. = 2·1 to 2·2. Colourless and white. C.c.: silica 43·8, alumina 23·8, lime 9·7, water 21. Storr in Skye (o, s), Ireland (at Glenarm, Island Magee, Londonderry, &c.), Iceland, Dalsnypen, and Naalsö in the Faroes.

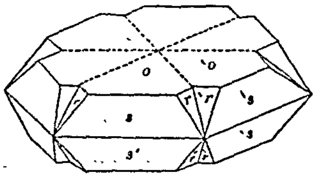

Fig. 557.

611. Herschelite, $\dddot{A}l\ddot{S}i_3 + (\dot{C}a\dot{N}a)\ddot{S}i + 5\dot{H}$.

Hexagonal prisms (c) surmounted by two trihedral pyramids of a_7 and one of $a\frac{11}{5}$ (fig. 558). $a_7 : c$ 122° 8′; $a\frac{11}{5} : c$ 107° 26′; c striated horizontally. Cl. c; fracture conchoidal; transparent; vitreous. White or colourless. H. = 5·5; G. = 2·06. C.c.: silica 47, alumina 21·2, lime 5·2, soda 4·8, potash 2, water 17·86. Aci-Castello and Palagonia in Sicily, Yarra in Australia.

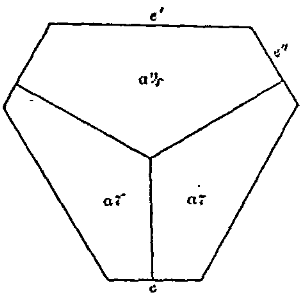

Fig. 558 (sp. 611).

612. Laumontite (*Leonhardite*), $\dddot{A}l\ddot{S}i_3 + \dot{C}a\ddot{S}i + 4\dot{H}$.

Oblique prismatic, C 80° 42′. ∞P (m) 86° 16′. ∞P : $-\infty\bar{P}$ (c) 113° 30′; P∞ (x_2) : $-\infty\bar{P}$ 111° 14′; $c : a$ 125° 41′; $a : b$ 90°; $e : z$ 149° 15′. Twin face a. Cl. m, perfect; very brittle. H. = 3 to 3·5; G. = 2·2 to 2·3. Pellucid when fresh; vitreous; pearly on cl. White, cream-coloured, brick-red. Decomposes rapidly through loss of water. B.B. intumesces, and melts first to a white enamel, ultimately to a clear glass. Gelatinizes in h. acid. C.c: silica 50·9, alumina 21·8, lime 11·9, water 16·3. Rapidly loses 1 equivalent or 3·86 per cent. of water, and becomes friable (*Hypostilbite*). Kilfinichen, Mull (fig. 559); Storr and Quiraing, Skye (hypostilbite); Tod Head, Snizort, Glen Farg (red); Bowling, Dumbarton (twins of m, c); Huelgoat in Brittany; Prague, Falun, Iceland, Faroes, Nova Scotia. *Caporcianite* from Tuscany has only 3 water.

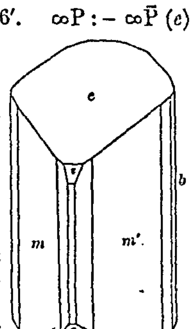

Fig. 559.

613. Epistilbite (*Reissite*), $\dddot{A}l\ddot{S}i_3 + \dot{C}a\ddot{S}i_3 + 5\dot{H}$.

Oblique prismatic, C 54° 53′. ∞P (m) 135° 10′; P∞ (t) 109° 46′; $\frac{1}{2}$P(s) 147° 40′ (fig. 560). Hemitropes united by m, with twins of the same united by the brachydiagonal (a). Cl. brachydiagonal, perfect. H. = 3·5 to 4; G. = 2·3 to 2·4. Pellucid; vitreous; pearly on cl. Colourless. Sol. without gelatinizing. C.c.: silica 59, alumina 17·5, lime 9, soda 1·5, water 14·5. Talisker in Skye (m, t, a); Hartlepool (in twins), Iceland, Faroes, Silesia, Viesch in Valais, Nova Scotia, and New Jersey.

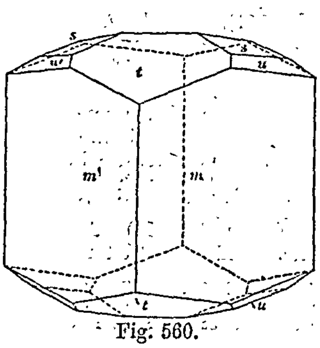

Fig. 560.

614. Heulandite, $\dddot{A}l\ddot{S}i_3 + \dot{C}a\ddot{S}i_3 + 5\dot{H}$.

Oblique prismatic, C 63° 40′. P°∞ (p) 50° 20′; 2P (z); $\frac{2}{3}$P (u); 2P^c∞ (r); 3P^c∞ (s); $\infty\bar{P}\infty$; ∞P^c; 0P. $z : z$ 136° 4′; $u : u$ 146° 52′. Crystals elongated along each of the axes present very varying forms, but generally tabular. Cl. clinodiagonal, perfect; pearly on this, vitreous on others; brittle. H. = 3·5 to 4; G. = 2·1 to 2·2. Transparent to translucent; colourless, white, brick-red, rose, green, hair-brown. B.B. melts with exfoliation and intumescence to a white enamel. Sol. in h. acid, leaving silica. Storr and Talisker, Skye (fig. 562); Sanda; Kilmalcolm; Catterline, Kincardine (fig. 563); Kilpatrick Hills (p, m, n, z, u, r, s) and Kintyre (red); Iceland, Faroes, Fassa Valley, Nova Scotia, Baltimore (*Beaumontite*) (p, m, n, z, t); Vindhya Mountains in India (fig. 564).

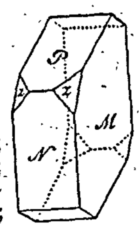

Fig. 561.

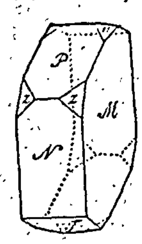

Fig. 562.

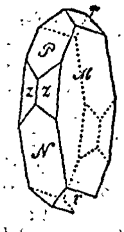

Fig. 563.

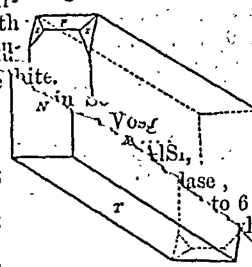

Fig. 564.

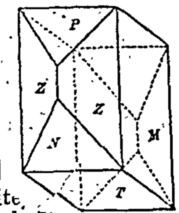

Fig. 565.

(fig. 565)

615. Brewsterite, $\dddot{A}l\ddot{S}i_3 + \dot{R}\ddot{S}i_3 + 5\dot{H}$. $\dot{R} = (\frac{4}{7}\dot{S}r + \frac{2}{7}\dot{B}a + \frac{1}{7}\dot{C}a)$.

Oblique prismatic, C 86° 56′. ∞P°∞ (a); ∞P^c∞ (b); 0P (o); nP^c∞ (e); ∞P (m); ∞P^{c}2 (c); ∞P$^c\frac{3}{2}$ (t). $e : e$ 173° 10′ (fig. 566). Cl. clinodiagonal, perfect; pearly on do., vitreous on others; pellucid. H. = 5 to 5·5; G. = 2·5 to 2·45. Colourless, yellow, or brown. Sol. with gelatinization in h. acid. C.c.: 54·3 silica, 15 alumina, 9 strontia, 6·6 baryta, 1·3 lime, 13·5 water. Strontian, Freiburg in the Breisgau, Pyrenees.

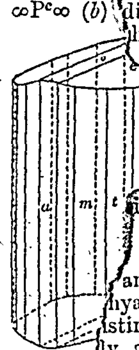

Fig. 566

616. Phillipsite, $\dddot{A}l\ddot{S}i_3 + (\dot{C}a, \dot{K})\ddot{S}i + 5\dot{H}$.

Oblique prismatic, C 55° 1′. ∞P (m); ∞P^c∞ (b); 0P (c). Polar edges 120° 42′ and 119° 18′. Faces b and m striated parallel to the intersections. Apparently always twinned; generally these duplicated by intersection on face b or face c (figs. 567, 568), and frequently arranged so that three of the above double twins in right angles to one another, forming the cruciform

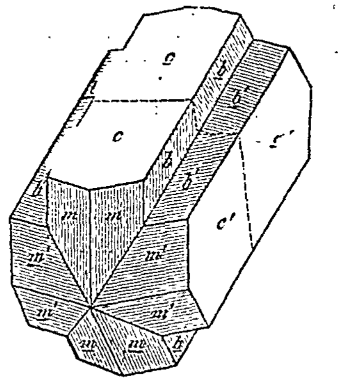

Fig. 567.

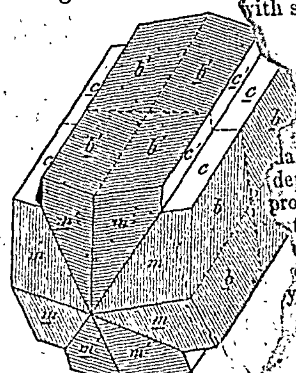

Fig. 568.

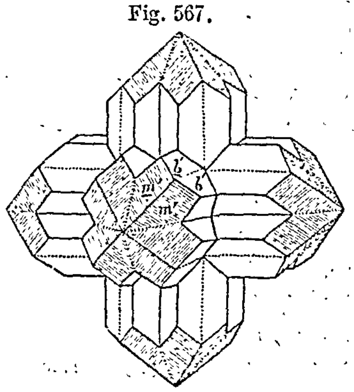

Fig. 569.

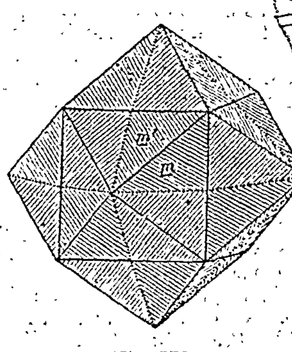

Fig. 570.

When the prismatic faces of these are short, the faces m of the

intersecting individuals fall nearly into one plane, presenting the form fig. 570; when long, fig. 190. Brittle; fracture uneven. H. = 4·5; G. = 2·15 to 2·2. Gelatinizes in h. acid. C.c.: silica 48·6, alumina 20·2, lime 7·3, potash 6·2, water 17·7. Giant's Causeway, Giessen, Marburg, Cassel, Capo di Bove, Vesuvius, Iceland.

617. HARMOTOME, $\dddot{\rm Al}\ddot{\rm Si}_3+\dot{\rm Ba}\ddot{\rm Si}_2+5\dot{\rm H}$.

Oblique prismatic, C 55° 10′. ∞P (s); ∞P ∞ (b); 0P (a). Forms like phillipsite, but more frequently in simple twins. Physical properties like phillipsite, but G. = 2·3 to 2·5, and fuses

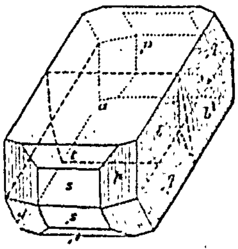

Fig. 571.

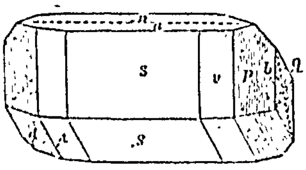

Fig. 572.

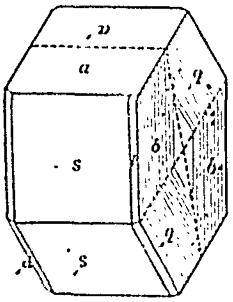

Fig. 573.

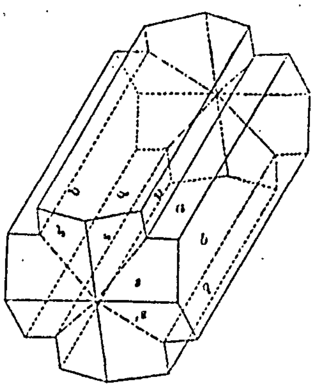

Fig. 574.

with difficulty. Difficultly sol. in h. acid. C.c.: 46·5 silica, 15·9 alumina, 23·7 baryta, and 13·9 water. Strontian, transparent (*Morvenite*, fig. 572) and opaque (figs. 571, 573); Glen Arbuck (fig. 574) and Bowling in Dumbarton; Corstorphine near Edinburgh; Andreasberg, Kongsberg, Oberstein.

618. STILBITE, $\dddot{\rm Al}\ddot{\rm Si}_3+\dot{\rm Ca}\ddot{\rm Si}_3+6\dot{\rm H}$.

Oblique prismatic, but with right prismatic habit; C 50° 49′. ∞P̄∞ (a); ∞P∞ (b); P (r); ∞P2 (m); 0P (p). Cl. a, perfect. H. = 3·5 to 4; G. = 2·1 to 2·2. Transparent; vitreous. Pearly on a. Colourless, white, yellow, pale brown, brick-red. Decomposed by h. acid, leaving silica. C.c.: silica 57·5, alumina 16·4, lime 8·9 water 17·2. Storr and Talisker in Skye (a, b, p) (fig. 575), and in Hebrides (colourless); Arran and Kilmalcolm (pale brown); Long Craig (Dumbarton) and Kinneff (Kincardine) (brick-red); Iceland, Faroes, Andreasberg, Vindhya Mountains, Wellington Mountains (Australia), Nova Scotia.

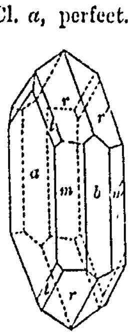

Fig. 575, (sp. 618).

619. PUFFLERITE, $\dddot{\rm Al}\ddot{\rm Si}_3+\dot{\rm Ca}_2\ddot{\rm Si}_3+5\dot{\rm H}$.

Fibrous globular concretions, with vitreous surface. H. = 4; G. = 2·21. Greyish white. Transparent. C.c.: silica 52·8, alumina 16·3, lime 11·2, water 17·2. Pufflatsch in the Seisser Alp.

620. EDINGTONITE, $4\dddot{\rm Al}\ddot{\rm Si}_2+3\dot{\rm Ba}\ddot{\rm Si}+12\dot{\rm H}$.

Pyramidal; hemihedral with inclined faces. P 87° 19′; ½P (n) 129° 8′; ∞P (a); polar edges 92° 51′ (fig. 576). Cl. a, perfect; fracture uneven. H. = 4 to 4·5; G. = 2·7 to 2·71. Translucent; vitreous. Colourless. C.c.: silica 37·3, alumina 23·75, baryta 26·52, water 12·46. Kilpatrick Hills in Dumbartonshire.

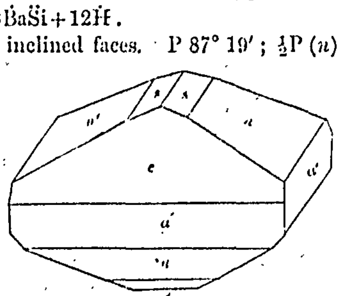

Fig. 576 (sp. 620).

621. FORESITE, $2\dddot{\rm Al}\ddot{\rm Si}_2+(\dot{\rm Na},\ \dot{\rm Ca}_3)\ddot{\rm Si}_2+6\dot{\rm H}$.

Right prismatic. ∞P̄∞; ∞P̆∞; 0P. Cl. brachydiagonal, perfect; lustre thereon pearly. G. = 2·4. White. C.c.: silica 50, alumina 27·4, lime 5·5, soda 1·4, water 15·1. San Piero in Elba.

622. NATROLITE, $\dddot{\rm Al}\ddot{\rm Si}_2+\dot{\rm Na}\ddot{\rm Si}+2\dot{\rm H}$.

Right prismatic. ∞P (m) 91°; P (o); polar edges 143° 20′ and 144° 40′, middle edge 53° 20′; ∞P̆∞ (b); ∞P̄∞ (a). Radiating acicular crystals, often fibrous. Cl. ∞P, perfect. H. = 5 to 5·5; G. = 2·17 to 2·26. Pellucid; vitreous. Colourless, ochre-yellow, reddish. Is not pyro-electric. B.B. melts quietly to a clear glass, colouring flame yellow. Sol. in oxalic acid. C.c.: 47·2 silica.

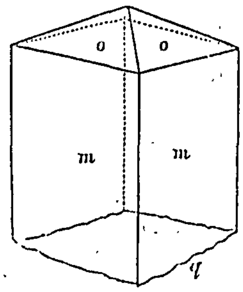

Fig. 577.

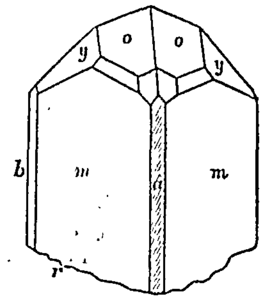

Fig. 578.

27 alumina, 16·3 soda, 9·4 water. Glen Farg (fig. 577), (colourless and reddish), Tantallon Castle (fig. 578), Dumbarton, Bowling (green), Campsie, Bishopton, Glenarm and Port Rush (Ireland), Auvergne, Hesse, Hohentwiel in Swabia, Norway. *Crocalite* is red, fibrous, and investing; Kintyre, Forfarshire, Wemyss Bay, and the Urals.

623. SCOLECITE, $\dddot{\rm Al}\ddot{\rm Si}_2+\dot{\rm Ca}\ddot{\rm Si}+3\dot{\rm H}$.

Oblique prismatic, C 89° 6′. ∞P (m) 91° 35′; P (o) 144° 20; −P. Prismatic and acicular crystals. Twins common, on face ∞P̊∞, one face with feathered striæ. Cl. ∞P, perfect. H. = 5 to 5·5; G. = 2·2 to 2·3. Pellucid; vitreous; pyro-electric. White to reddish white. B.B. twists in a vermicular manner; melting readily to a porous glass. Only partially sol. in oxalic acid. C.c.: silica 45·8, alumina 26·2, lime 14·3, water 13·7. Staffa; Loch Screden, Mull; Talisker, Skye; Berufiord, Iceland (fig. 579); Faroes; Vindhyas, India. Natrolite and scolecite pass into one another. There are two definite intermediates—*Fargite*, consisting of two equivalents of natrolite and one of scolecite, and *Mesolite*, consisting of one of the former and two of the latter. The first of these occurs at Glen Farg and at Bishopton (*Galactite*); the second is the ordinary radiated zeolite of the amygdaloids of the Tertiary igneous rocks of the Hebrides and the Faroes. It there occurs in matted crystals of extreme tenuity (*Cottonstone*), also in delicate feathery tufts; in Renfrewshire in spheres with an internally radiated structure, and also in needle form and in downy tufts.

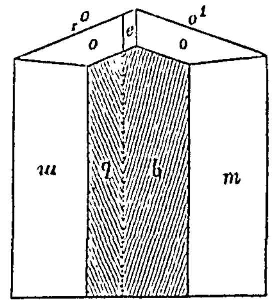

Fig. 579.

624. GISMONDINE, $\dddot{\rm Al}\ddot{\rm Si}+\dot{\rm Ca}\ddot{\rm Si}+4\dot{\rm H}$.

Pyramidal. P (b) 92° 30′; polar angle 118° 31′; ∞P∞ (fig. 580). Cl. P. H. = 5, on edges and angles 5 to 6; G. = 2·26. Translucent; vitreous. Bluish white to pale red. C.c.: silica 35·9, alumina 27·3, lime 13·1, potash 2·8, water 21·1. Island Magee and Larne, Ireland; Vesuvius, Aci-Castello, and Capo di Bove; Schiffenberg near Giessen; Schlauroth near Görlitz.

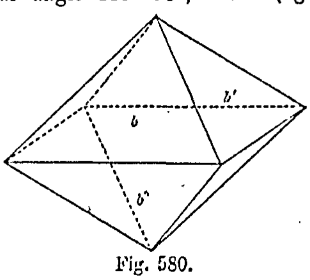

Fig. 580.

625. ZEAGONITE, $\dddot{\rm Al}\ddot{\rm Si}+(\dot{\rm Ca}\dot{\rm K})\ddot{\rm Si}+4\dot{\rm H}$.

Right prismatic. P polar angle 120° 37′ and 121° 44′; middle angle 89° 13′. Crystals like fig. 419. H. = 5, on edges and angles 7; G. = 2·2. Transparent; vitreous. Colourless, white, or bluish. C.c.: silica 44, alumina 23·3, lime 5·3, potash 11·1, water 15·3. Capo di Bove.

626. THOMSONITE, $2\dddot{\rm Al}\ddot{\rm Si}+2(\dot{\rm Ca}\dot{\rm Na})\ddot{\rm Si}+5\dot{\rm H}$.

Right prismatic. ∞P (m) 90° 26′; ∞P̄∞ (a); ∞P̆∞ (b); ⅓P̆∞ (y); P̄∞ (r); $\frac{1}{18}$P̆∞ (x). x : x 177° 34′ 20″. Cl. macrodiagonal and brachydiagonal, both perfect. H. = 5 to 5·5; G. = 2·35 to 2·38. Translucent; vitreous; pearly on macrodiagonal. Colourless. B.B. difficultly fusible with intumescence to a white enamel. Sol. with gelatinization in h. acid. C.c.: silica 38·7, alumina 30·8, lime 13·4, soda 4·4, water 13·1. Lochwinnoch, Renfrew; Kilpatrick (fig. 582); Quiraing and Talisker (sometimes

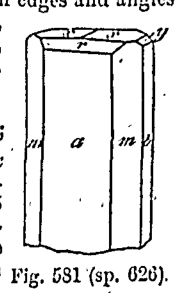

Fig. 581 (sp. 626).

massive-granular); Rathlin and Magee Island, Ireland; Faroes, Vesuvius (fig. 581), Sicily, Bohemia, Tyrol, Nova Scotia.

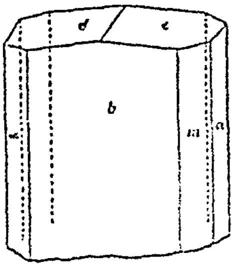

Fig. 582 (sp. 626).

Faroelite is a variety with 42·5 of silica. It replaces thomsonite generally in Tertiary igneous rocks, occurring at Storr and elsewhere in the Hebrides, Faroes, Iceland, and Nova Scotia. The angle of the vertical prism is within 8′ of that of thomsonite. It contains an equivalent more silica.

627. PREHNITE, $\dddot{Al}\dddot{Si}+2\dot{Ca}\dddot{Si}+\dot{H}$.

Right prismatic. ∞P (*m*) 99° 58′; 0P (*c*); $3\breve{P}\infty$ (*e*) 33° 26′; $\frac{4}{3}\bar{P}\infty$ (*v*) 90° 32′; $\infty\breve{P}\infty$ (*a*); $\infty\bar{P}\infty$ (*b*); P (*s*). Crystals either tabular of *c*, or prismatic along both the vertical and the brachydiagonal axes, hence varying much in form. Also in fan-shaped and botryoidal aggregations. Cl. *c*, perfect; pearly thereon, vitreous elsewhere. H. = 6 to 7; G. = 2·8 to 3. Transparent to translucent. Colour-

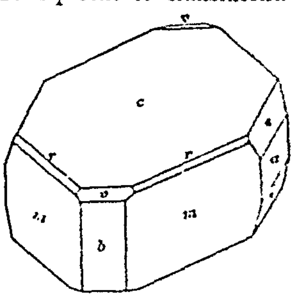

Fig. 583.

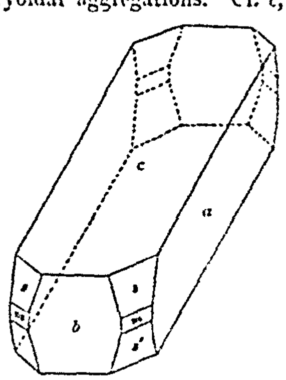

Fig. 584.

less, but generally green of bright but pale tints, also lemon-yellow. Becomes electrically polar by heat. B.B. intumesces greatly, melting to a porous enamel. Decomposed by h. acid. C.c.: silica 43·6, alumina 24·9, lime 27·1, water 4·4. Glen Gairn, Aberdeen (fig. 583); Skye and Mull; Corstorphine Hill (green and pink), Castle Rock (white), and Salisbury Crags (yellow), Edinburgh; Frisky Hall, Dumbartonshire (fig. 584); Hartfield Moss, Renfrew (botryoidal); Cornwall; Dauphiné; Tyrol: Cape of Good Hope; China (*Fu*).

628. FRIEDELITE, $\dot{Mn}_4\ddot{Si}_3+2\dot{H}$.

Rhombohedral; R 123° 42′. 0R; ∞R. Tabular habit, and in granular aggregates. Cl. basal, perfect. H. = 4 to 5; G. = 3·1. Rose-red, with paler streak. C.c.: silica 36, protoxide of manganese 53, lime 2·96, water 7·9. Adervielle on the Neste de Louron (Pyrenees).

HYDROUS SILICATES OF ALUMINA.

These are probably for the most part products of decomposition of felspars under atmospheric exposure.

629. KAOLIN (*Porcelain Earth*), $\dddot{Al}\ddot{Si}_2+2\dot{H}$.

Massive; in beds and veins. Fracture uneven; fine earthy, very soft, sectile, and friable. H. = 1; G. = 2·2. Opaque, dull. White or grey, inclining to blue, green, yellow, or red. Feels meagre, not greasy when dry, and plastic when wet. B.B. infusible. Not affected by h. acid, but decomposed by warm s. acid, leaving silica. C.c. very variable, but approximates to 46 silica, 40 alumina, and 14 water. Chiefly a product of the decomposition of orthoclase, or of granite, porphyry, and other rocks containing that mineral. Cornwall and Devonshire in England are the chief European localities for the kaolin used in manufacturing porcelain.

Clays are merely varieties of kaolin, mixed with quartz-sand, carbonate of lime, magnesia, and the oxyhydrates of iron. Often 40 to 50 silica, 30 alumina, 13 to 20 water, and 4 iron peroxide, with lime and potash. In the fire they are infusible, burning hard. Generally they are compact and friable, of white, yellow, red, blue, grey, or brown colours. Their specific gravity varies from 1·8 to 2·7. The following are varieties. *Pipe-clay*, greyish or yellowish white, with a greasy feel, adheres strongly to the tongue, when wet is very plastic and tenacious, and in the fire burns white. Abundant in Devonshire, and in the Trough of Poole in Dorsetshire; in France, Belgium, and Germany. Used for manufacturing tobacco-pipes and similar articles. *Potter's Clay*, red, yellow, green, or blue, becoming yellow or red when burnt; more easily fused than the former, and often effervesces with acids. That used in the potteries in England comes chiefly from Devonshire. *Loam*, coarser and more impure, with more sand, and consequently less plastic. *Shale* or *Slate Clay*, greyish black, and much mixed with bituminous or carbonaceous matter. *Bituminous Shale*, known by its shining resinous streak. *Black Chalk*, with more carbon, leaves a black mark on paper. *Iron Clay* contains much peroxide of iron, is reddish-brown, and forms the basis of many amygdaloids and porphyries.

630. NACRITE, $\dddot{Al}\ddot{Si}_2+2\dot{H}$.

Right prismatic; minute six-sided tables in fan-like group; and scaly. H. = 0·5 to 1; G. = 2·35 to 2·6. Glimmering to pearly, snow-white or yellowish white. C.c.: silica 46·3, alumina 39·8, water 13·9. A crystalline form of kaolin. Fins in Allier, Mons, Freiberg, Pennsylvania, and coal formation commonly.

631. LITHOMARGE.

Kaolinic substances, compact, earthy, and pseudomorphous. H. = 2·5 to 3; G. = 2·4 to 2·6. White, yellow, or red. Greasy, adheres to tongue. Klausthal, Harz, &c. Similar are *Carnat*, *Myelin*, *Melopsite*.

632. HALLOYSITE, $\dddot{Al}\ddot{Si}+4\dot{H}$.

Massive and reniform. H. = 1·5 to 2·5; G. = 1·9 to 2·1. Translucent when moist. Bluish white, green, or yellow. C.c.: 41·5 silica, 34·4 alumina, 24·1 water. Hospital Quarry near Elgin, on the Tweed, Liége, Tarnowitz, Eifel (*Lenzinite*). *Fuller's Earth* may be an impure ferruginous variety. Maxton in Scotland, Reigate and Maidstone in England, Saxony, Bohemia, &c.

633. GLAGERITE, $\dddot{Al}_2\ddot{Si}_3+6\dot{H}$.

H. = 1; G. = 2·35. Bergnersreuth. *Malthazite*, from Steindörfel near Bautzen, has less alumina.

634. KOLLYRITE, $\dddot{Al}_2\ddot{Si}+9\dot{H}$.

H. = 1 to 2; G. = 2. Also similar. Schemnitz, Pyrenees, and Saxony. *Scarbroite* from Scarborough has $10H_2O$.

635. MILOSCHIN.

Conchoidal or earthy. H. = 2; G. = 2·1. Indigo-blue to celadon-green; has 2 to 4 chrome oxide. Rudnik in Servia.

636. MONTMORILLONITE, $\dddot{Al}_2\ddot{Si}_7+2\dot{H}$.

Massive. Rose-red. Montmorillon and elsewhere in France, Poduruoj in Transylvania.

637. RAZOUMOFFSKIN, $\dddot{Al}\ddot{Si}_3+3\dot{H}$.

From Carinthia. *Chrome Ochre*, with 2 to 10 per cent. of chrome oxide, from Waldenburg in Silesia and Creusot in France, is similar.

638. CIMOLITE, $\dddot{Al}_2\ddot{Si}_9+6\dot{H}$.

Pseudomorphous after augite. Bilin, Limburg, Kaiserstuhl, Argentiera and Milo.

639. ALLOPHANE, $\dddot{Al}\ddot{Si}+5\dot{H}$.

Botryoidal and reniform. Fracture conchoidal; brittle. H. = 3; G. = 1·8 to 2. Pellucid; vitreous. Pale blue, white, green, or brown. Colour due to copper. Charlton, Woolwich, Baden, and Bonn.

640. PYROPHYLLITE, $\dddot{Al}\ddot{Si}_4+\dot{H}$.

Right prismatic, but radiated, foliated. Cl. perfect; flexible, sectile. H. = 1; G. = 2·8 to 2·9. Translucent, pearly. Light verdigris-green to yellowish white. B.B. swells up with many twistings to a white infusible mass. C.c.: 67 silica, 28 alumina, and 5 water. Urals, Spa, Morbihan, Westana in Sweden, Carolina, and Brazil. *Talcosite*, from Heathcote in Victoria, has silica and alumina about equal.

641. ANAUXITE, $\dddot{Al}\ddot{Si}_4+3\dot{H}$.

Granular. H. = 2 to 3; G. = 2·2 to 2·4. Translucent, pearly. Greenish white. C.c.: 60·5 silica, 26 alumina, and 13·5 water. Bilin in Bohemia.

HYDROUS SILICATES OF ZIRCONIA, THORIA, &c.

642. MALACONE, $3\ddot{Zr}\ddot{Si}+\dot{H}$.

Pyramidal. P 83° 30′. Typical form $\infty P\infty$, P, ∞P. H. = 6; G. = 3·9 to 4·1. Conchoidal fracture. Lustre vitreous. C.c. same as zircon, but with 3 of water in the Hitterö variety and over 9 in that from Finland. Has a surface opalescence, and may be altered zircon. Hitterö, Chanteloube (near Limoges), near Dresden, Rosendal, Finland, Miask.

643. EUCRASITE.

Right prismatic (?). H. = 4·5 to 5; G. = 4·39. Lustre greasy. Blackish brown; streak brown. Translucent on edges. Fracture uneven; brittle. C.c. very complex: silica 16, thoria 36, cerium protoxide 5·5, peroxide 6, lanthania 2·4, yttria 4·3, erbia 1·6, titanic acid 1·8, ferric oxide 4·25, alumina 1·8, water 9. Barkevig near Brevig.

644. THORITE, $\ddot{Th}\ddot{Si}+2\dot{H}$.

Pyramidal. ∞P : P 133° 30′. Generally massive. H. = 4·5 to 5. G. = 5 to 5·4. Lustre brilliant vitreous; when weathered resinous. Fracture conchoidal when fresh, splintery when weathered. Brownish black to clove-brown. C.c. complex, but essentially 18 silica, 73 thoria, 9 water. In syenite at Lochan

Hacon, and in a boulder on Ben Bhreck in Sutherland, in crystals (fig. 585); Löwö near Brevig, Norway. *Uranothorite*, from Arendal, has 50 per cent. thoria and 10 uranous oxide; found also at Hitterö and at Champlain (U. S.)

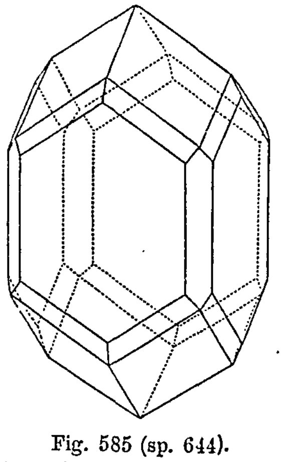

Fig. 585 (sp. 644).

645. ORANGITE, $3\ddot{Th}\dddot{Si}+2\dot{H}$.

Massive. Orange-yellow to cinnamon-red. Other characters like thorite. C.c.: 17 silica, 75 thoria, 7 water. Ben Bhreck, Langesund near Brevig. The mineral from Ben Bhreck passes gradually into thorite, which thus would appear to be altered orangite.

646. TRITOMITE, $\dddot{R}_2\dddot{Si}_3+4\dot{H}$.

Cubic. In tetrahedra. H. = 5·5; G. = 3·9 to 4·66. Lustre vitreous. Dull brown; streak yellowish grey. Subtranslucent. C.c. complex: silica 21, alumina 2·5, ceria 40, lanthania 15, yttria 4·6, lime 4, water 8. Lamö near Brevig.

MAGNESIAN SILICATES.

647. AGALMATOLITE (*Figure Stone*), $4\dddot{Al}\dddot{Si}_3+\dot{K}\dddot{Si}_3+3\dot{H}$.

Massive or slaty. Fracture splintery, rather sectile. H. = 2 to 3; G. = 2·8 to 2·9. Translucent; glimmering. Green, grey, red, and yellow. Feels somewhat greasy, but does not adhere to the tongue. Sol. in s. acid. C.c.: 55 silica, 33 alumina, 7·6 potash, and 5 water; but in many localities magnesian. Calligaig in Sutherland; China, where it is cut into various works of art; also Nagyag in Hungary, and Saxony.

648. ONCOSIN, $2\dddot{Al}\dddot{Si}_2+(\dot{K},\dot{M}g)\dddot{Si}_2+2\dot{H}$.

Fracture uneven or splintery; sectile. H. = 2; G. = 2·8. Translucent; slightly resinous. Apple-green or brown. Sol. in s. not in h. acid. Salzburg.

649. LIEBENERITE.

Hexagonal. ∞P; 0P. Cl. prismatic, perfect; fracture hackly. H. = 3·5; G. = 2·8. Oil-green, bluish green, and greenish grey. Greasy lustre. C.c.: silica 44·7, alumina 36·5, potash 9·9, water 5·5. Monte Viesena near Forno, Predazzo in Tyrol.

650. GIESECKITE.

Hexagonal. ∞P; 0P. Fracture splintery. H. = 3 to 3·5; G. = 2·7 to 2·9. Kangerdluarsuk in Greenland, Diana in New York.

651. KILLINITE, $2\dddot{Al}\dddot{Si}_2+\dot{R}\dddot{Si}_2+3\dot{H}$.

Crystalline, foliated. Cl. along a prism of 135° 44′. G. = 2·65. Greenish grey, yellow, or brownish green. C.c.: 48 silica, 31 alumina, 2·3 protoxide of iron, 6·5 potash, 10 water. Killiney near Dublin.

652. HYGROPHILITE.

Scaly. H. = 2 to 2·5; G. = 2·7. Greenish grey. Lustre and feel greasy. C.c.: silica 48·4, alumina 32·1, protoxide of iron 3·3, potash 5·7, water 9. Sol in h. acid. Halle on the Saale.

653. BRAVAISITE, $\dot{R}_2\dddot{Si}_3+2\dddot{Al}\dddot{Si}_3+4\dot{H}$.

Aggregates of thin plates. H. = 1 to 2; G. = 2·6. C.c.: silica 51·4, alumina 18·9, peroxide of iron 4, magnesia 3·3, potash 6·5, water 13·3. Noyant in Allier.

654. PINITOID.

Massive. Leek- and oil-green. H. = 2·5; G. = 2·8. C.c.: silica 48·5, alumina 28, protoxide of iron 8, potash 5·8, water 4·5. Freiberg and Chemnitz in Saxony.

655. BOLE.

Earthy, in nests and veins. Conchoidal. H. = 1 to 2; G. = 2·2 to 2·5. Opaque; dull resinous; streak shining. Brown, yellow, or red. Feels greasy; some adhere strongly to the tongue, others not at all. In water crackles and falls to pieces. C.c. hydrous silicates of alumina and iron peroxide, in various proportions. Scotland, Ireland, Dransfeld, Clermont in Auvergne. *Stolpenite, Rock Soap, Plinthite, Yellow Earth* or *Felinite, Fetbol*, and *Ochran* are varieties.

656. CARPHOLITE, $\dddot{Al}\dddot{Si}+\dot{M}n\dddot{Si}+2\dot{H}$.

Right prismatic. P 111° 27′. Radiating stellated. H. = 5 to 5·5; G. = 2·9. Translucent; silky; straw- to wax-yellow. B.B. intumesces and fuses to an opaque brown glass. C.c.: silica 38, alumina 29·4, protoxide of iron 2·9, peroxide of iron 4, protoxide of manganese 11·8, water 10·8. Schlaggenwald, Wippra in the Harz, Meuville in the Ardennes.

657. NONTRONITE, $\dddot{Fe}\dddot{Si}_3+5\dot{H}$.

Massive; fracture uneven. H. = 2 to 3; G. = 2 to 2·3. Opaque; dull or glimmering; streak resinous. Straw-yellow or siskin-green. B.B. decrepitates, becomes black and magnetic, but without fusing; sol. and gelatinizes in warm acids. C.c.: 43 silica, 36 iron peroxide, and 21 water, with 3·5 alumina and 2 magnesia. Nontron in France, Harz, and Bavaria. *Chloropal* is similar. B.B. brown. Unghvar in Hungary, and Passau.

658. PINGUITE.

Massive; fracture splintery; sectile. H. = 1; G. = 2·3. Light to dark green. Lustre vitreous. Feels greasy. C.c.: silica 36·9, peroxide of iron 29·5, protoxide of iron 6·1, water 25·1. Wolkenstein, Suhl.

659. HISINGERITE, $\dddot{Fe}_2\dddot{Si}_3+2\dot{F}e\dddot{Si}+9\dot{H}$.

Reniform, and in crusts. H. = 3·5 to 4; G. = 2·6 to 3. Opaque, resinous. Brownish or bluish black; streak liver-brown or yellowish brown. C.c.: various, but 32·5 silica, 33·5 iron peroxide, 15·1 iron protoxide, and 19 water, in the *Thraulite* from Bodenmais. Also Gilling and Riddarhyttan in Sweden, and Breitenbrunn (*Polyhydrite*).

660. BERGHOLZ.

Fine fibrous; glimmering lustre. Wood-brown to green. G. = 2·4. C.c.: silica 55·5, peroxide of iron 19·5, magnesia 15, water 10·3. Sterzing in Tyrol. *Xylite*, probably from the Urals, is similar.

661. UMBER.

Massive; fracture conchoidal. H. = 1·5; G. = 2·2. Liver-brown; streak shining. Mixtures of peroxide of iron, oxide of manganese, and alumina with water. Cyprus. *Hypoxanthite* and *Siderosilicite* are similar.

662. KLIPSTEINITE, $(\dot{R}_3,\dddot{R}_3)_2\dddot{Si}_3+\dot{R}_3\dot{H}_3$.

Compact. H. = 5 to 5·5; G. = 3·5. Liver-brown to black; streak yellow-brown. C.c.: silica 25, peroxide of iron 4, sesquioxide of manganese 57, water 9. Klapperud in Dalecarlia, Herborn near Dillenburg.

663. WOLKONSKOITE.

Amorphous. Horny; bluish green to grass-green. Fracture conchoidal; brittle. C.c.: silica 36, alumina 3, sesquioxide of chromium 19, ferric oxide 10, water 21. Okhansk in Siberia.

664. RÖTTISITE, $3\dot{N}i\dddot{Si}+4\dot{H}$.

Amorphous and reniform. Apple-green to emerald-green. H. = 2 to 2·5; G. = 2·35 to 2·37. C.c.: silica 43·7, nickel oxide 35·9, water 11·2. Röttis near Reichenbach in Saxony. *Komarit* is similar.

665. URANOPHANE, $3\dot{C}a\dddot{Si}+\dddot{U}_5\dddot{Si}_3+18\dot{H}$.

Right prismatic. ∞P 146°; ∞P̄∞; P̆∞; with polar angle 90°. Crystals honey-yellow; when massive leek-green. H. = 2·5; G. = 2·6 to 2·8. C.c.: silica 17, alumina 6·1, oxide of uranium 53·3, lime 5·1, water 15·1. Kupferberg in Silesia.

666. URANOTILE, $\dot{C}a\dddot{Si}+\dddot{U}_3\dddot{Si}_2+9\dot{H}$.

Right prismatic. ∞P 164. In stellate groups. Lemon-yellow. G. = 3·96. C.c.: silica 13·8, oxide of uranium 66·75, lime 5·27, water 12·67. Wölsendorf in Bavaria, Joachimsthal, Mitchel county in North Carolina.

667. BISMUTOFERRITE, $\dddot{Bi}, \dddot{Si}_2, +2\dddot{Fe}, \dddot{Si}$.

Crypto-crystalline; oblique prismatic. Siskin- to olive-green. H. = 3·5; G. = 4·48. C.c.: silica 24, oxide of bismuth 42·8, peroxide of iron 33·1. Schneeberg in Saxony. *Hypochlorite* is a variety containing 13 of bismuth. In a third variety, from Bräunsdorf, antimony replaces bismuth.

SILICATES WITH TITANATES, NIOBATES, &c.

668. SPHENE, $\dot{C}a\dddot{Si}_2+\dot{C}a\dddot{Ti}_2$.

Oblique prismatic, C 85° 22′. ∞P (*l*) 133°2′; $\frac{1}{2}$P°∞ (*x*) 55° 21′; P°∞ (*y*) 34° 21′; ∞P^c∞ (*q*): 0P (*P* or *c*) 90°; ∞P^{c}3 (*M*) 76° 7′; P^c∞ (*r*) 113° 30′; $\frac{2}{3}$P^{c}2 (*n*) 136° 12′; 4P^{c}4 (*s*) 67° 57′. Crystals vary extremely in form, being generally apparently oblique-tabular, from predominance of *n*, which are hemidomes in alternate position on opposite ends; also, but more rarely, prismatic, with dominance of *l* and *M*. Twins frequent. Twin face *c*, and formed by revolution either (*a*) on an axis normal to *c* or (*b*) on a vertical axis; the former very common and usually producing thin tables with a re-entering angle along one side, and sometimes elongated. Occasionally in double twins. Sometimes granular or foliated. Cl. in some (*l*), in others (*r*). H. = 5 to 5·5; G. = 3·4 to 3·6. Semitransparent; adamantine or resinous.

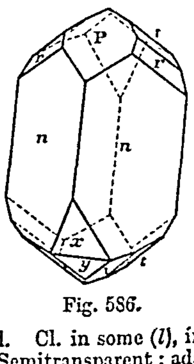

Fig. 586.

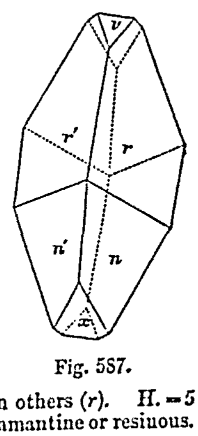

Fig. 587.

Yellow, brown, and green. B.B. fuses with micro-salt in the red. flame, gives reaction for titanic acid. C.c.: silica 30·6, titanic acid 40·8, lime 28·6. In Scotland, typical of syenites and primary limestones. In minute hair-brown crystals in the first; as at Lairg (Sutherland), Achavarasdale (Caithness), and Criffel (Kirkcud-

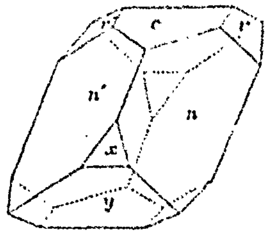

Fig. 588.

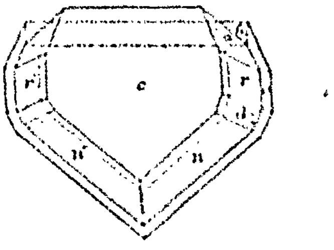

Fig. 589.

bright) (figs. 586 to 588). In the latter often in highly complex twins, yellow to brown, at Shiness (figs. 193, 589), Urquhart, Dalnain, Torbane, &c., also with ilmenite and allanite in exudation veins of grey granite. Dauphiné, Mont Blanc, St Gotthard, Tyrol, Arendal, America. *Greenovite*, flesh-red from Glen Gairn in Aberdeenshire (like 194), and St Marcel in Piedmont; contains manganese at the latter locality.

669. Keilhauite (*Yttrotitanite*), $5(\dot{C}a\dot{Y})(\ddot{S}i\ddot{T}i) + (\dddot{A}l\dddot{F}e)(\ddot{S}i\ddot{T}i)_3$.

Oblique prismatic, C 58°. ∞P 114. Cl. -2P, 135°. H. = 6 to 7; G. = 3·5 to 3·7. Blackish brown; streak greyish yellow. B.B. with borax forms blood-red glass in the red. flame; other features like sphene. C.c.: 29·7 silica, 28·7 titanic acid, 21·1 lime, 10·3 yttria, 6·2 alumina, and 6·5 iron peroxide. Near Arendal.

670. Schorlomite (*Ferrotitanite*), $\dot{C}a_3\ddot{S}i + \dddot{F}e_2\ddot{S}i_3 + \dot{C}a\ddot{T}i_2$.

Cubic; ∞O and 2O2; generally massive; fracture conchoidal. H. = 7 to 7·5; G. = 3·8. Black; streak grey-black; vitreous. C.c.: silica 26, titanic acid 23·3, peroxide of iron 20, lime 29·1. Arkansas, Kaiserstuhl, Ivaara in Finland. Perhaps a titaniferous garnet.

671. Tschewkinite.

Massive; fracture flat conchoidal. H. = 5 to 5·5; G. = 4·5. Opaque, vitreous, splendent. Velvet-black; streak dark brown. B.B. intumesces greatly, becomes porous, and often incandesces; in white heat fuses to black glass; gelatinizes with h. acid. C.c.: 21 silica, 20 titanic acid, 11 iron protoxide, 45 peroxides of cerium metals with perhaps thoria, lime 4. Miask, Coromandel.

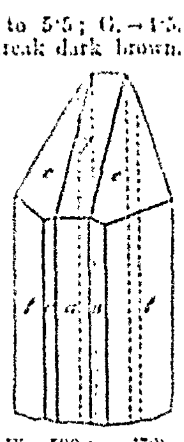

Fig. 590 (sp. 672).

672. Mosandrite.

Oblique prismatic, C 71° 24½′. ∞P (*t*) 88° 36′; ∞P∞2 (*n*); ∞P∞ (*a*); $-$P (*e*) 124° 1′; $-$P∞ (*q*); ∞P∞. *t* : *a* 134° 18′; *n* : *a* 152° 52′; *q* : *a* 138° 2′. Twin face the orthopinacoid. Generally massive. Fracture uneven. H. = 4; G. = 2·93 to 3. Yellowish or reddish brown; streak pale green. Vitreous to resinous lustre. C.c.: silica 29·9, titanic acid 9·9, oxide of cerium metals 26·5, lime 19, water 8·9. Brevig and Langesundfiord.

673. Eudialite (*Eukolite*), $6\dot{R}\ddot{S}i_2 + \dot{R}\ddot{Z}r$.

Rhombohedral; R 73° 10′. R (*p*), 0R (a_1), ∞P2 (d_1), ¼R (a_2); also ∞R, ⅝R, $-\frac{1}{2}$R, -2R, $-\frac{1}{4}$R, R3, ⅔P2 (fig. 591). Generally massive, granular. Cl. a_1 and a_2; fracture uneven. H. = 5 to 5·5; G. = 2·81 to 2·95. Peachblossom-red to brownish red; streak white. Translucent; vitreous. B.B. fuses easily to a light-green opaque glass; gelatinizes in h. acid. C.c.: silica 50, zirconia 16·9, protoxide of iron 7, lime 11, soda 12. Kangerdluarsuk in Greenland, Sedlovatoi Island in White Sea, Brevig (*Eukolite*), Magnet Cove in Arkansas.

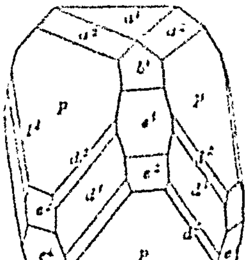

Fig. 591 (sp. 673).

674. Catapleite, $2(\dot{N}a_2\dot{C}a)(\ddot{S}i\ddot{Z}r)_3 + 9\dot{H}$.

Hexagonal. P 114° 43′. 0P, ∞P, P, also with 2P, and ½P. In lamellar aggregates. Cl. prismatic and P; fracture uneven. H. = 6; G. = 2·8. Yellowish brown to pale green; streak yellow, lustrous. C.c.: silica 46·7, zirconia 29·6, soda 10·8, water 9. Brevig.

675. Œrstedite.

Pyramidal. P 84° 25′. P, ∞P, ∞P∞. Like zircon. H. = 5·5; G. = 3·63. Lustre adamantine. Reddish brown. C.c.: silica 19·7, titanate of zirconia 68·96, water 5·6. Arendal.

676. Wöhlerite, $9\dot{R}\ddot{S}i + 3\dot{R}\ddot{Z}r + \dot{R}\ddot{\ddot{N}}b$.

Oblique prismatic, C 70° 45′. ∞P 90° 14′; ∞P∞2 127° 4′; $-$P∞ 43° 13′. 0P : ∞P∞ 109° 15; $-$P∞ : ∞P∞ 136° 42′; 0P : ∞P 103° 31′. Crystals tabular and prismatic. Cl. clinodiagonal; fracture conchoidal. H. = 5 to 6; G. = 3·4. Light yellow, honey-yellow to brownish grey; streak yellowish white. C.c.: silica 28, zirconia 19, niobic acid 13·9, lime 27·3, soda 8·3, protoxide of iron 3. B.B. fuses to yellowish glass. Sol. in h. acid. Langesundfiord, Brevig.

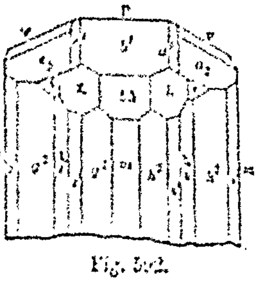

Fig. 592.

677. Ardennite.

Right prismatic. ∞P 131° 2′; P∞ 112° 23′; P⅓; ∞P⅓; ∞P2; ∞P∞; ∞P∞. Crystals like ilvanite. Cl. brachydiagonal, and ∞P. H. = 6 to 7; G. = 3·62. Yellow to yellow-brown. Dichroic; brittle. C.c.: silica 27·8, alumina 24, protoxide of manganese 26·7, lime 2·2, magnesia 1·3, vanadic acid 3·2, arsenic acid 6·3, water 5. Ottrez in the Ardennes (Luxemburg).

678. Roscoelite.

Foliated masses, sometimes stellated. H. = 1; G. = 2·3 to 2·9. Dark green to greenish blue. Pearly lustre. C.c.: silica 47·7, vanadic acid 22, alumina 14·1, magnesia 2, potash 7·6, water 5. Eldorado in California.

TITANATES WITH NIOBATES.

679. Titanomorphite, $\dot{C}a\ddot{T}i_2$.

Oblique prismatic. Like sphene. ∞P, 0P, ½P∞, P∞, ½P2. C.c.: titanic acid 74·3, lime 25·3. Lampersdorf in Silesia, Weistritz.

680. Perovskite, $\dot{C}a\ddot{T}i$.

Right prismatic. In complicated twins, often distorted, pseudo-cubic. H. = 5·5; G. = 4 to 4·1. Lustre metallic-adamantine. Pale yellow, reddish brown to iron-black; streak grey. C.c.: 58·8 titanic acid, 41·2 lime. B.B. with micro-salt in outer flame gives a bead greenish while hot, colourless on cooling; in inner flame grey-green when hot, violet-blue when cold. Decomposed by boiling s. acid. Zlatoust, Schelingen, Zermatt, Malenco Valley near Sondrio, Pfitsch in Tyrol, Magnet Cove in Arkansas.

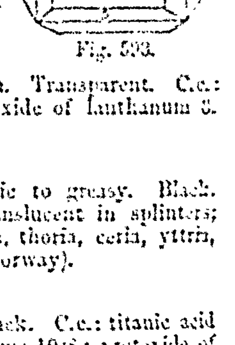

Fig. 593.

681. Koppite, $\dot{R}_2\ddot{\ddot{N}}b_2$.

Cubic; ∞O∞. G. = 4·45 to 4·56. Brown. Transparent. C.c.: niobic acid 62·46, oxide of cerium 6·7, oxide of lanthanum 3. Schelingen on the Kaiserstuhl in Baden.

682. Annerödite, $2\dot{R}_3\ddot{\ddot{N}}b + 5\dot{H}$:

Right prismatic. H = 6. G 5·7. Metallic to greasy. Black. Streak black, brown, greenish grey. Translucent in splinters; brittle. C.c.: 48 niobic acid, with zirconia, thoria, ceria, yttria, and uranium oxide. Annerod near Moss (Norway).

683. Dysanalyte, $6\dot{R}\ddot{T}i + \dot{R}\ddot{\ddot{N}}b$.

Cubic; ∞O∞. Cl. cubic. G. = 4·13. Black. C.c.: titanic acid 41·5, niobic acid 23·2, cerium oxide 5·7, lime 19·8; protoxide of iron 5·8, soda 3·0. Vogtsburg on the Kaiserstuhl.

684. Pyrochlore, $5\dot{R}\ddot{\ddot{N}}b + 1\dot{R}(\ddot{T}i\ddot{T}h)_2 + 4NaF$.

Cubic (fig. 594). Cl. octahedral; brittle; fracture conchoidal. H. = 5; G. = 4·2 to 4·4. Resinous, opaque. Red-brown to black, ruby-red and transparent rarely; streak pale brown. C.c.: niobic acid 53·2, titanic acid 10·5, thoria 7·6, cerium oxide 7, lime 14·2, soda 5, fluorine 3·1. Miask, Kaiserstuhl, Brevig, and Frederiksvärn. *Microlite*, from Chesterfield in Massachusetts, has tantalic acid 68·4, niobic acid 7·75, 11·7 lime and 7·7 protoxide of manganese. *Pyrrhite* from Mursinsk in the Urals, San Piero in Elba, and the Azores may be the same; at the last locality it is in orange-red octahedra, and is a niobate of zirconia.

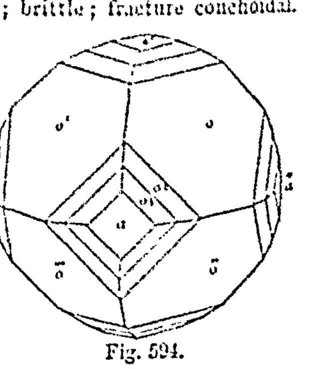

Fig. 594.

685. Blomstrandite, $(\dot{C}a, \dot{F}e), \ddot{T}i + \ddot{U}\ddot{\ddot{N}}b_3 + \dot{H}$.

Massive. H = 5·5. G. = 4·17 to 4·25. Vitreous, black. Streak

brown. Translucent in splinters. C.c.: niobic acid 49·8, titanic acid 10·7, uranium oxide 23·7, protoxide of iron 3·3, lime 3·5, water 7·9. Nohl (Sweden).

686. Polycrase, $4\ddot{R}\ddot{T}i + \dot{R}\dddot{N}b$.

Right prismatic (fig. 595). $\infty\breve{P}\infty$, ∞P (140°), P, $2\bar{P}\infty$ (56°). Fracture conchoidal. H. = 5 to 6; G. = 5·1. Black; streak grey-brown. B.B. decrepitates violently, incandescing, but does not fuse. Sol. in s. acid. C.c.: titanic acid 26·6, niobic acid 20·4, yttria 23·3, erbia 7·5, oxide of uranium 7·7, water 4. Hitterö (Norway), Slettåkra in Jönköping (Sweden).

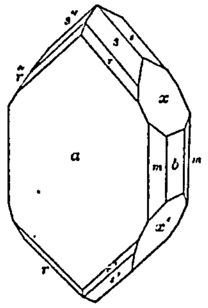

Fig. 595.

687. Euxenite, $2\ddot{R}\ddot{T}i + \dot{R}\dddot{N}b + \dot{H}$.

Right prismatic (fig. 596). ∞P (m) 140°; $\infty\breve{P}\infty$ (b); $2\bar{P}\infty$ (d) 52°; P (p) 102° 58′. $p : b$ 103° 6′. Fracture conchoidal. Opaque; metallic to vitreous. Black and brownish black; streak red-brown. B.B. infusible. Not acted on by acids. C.c.: niobic acid 32, titanic acid 19·2, uranium oxide 19·5, yttria 18·2, cerium oxide 2·8, but variable. Jölster, Tromö, Alvö, &c., in Norway; also Hitterö and Cape Lindesnaes.

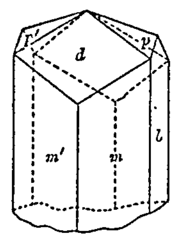

Fig. 596.

688. Æschynite.

Right prismatic. ∞P (M) 128° 34′; $2\breve{P}\infty$ (y) 73° 16′; P ($o : o$) 137° 14′; $\infty P3$ 69° 23′; $\bar{P}\infty$; 0P. Crystals long prismatic (fig. 597). Cl. traces; fracture imperfect conchoidal. H. = 5 to 5·5; G. = 4·9 to 5·1. Opaque; submetallic or resinous. Iron-black or brown; streak yellowish brown. B.B. swells and becomes yellow or brown, but is infusible. Not sol. in h. acid, partially in s. acid. C.c.: niobic and tantalic acids 28·8, titanic acid 22·6, thorium oxide 15·7, cerium protoxide 18·5, lanthanum oxide and didymium oxide 5·6. Miask, Hitterö.

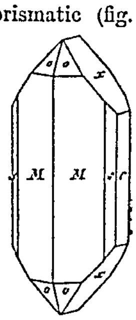

Fig. 597 (sp. 688).

689. Polymignite.

Right prismatic. P (p) polar 136° 28′ and 116° 22′; ∞P 109° 46′; $\infty\bar{P}\infty$; $\infty\breve{P}\infty$ (fig. 598). Cl. macro- and brachydiagonal, imperfect; fracture conchoidal. H. = 6·5; G. = 4·7 to 4·8. Opaque; semimetallic. Iron-black; streak dark brown. B.B. infusible. Sol. in h. acid. C.c.: titanic acid 46·3, zirconia 14·1, yttria 11·5, lime 4·1, iron peroxide 12·2, cerium oxide 5. Frederiksvärn.

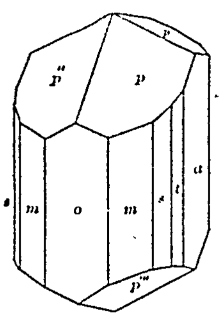

Fig. 598 (sp. 689).

690. Mengite, ($\dddot{F}e$, $\ddot{Z}r$) $\ddot{T}i$.

Right prismatic. P (e) polar angle 151° 27′ and 101° 10′; ∞P 136° 20′; $\infty\breve{P}3$; $\infty P\infty$ (fig. 599). Fracture uneven. H. = 5 to 5·5; G. = 5·48. Opaque; semimetallic. Iron-black; streak chestnut-brown. B.B. infusible, but becomes magnetic. Sol. in s. acid. Miask, Groix island in Morbihan.

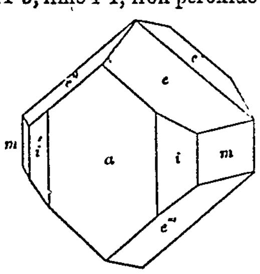

Fig. 599 (sp. 690).

691. Tantalite, $\dot{F}e$ ($\dddot{T}a$, $\dddot{N}b$).

Right prismatic. P (p) with polar edges 126° and 112° 30′, middle 91° 42′. $\infty\breve{P}\frac{4}{3}$ (r) 122° 53 $\infty\bar{P}\infty$ (s); $\infty\breve{P}\infty$ (t); $\breve{P}\infty$ (m) 113° 48; $3\breve{P}\infty$ (q) 54° 10′; $\frac{1}{6}\breve{P}\infty$ (n) 167° 36′; $\frac{4}{3}\breve{P}\frac{4}{3}$ (v); $2\breve{P}2$ (o). Fracture conchoidal or uneven. H. = 6 to 6·5; G. = 6·1 to 8. Opaque; semimetallic, adamantine, or resinous. Iron-black; streak cinnamon- or coffee-brown. B.B. infusible; scarcely affected by acids. C.c.: 76 to 50 tantalic acid, 7·5 to 29 niobic acid, 9 to 16 iron protoxide, and 1 to 6 manganese protoxide; some with 1 to 10 tin oxide (*Cassiterotantalite*); also in union with iron (manganese) protoxide. Kimito and Tammela in Finland, Broddbo and Finbo near Falun, and Chanteloube near Limoges; always in granite.

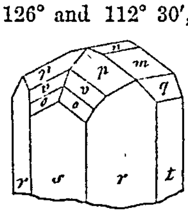

Fig. 600.

692. Tapiolite, $4\dot{F}e\dddot{T}a + \dot{F}e\dddot{N}b$.

Pyramidal. P middle angle 84° 52′, summit 123° 1′. H. = 6; G. = 7·2 to 7·5. Black. Lustrous. C.c.: tantalic acid 73·9, niobic acid 11·2, protoxide of iron 15. Tammela in Finland.

693. Columbite, $m\dot{F}e\dddot{N}b + n\dot{F}e\dddot{T}a$.

Right prismatic. P (u) polar angles 104° 10′ and 151°, middle angle 83° 8′; 0P (c); $\infty\breve{P}\infty$ (b); $\infty\bar{P}\infty$ (a); ∞P (g) 135° 40′; $\infty\breve{P}\infty$ (m) 101° 26′; 2P (s); $3\breve{P}3$ (o); $3\breve{P}\frac{3}{2}$ (π); $\frac{1}{2}\breve{P}\infty$ (l) 161°; $\breve{P}\infty$ (k) 143°; $2\breve{P}\infty$ (h) 112° 26′; $\bar{P}\infty$ (i) 101° 12′; $2\bar{P}\infty$ (e) 62° 40′. Hemitropes, face e; vertical axes forming an angle of 62° 40′; also on faces 2P2 (n), and rarely b. Also granular and foliated. Cl. brachydiagonal, perfect, also macrodiagonal. H. = 6; G. = 5·4 to 6·4. Metallic, adamantine. Iron-black to brownish; streak black or reddish brown. B.B. infusible; not affected by acids. C.c.: isomorphic mixtures of niobic and tantalic acids with protoxide of iron (or manganese). Pure columbite would give 78·8 niobic acid, pure tantalite 86 tantalic acid. The niobic acid generally prevails, and the crystals are better formed the more this is the case. Rabenstein, Bodenmais, Chanteloube, Finland, Ilmen Hills, Evigtok in Greenland, Haddam and Middletown in Connecticut, Acworth in New Hampshire, Pike's Peak in Colorado.

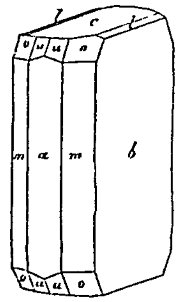

Fig. 601.

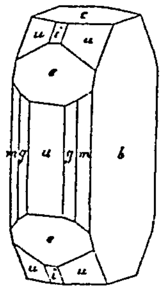

Fig. 602.

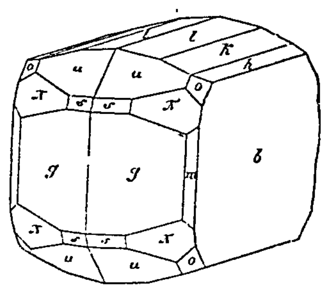

Fig. 603.

694. Yttrotantalite, ($\dot{Y}$, $\dot{C}a$, $\dot{F}e$, $\dot{U}$)$_2$($\dddot{T}a$, $\dddot{W}$, $\dddot{N}b$).

In two varieties. (*a*) *Black*. Right prismatic; in short prismatic or tabular crystals. $\infty\breve{P}\infty$; ∞P (m) 121° 48′. 0P : $2\breve{P}\infty$ 103° 26′; $\breve{P}\infty$: 0P 131° 26′; $i : i$ 149° 42′ (fig. 604); also in grains and lamellæ. Cl. brachydiagonal, indistinct; fracture conchoidal or uneven. Opaque, or in thin splinters translucent. Velvet-black, semimetallic lustre, and greenish grey streak. H. = 5·5; G. = 5·4 to 5·7. (*b*) *Yellow*. Amorphous, yellowish brown, or yellow, often striped or spotted; resinous or vitreous; streak white. G. = 5·46 to 5·88. Both varieties B.B. infusible, but become brown or yellow. Not affected by acids. C.c.: 57 to 60 tantalic acid, 1 to 8 tungstic acid, 0 to 20 niobic acid, 20 to 38 yttria, 0·5 to 6 lime, 0·5 to 6 uranium peroxide, and 0·5 to 3·5 iron peroxide. Ytterby, and near Falun.

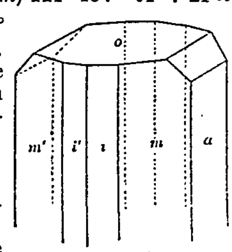

Fig. 604.

695. Fergusonite, ($\dot{Y}$, $\dot{E}r$, $\dot{C}e$)$_3$($\dddot{N}b$, $\dddot{T}a$).

Pyramidal and hemihedric; P (s) 128° 28′. Usual form ($\frac{1}{2}$) $3P\frac{3}{2}$ (z), P, $\frac{1}{2}\infty P\frac{3}{2}$ (g), 0P (c) (fig. 605). $s : s$ 100° 54′, $s : c$ 115° 16′, $z : r$ 169° 17. Cl. traces along P; fracture imperfect conchoidal; brittle. H. = 5·5 to 6; G. = 5·6 to 5·9. Translucent in thin splinters; semimetallic. Brownish black; streak pale brown. B.B. infusible. C.c.: chiefly niobic acid and yttria, with erbia, also a little cerium protoxide, tin oxide, uranium oxide, and iron protoxide. Cape Farewell in Greenland, Ytterby, Riesengebirge, Rockport in Massachusetts. *Tyrite*, from Helle near Arendal, is similar.

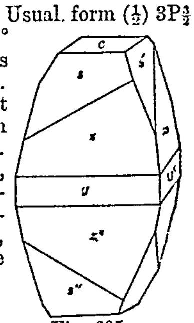

Fig. 605.

696. Hjelmite.

Massive, with granular fracture and traces of crystals. H. = 5; G. = 5·82. Velvet-black; streak greyish black. Lustre metallic. C.c.: tantalic acid 62·4, tin 6·6, uranium 4·9, protoxide of iron 8·1, yttria 5·2. B.B. infusible. In closed tube decrepitates and yields water. Kararfvet near Falun.

697. Samarskite (*Uranotantalite*), ($\dot{R}_3$, $\dddot{R}$, $\ddot{R}\frac{3}{2}$)$_5$($\dddot{N}b\dddot{T}a$)$_3$.

Right prismatic. ∞P 122° 46′; $\infty\breve{P}2$ 95°; $\bar{P}\infty$ 93°; P; $\infty\bar{P}\infty$; $\infty\breve{P}\infty$; $3\breve{P}\frac{3}{2}$; also in grains. Fracture conchoidal; brittle. H. = 5·56; G. = 5·6 to 5·76. Opaque; strong semimetallic. Velvet-black; streak dark reddish brown. B.B. fuses on the edges to a black glass. In the closed tube decrepitates, yields water, incandesces, and becomes brown. Sol. in h. acid to a greenish fluid.

C.c.: 37·2 niobic acid, 18·6 tantalic acid, 12 iron protoxide, 14 to 20 uranium oxide, 6 thorium oxide, 4 zirconia, and 16 yttria with lime and magnesia. Miask, Mitchell county in North Carolina. The *Yttroilmenite* of Hermann.

698. NOHLITE, $\dot{\mathrm{R}}_3\ddot{\ddot{\mathrm{N}}}\mathrm{b}$.

Massive. H=4·5 to 5; G.=5·04. Black-brown. Splintery. Brittle. Opaque; vitreous. Niobic acid 50·4, uranium oxide 14·4, zirconia 3, ferrous oxide 8, yttria 14·4, lime 4·7, water 4·6. Nohl near Kongelf (Sweden).

699. HATCHETTOLITE.

Cubic; O, ∞O∞. Yellowish brown. Resinous lustre. Fracture conchoidal. H.=5; G.=4·8 to 4·9. C.c.: niobic acid 34·3, tantalic acid 29·8, uranium oxide 15·5, lime 8·9, water 4·5. North Carolina.

ANTIMONIATES.

700. ROMEITE, $\dot{\mathrm{C}}\mathrm{a}_3\dddot{\mathrm{S}}\mathrm{b}\ddot{\ddot{\mathrm{S}}}\mathrm{b}$.

Pyramidal; P 110° 50′. Scratches glass. G.=4·7. Honey-yellow or hyacinth-red. B.B. fuses to a blackish slag. Sol. in acids. C.c.: 41·3 antimonic acid, 37·3 antimony oxide, and 21·4 lime, but with 2 to 3 manganese and iron protoxide. St Marcel in Piedmont. *Schneebergite*, from Tyrol, may be an impure variety.

701. BLEINIERE, $\dot{\mathrm{P}}\mathrm{b}(\dddot{\mathrm{S}}\mathrm{b}, \ddot{\ddot{\mathrm{S}}}\mathrm{b})+\dot{\mathrm{H}}$.

Reniform and massive. H.=4; G.=3·9 to 4·8. Translucent; resinous to earthy. Colourless, yellow, brown, and grey. B.B. reduced on charcoal. C.c.: oxide of lead 41 to 62, antimonious acid 32 to 47, water 6 to 12. Lostwithiel, Horhausen, Nertchinsk.

702. NADORITE, $\dot{\mathrm{P}}\mathrm{b}\dddot{\mathrm{S}}\mathrm{b}+\mathrm{PbCl}_2$.

Right prismatic; ∞P 132° 51′. Crystals tabular. Cl. macrodiagonal. H.=3; G.=7. Yellowish or greyish brown. Resinous to adamantine; translucent. C.c.: lead 52·2, antimony 30·8, oxygen 8, chlorine 9. Constantine (Algeria).

703. RIVOTITE.

Massive. Yellowish to greyish green. Opaque; fracture uneven; brittle. H.=3·5 to 4; G.=3·6. C.c.: oxide of copper 39·5, oxide of silver 1·2, antimonic acid 42, carbonic acid 21. Sierra del Cadi in the province of Lerida. *Thrombolite* from Rezbanya, Hungary, may be a hydrated variety.

704. MELLITE, $\dddot{\mathrm{A}}\mathrm{l}(\mathrm{C}_{12}\mathrm{O}_9)+18\dot{\mathrm{H}}$.

Pyramidal; P 93° 5′. 0P; P∞; and ∞P∞. Cl. P; fracture conchoidal; brittle. H.=2 to 2·5; G.=1·5 to 1·6. Transparent; doubly refractive; vitreous. Honey-yellow or reddish; streak white. In closed tube yields water. B.B. chars without odour. Burns white and acts like alumina. Sol. in n. acid or potash. C.c.: alumina 14·4, mellic acid 40·3, water 45·3. In lignite at Artern in Thuringia and Luschitz in Bohemia; Walchow in Moravia (cretaceous); in coal at Malovka in Tula.

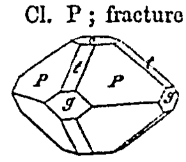

Fig. 606.

705. OXALITE, $2\dot{\mathrm{F}}\mathrm{e}\bar{\mathrm{C}}_3+3\dot{\mathrm{H}}$.

Capillary crystals, also botryoidal or compact; fracture uneven; sectile. H.=2; G.=2·2. Opaque; resinous to dull. Straw-yellow. B.B. turns black, then red. Sol. to yellow solution in acids. C.c.: 42·1 iron protoxide, 42·1 oxalic acid, 15·8 water. In lignite at Kolosoruk near Bilin, Duisburg, and Gross Almerode in Hesse.

706. WHEWELLITE, $\dot{\mathrm{C}}\mathrm{a}\bar{\mathrm{C}}+\dot{\mathrm{H}}$.

Oblique prismatic, C 72° 41′. ∞P 100° 36′. Cl. basal, perfect; brittle. H.=2·5 to 2·8; G.=1·838. Transparent to opaque; vitreous. Colourless. C.c.: 49·31 oxalic acid, 38·36 lime, 12·33 water. Hungary.

THE MINERAL RESINS.

Many of these are only vegetable resins slightly altered. Naphtha is fluid; the others solid, with H.=1 to 2 or 2·5. Most are amorphous, a few crystalline and monoclinic. G.=0·6 to 1·6. Mostly resinous; colourless, or coloured brown, yellow, or red, with paler streak. Sol. in acids, alcohol, ether, and oils. Melt readily, and burn with flame and smoke.

707. NAPHTHA, PETROLEUM, CH_2.

Liquid. Colourless, yellow, or brown. Transparent or translucent. G.=0·7 to 0·9. Volatilizes in the atmosphere with an aromatic bituminous odour. C.c.: 84 to 88 carbon, and 12 to 16 hydrogen. Varieties are—

Naphtha.—Very fluid, transparent, and light yellow. Tegern Lake in Bavaria, Amiano near Parma, Salies in the Pyrenees, Rangoon, Baku on the Caspian Sea, China, Persia, and North America. Used for burning, and in preparing varnishes.

Petroleum.—Darker yellow or blackish brown; less fluid or volatile. Ormskirk in Lancashire; Coalbrookdale, Pitchford, and Madeley in Shropshire; St Catherine's Well, south of Edinburgh; Mainland of Orkney; and many other parts of Europe.

708. ELATERITE (*Elastic Bitumen, Mineral Caoutchouc*), CH_2.

Compact; reniform or fungoid; elastic and flexible like caoutchouc, very soft. G.=0·8 to 1·23. Resinous. Blackish, reddish, or yellowish brown. Strong bituminous odour. C.c.: 84 to 86 carbon, 12 to 14 hydrogen, and a little oxygen. Derbyshire, Montrelais near Nantes, and Woodbury in Connecticut.

709. ASPHALTUM, BITUMEN.

Compact and disseminated; fracture conchoidal, sometimes vesicular; sectile. H.=2; G.=1·1 to 1·2. Opaque, resinous, and pitch-black; strong bituminous odour, especially when rubbed. Takes fire easily, and burns with a bright flame and thick smoke. Sol. in ether, except a small remainder, which is dissolved in oil of turpentine. C.c.: 76 to 88 carbon, 2 to 10 oxygen, 6 to 10 hydrogen, and 1 to 3 nitrogen. Limmer near Hanover, Seyssel on the Rhone, Val Travers in Neufchatel, Lobsann in Alsace, in the Harz, Dead Sea, Persia, and Trinidad; Cornwall, Haughmond Hill (Shropshire), East and West Lothians, Elie and Burntisland (Fife).

710. ALBERTITE.

Massive. Velvet-black. Adamantine lustre; brittle. C.c.: carbon 86, hydrogen 9, nitrogen 2·9, oxygen 2. Hoy, Orkney; Strathpeffer, Ross; Hillsborough, New Brunswick.

711. PIAUZITE.

Massive; imperfect conchoidal, sectile. H.=1·5; G.=1·22. Dimly translucent on very thin edges; resinous. Blackish brown; streak yellowish brown. Fuses at 600° Fahr., and burns with an aromatic odour, lively flame, and dense smoke. Sol. in ether and caustic potash. Piauze near Rudolfswerth in Carniola.

712. IXOLYTE.

Massive; conchoidal fracture. H.=7; G.=1·008. Resinous. Hyacinth-red; streak ochre-yellow. Rubbed between the fingers it emits an aromatic odour; becomes soft at 119°, but is still viscid at 212°. Oberhart near Gloggnitz in Austria.

713. AMBER (*Succinite*), $\mathrm{C}_{10}\mathrm{H}_8\mathrm{O}$.

Round irregular lumps, grains, or drops. Fracture perfect conchoidal; slightly brittle. H.=2 to 2·5; G.=1 to 1·1. Transparent to translucent or almost opaque; resinous. Honey-yellow, hyacinth-red, brown, yellowish white; also streaked or spotted. When rubbed emits an agreeable odour, and becomes negatively electric. It melts at 550°, emitting water, an empyreumatic oil, and succinic acid; it burns with a bright flame and pleasant odour, leaving a carbonaceous remainder; only a small part is soluble in alcohol. C.c.: 79 carbon, 10·5 hydrogen, and 10·5 oxygen. Derived chiefly from an extinct coniferous tree (*Pinites succinifer*), and found in the Tertiary and diluvial formations of many countries, especially northern Germany and shores of the Baltic, Sicily, Spain, and northern Italy, rarely in Britain (on the shores of Fife, Norfolk, Suffolk, and Essex, and at Kensington, near London). Used for ornamental purposes, and for preparing succinic acid and varnishes. *Krantzite*, from Nienburg, is essentially the same.

714. RETINITE (*Retinasphalt*).

Roundish or irregular lumps; fracture uneven or conchoidal; very easily frangible. H.=1·5 to 2; G.=1·05 to 1·15. Translucent or opaque; resinous or glistening. Yellow or brown. Melts at a low heat, and burns with an aromatic or bituminous odour. C.c.: in general carbon, hydrogen, and oxygen, in very uncertain amount. Bovey, Halle, Cape Sable, and Osnabrück. *Pyroretinite* from Aussig in Bohemia is similar.

715. WALCHOWITE, $\mathrm{C}_{12}\mathrm{H}_9\mathrm{O}$.

Rounded pieces, with a conchoidal fracture. H.=1·5 to 2; G.=1·035 to 1·069. Translucent, resinous. Yellow with brown stripes, and a yellowish white streak. It fuses at 482°, and burns readily. Soluble partially (7·5 per cent.) in ether; in s. acid forms a dark-brown solution. C.c.: 80·4 carbon, 10·7 hydrogen, and 8·9 oxygen. Walchow in Moravia.

716. COPALINE (*Fossil Copal, Highgate Resin*), $\mathrm{C}_{40}\mathrm{H}_{64}\mathrm{O}$.

Irregular fragments. H.=1·5; G.=1·046. Translucent, resinous; burns with light yellow flame and much smoke; alcohol dissolves little of it; becomes black in sulphuric acid. C.c.: 85·54 carbon, 11·63 hydrogen, 2·76 oxygen. Highgate near London. A similar resin from Settling-Stones mine in Northumberland, found in flat drops or crusts on calc-spar, is infusible at 500° Fahr.; G.=1·16 to 1·54; it contains 85·13 carbon, 10·85 hydrogen, and 3·26 ashes.

717. BERENGELITE, $\mathrm{C}_{40}\mathrm{H}_{62}\mathrm{O}_8$.

Amorphous; conchoidal fracture. Dark brown, inclining to green; yellow streak. Resinous; unpleasant odour, and bitter taste. Fuses below 212°, and continues soft afterwards at ordinary temperatures; easily soluble in alcohol. C.c.: 72·40 carbon, 9·28 hydrogen, 18·31 oxygen. San Juan de Berengela in Peru.

718. GUAYAQUILLITE, $\mathrm{C}_{20}\mathrm{H}_{26}\mathrm{O}_3$.

Amorphous; yielding easily to the knife, and very friable. G.

=1·092. Pale yellow. Slightly resinous. Fluid at 212°, viscid when cold; slightly soluble in water, and largely in alcohol, forming a yellow fluid with a bitter taste. C.c.: 77·01 carbon, 8·18 hydrogen, and 14·80 oxygen. Guayaquil in South America.

Bogbutter, from the Irish peat mosses, is similar; it melts at 124°, is easily soluble in alcohol, and contains 73·70 carbon, 12·50 hydrogen, and 13·72 oxygen.

719. HARTINE, $C_{20}H_{20}+\dot{H}$.

Round masses or thin layers. Brittle, but easily cut with a knife. G.=1·6. Resinous. Reddish brown by reflected and deep red by transmitted light; streak light brown. Becomes black on exposure. C.c.: 86·43 carbon, 8·01 hydrogen, 5·56 oxygen. In the main coal seam at Middleton near Leeds, and at Newcastle.

720. OZOCERITE (*Native Paraffin*), CH.

Amorphous, sometimes fibrous. Very soft, pliable, and easily fashioned with the fingers. G.=0·94 to 0·97. Glimmering or glistening; semitranslucent. Yellowish brown or hyacinth-red by transmitted, dark leek-green by reflected light. Strong paraffin or aromatic odour; fuses easily to a clear oily fluid; at higher temperature burns with a clear flame, seldom leaving any ashes; readily soluble in oil of turpentine, with great difficulty in alcohol or ether. C.c.: 85·7 carbon, and 14·3 hydrogen. Binny (Linlithgow), and Edinburgh; Slanik and Zietriska in Moldavia, near Garning in Austria, and Baku; also at Urpeth coal-mine near Newcastle-on-Tyne. *Pyropissite* may be a variety.

721. HATCHETTINE (*Mineral Tallow*).

Flaky, like spermaceti; or subgranular, like beeswax; soft and flexible. G.=0·6. Translucent; weak pearly. Yellowish white, wax-yellow, or greenish yellow. Greasy inodorous; readily soluble in ether. C.c.: 85·91 carbon, 14·62 hydrogen, or similar to ozocerite. Loch Fyne (fusible at 115°), Merthyr-Tydvil, Schaumburg.

722. FICHTELITE, C_4H_3.

Crystalline (oblique prismatic) lamellæ, which swim in water, but sink in alcohol. White and pearly. Fuse at 114°, but again become crystalline on cooling. Very easily soluble in ether, and precipitated by alcohol. C.c.: 88·9 carbon and 11·1 hydrogen. In pine wood in a peat-moss near Redwitz in Bavaria.

723. HARTITE, C_6H_5.

Anorthic; but mostly like spermaceti or white wax, and lamellar. Sectile, but not flexible. H.=1; G.=1·046. Translucent; dull resinous. White. Melts at 165°, and burns with much smoke. Very soluble in ether, much less so in alcohol. C.c.: 87·8 carbon, and 12·2 hydrogen. Oberhart in Austria.

724. KÖNLITE, C_2H.

Crystalline folia and grains. Soft. G.=0·88. Translucent; resinous. White, without smell. Fuses at 120° to 137°. Sol. in n. acid; precipitated by water in a white crystalline mass. C.c.: 92·3 carbon, 7·7 hydrogen. Uznach near St Gall, Redwitz.

725. SCHEERERITE, CH_2.

Oblique prismatic; tabular or acicular. Soft and rather brittle. G.=1 to 1·2. Translucent; resinous or adamantine. White, inclining to yellow or green. Feels greasy, has no taste, and when cold no smell, but when heated a weak aromatic odour. Insoluble in water; readily sol. in alcohol, ether, and n. and s. acids. C.c.: 75 carbon, 25 hydrogen. Uznach. *Branchite*, white, translucent, fusing at 167°, is similar; Montevaso in Tuscany.

726. IDRIALITE, C_3H_2.

Massive; fracture uneven or slaty; sectile. H.=1 to 1·5; G.=1·4 to 1·6 (1·7 to 3·2). Opaque; resinous. Greyish or brownish black; streak blackish brown, inclining to red. Feels greasy. Burns with a thick smoky flame, giving out sulphurous acid, and leaving some reddish brown ashes. C.c.: 77 idrialine (=94·7 carbon and 5·3 hydrogen) and 18 cinnabar, with a little silica, alumina, pyrite, and lime. The idrialine may be extracted by warm olive oil or oil of turpentine as a pearly shining mass, difficultly fusible. Idria.

727. TORBANITE.

Massive; fracture subconchoidal. Yellow, brown-grey, and light brown. H.=1·5 to 2; G.=1·28. C.c.: 60 to 65 carbon, 9 hydrogen, 4 to 5 oxygen, 10 to 20 silicate of alumina. When distilled below redness yields a burning fluid holding paraffin in solution; above redness a large quantity of highly illuminating gas. Shown by the microscope to consist of granules of a yellow bituminoid wax, with interstitial shaly matter. Torbanehill in Scotland, Pilsen in Bohemia, Kurakina and Murayevna in Russia.

728. DOPPLERITE.

Jelly-like elastic masses. Brownish black; streak brown. Greasy lustre. H.=0·5; G.=1·1. After drying H.=2·5; G.=1·5. Insoluble in alcohol and ether. An acid substance related to humic acid. From peat beds, Aussee (Styria) and Switzerland.

THE COALS.

729. ANTHRACITE (*Glance Coal*).

Massive and disseminated; rarely columnar. Fracture conchoidal; brittle. H.=2 to 2·5; G.=1·4 to 1·7. Opaque; brilliant metallic. Iron-black; streak unaltered. Perfect conductor of electricity. Burns difficultly with a very weak or no flame, and does not cake; in the closed tube yields a little moisture, but no empyreumatic oil; detonates with nitre. C.c.: carbon above 90 per cent., with 1 to 3 oxygen, 1 to 4 hydrogen, and 0 to 3 nitrogen; and ashes chiefly of silica, alumina, lime, and peroxide of iron. Common in some parts of all coal-fields; and especially in the United States, as in Rhode Island, Massachusetts, and above all in Pennsylvania. Used chiefly for manufacturing metals.

730. COMMON COAL (*Black Coal, Stone or Mineral Coal, Bituminous Coal*).

Compact, slaty, or confusedly fibrous; often dividing into rhomboidal, columnar, or cubical fragments. Fracture conchoidal, uneven, or fibrous; rather brittle or sectile. H.=2 to 2·5; G.=1·2 to 1·5. Vitreous, resinous, or silky in the fibrous variety. Blackish brown, pitch-black, or velvet-black. Burns easily, emitting flame and smoke, with a bituminous odour; heated in the closed tube yields much oil. C.c.: 74 to 90 carbon, with 0·6 to 8 or 15 oxygen, 3 to 6 hydrogen, 0 to 1 to 2 nitrogen, 0·1 to 3 sulphur, and 1 to 11 earthy matters or ash, in 100 parts.

Slate Coal or *Splint* has a thick slaty structure, and an uneven fracture. *Cherry Coal* is the name applied to the brittle highly lustrous variety common in the English coal-fields. *Caking Coal* is a more bituminous variety which undergoes semifusion when ignited, caking or agglutinating during combustion. *Cannel Coal* has a resinous, glimmering lustre, and a flat-conchoidal fracture, breaks into irregular cubical fragments, but is more solid and takes a higher polish than other varieties. This burns with a bright flame, and yields much gas. Abundant in many lands, as in England, Scotland, and Ireland, in Belgium and France, in Germany and southern Russia. British America and the United States possess immense fields, especially in the valley of the Mississippi. Also found in China, Japan, Hindustan, Australia, Borneo, and several of the Indian islands.

731. LIGNITE (*Jet, Brown Coal*).

Distinctly vegetable in origin,—the external form, and very often the internal woody structure, being preserved. The texture is compact, woody, or earthy. Fracture conchoidal, woody, or uneven; soft and often friable. G.=0·5 to 1·5. Lustre sometimes resinous, mostly glimmering or dull. Brown, black, or rarely grey. Burns easily with an unpleasant odour; colours solution of potash deep brown. C.c.: 47 to 73 carbon, 2·5 to 7·5 hydrogen, 8 to 33 oxygen (with nitrogen), and 1 to 15 ashes. *Jet* is pitch-black, with conchoidal fracture and resinous lustre. Brown coal occurs at Bovey-Tracy in Devonshire; also in Germany, Hungary, France, Italy, and Greece. The *Surturbrand* of Iceland seems a variety. Used as fuel, but much inferior to common coal. The Oolitic coals of Yorkshire, Antrim, Brora, Mull, and Skye are intermediate varieties.

INDEX OF MINERAL SPECIES.

(M. F. H.)

MINERAL WATERS. No absolute line of demarcation can be drawn between ordinary and mineral waters. There is usually in the latter an excess of mineral constituents or of temperature, but some drinking waters contain more mineral constituents than others that are called mineral waters, and many very pure waters, both cold and warm, have been regarded for ages as mineral springs.

As to the origin of mineral waters, there is much in what the elder Pliny said, that waters are such as the soil through which they flow. Thus in limestone and chalk districts an excess of lime is usually present; and the waters of a particular district have much resemblance to each other—as in the Eifel, in Auvergne, and in the Pyrenees. But this is only a partial explanation, for waters are by no means necessarily uniform throughout a particular geological formation. We do not know with any certainty the depth from which various mineral waters proceed, nor the various distances from the surface at which they take up their different mineral constituents.

The source of the temperature of thermal waters remains a subject of much uncertainty. Among the assigned causes are the internal heat of the globe, or the development of heat by chemical or electrical agencies in the strata through which they arise.

Their occasional intermittence is doubtless often dependent on the periodical generation of steam, as in the case of the Geysers. A few geological facts are certain, which bear on the origin of mineral waters. Such springs are most abundant in volcanic districts, where many salts of soda and much carbonic acid are present. They occur most frequently at meetings of stratified with unstratified rocks, in saddles, and at points where there has been dislocation of strata.

The diffusion of mineral waters is very extended. Pliny was quite correct in observing that they are to be found on alpine heights and arising from the bottom of the ocean. They are found at the snow in the Himalayas and they rise from the sea at Baiæ and Ischia. They are to be found in all quarters of the globe, but more particularly in volcanic regions, as in the Eifel and Auvergne, in the Bay of Naples, and parts of Greece, in Iceland, New Zealand, and Japan. But there are few countries in which they are not to be found, except in very flat ones and in deltas of rivers,—for instance, in the north of France, where they are very few, and in Holland, from which they are absent. France, Germany, Italy, and Spain, as well as Greece, Asia Minor, and the Caucasus, are all rich in mineral waters. The British Isles have a fair though not very large proportion of them. There are a few in Sweden and Norway. They are abundant in the United States, less so in Canada. They are found in the Azores and in the West India Islands. Of their occurrence in the interior of Africa or of Australia we know little; and the same is true of South America. But they are met with in Algiers, in Egypt, and in the Holy Land. The vast Indian peninsula has for its size a comparatively small supply.

As the effects of mineral waters on the bodily system have been found to be different from those of drinking waters, an explanation of this has been naturally sought for. It has been imagined that there is something special in the nature of mineral waters, that their heat is not ordinary heat, that their condition is a peculiar electric one. Some French modern writers even say that they have a certain life in them, that their constitution is analogous to that of the serum of the blood. But we must pass by these speculations, and be guided as far as possible by ascertained facts, respecting the action on the system of water, of heat and cold, and of the mineral constituents present.

Mineral waters, when analysed, are found to contain a great many substances, although some of them occur only in very minute quantities:—soda, magnesia, calcium, potash, alumina, iron, boron, iodine, bromine, arsenic, lithium, cæsium, rubidium, fluorine, barium, copper, zinc, manganese, strontium, silica, phosphorus, besides extractive matters, and various organic deposits known under the name of glairin or baregin. Of gases, there have been found carbonic acid, hydrosulphuric acid, nitrogen, hydrogen, oxygen, and ammonia. Of all these by far the most important in a therapeutic point of view are sodium, magnesia, and iron, carbonic acid, sulphur, and perhaps hydrosulphuric acid. These substances, detected separately by chemists, are in their analyses combined by them into various salts, if not with absolute certainty, undoubtedly

with a close approximation to it. Those combinations are very numerous, and some waters contain ten to twenty of them; but there are always some predominating ones, which mark their character, while many of them, such as cæsium, rubidium, or fluorine, occur in mere traces, and can not be assumed to be of any real importance. Mineral waters therefore resolve themselves into weaker or stronger solutions of salts and gases in water of higher or lower temperature. For medical purposes they are used either externally or internally, for bathing or for drinking. As the quantity of salts present commonly bears but a very small proportion to that of the fluid containing them, water becomes a very influential agent in mineral-water treatment, about which it is therefore necessary to say something.

For the action of hot and cold baths the reader is referred to the article BATHS. But it may be observed here that, according to the most generally received opinion, the cutaneous surface does not absorb any portion of the salts in a mineral-water bath, although it may absorb a little gas (an alkaline water, for instance, at most acting as a slight detergent on the skin), and that neither salts nor gases have any action on the system, except as stimulants of the skin, with partial action on the respiratory organs.

It seems to be ascertained that drinking considerable amounts of cold water reduces the temperature of the body, diminishes the frequency of the pulse, and increases the blood pressure temporarily. Water when introduced into the stomach, especially if it be empty, is quickly absorbed; but, although much of the water passes into the veins, there is no proof that it ever produces in them, as is sometimes supposed, a state of fluidity or wateriness. Therapeutically, the imbibition of large quantities of water leads to a sort of general washing out of the organs. This produces a temporary increase of certain excretions, augmented diuresis, and a quantitative increase of urea, of chloride of sodium, and of phosphoric and sulphuric acids in the urine. Both the sensible and the insensible perspirations are augmented. A draught of cold water undoubtedly stimulates the peristaltic action of the intestines. On the whole water slightly warm is best borne by the stomach, and is more easily absorbed by it than cold water; and warm waters are more useful than cold ones when there is much gastric irritability.

In addition to the therapeutic action of mineral waters, there are certain very important subsidiary considerations which must not be overlooked. An individual who goes from home to drink them finds himself in a different climate, with possibly a considerable change in altitude. His diet is necessarily altered, and his usual home drinks are given up. There is change in the hours of going to bed and of rising. He is relieved from the routine of usual duties, and thrown into new and probably cheerful society. He takes more exercise than when at home, and is more in the open air, and this probably at the best season of the year. So important has this matter of season and climate been found that it is an established axiom that waters can be used to the greatest advantage during the summer months and in fine weather, and during the periods most convenient for relaxation from business. Summer is therefore the bath season, but of late years provision has been made in many places, with the aid of specially constructed rooms and passages, for carrying out cures satisfactorily during the winter season, *e.g.*, at Aix-la-Chapelle, Wiesbaden, Baden Baden, Baden in Switzerland, Dax, Vichy, and Bath. The ordinary bath season extends from the 15th of May to the 20th or 30th September. The season for baths situated at considerable elevations commences a month later and terminates some ten days earlier. Mineral waters may be employed at home, but patients seldom so use them; and this necessarily limits the time of their use. It is common to declare that the treatment should last for such or such a period. But the length of time for which any remedy is to be used must depend on its effect, and on the nature of the particular case. It is found, however, that the continued use of mineral waters leads to certain disturbances of the system, which have been called crises, such as sleeplessness, colics, and diarrhœa, and to skin eruptions known as *la poussée*. This cause, and also certain peculiarities of the female constitution, have led to the period of three weeks to a month being considered the usual period for treatment. A certain after-treatment is often prescribed —such as persistence in a particular diet, visiting springs or climates of a different and usually of a tonic character, or continuing for a certain time to drink the waters at home. It may be added that the advantage of having recourse to mineral waters is often felt more after than during treatment.

Since improved methods of bottling have been discovered, and the advantage of an additional supply of carbonic acid has been appreciated, the export of waters from their sources has increased enormously, and most of the principal waters can now be advantageously used at home. It may be added that many of the artificial imitations of them are excellent.

The history of the use of mineral waters can only just be alluded to. They have been employed from the earliest periods, and traces of Roman work have been found at most of the European baths which are now in favour,—at almost all the thermal ones. Occasionally new springs are discovered in old countries, but the great majority of them have been long known. They have varied in popularity, and the modes of applying them have also varied, but less so than has been the case with most of the ordinary medicines. Warm waters, and those containing small quantities of mineral constituents, appear to have remained more steadily in favour than any other class within the appropriate sphere of mineral waters, which is limited to the treatment of chronic disease.

The attempt has been made to range mineral waters according to their therapeutic action, according to their internal or external use, but most generally according to their chemical constituents so far as they have been from time to time understood; and a judicious classification undoubtedly is a help towards their rational employment. But their constituents are so varied, and the gradations between different waters are so finely shaded off, that it has been found impossible to propose any one definite scientific classification that is not open to numberless objections. Thus a great many of the sulphur waters are practically earthy or saline ones. Yet because they contain very minute amounts of such a gas as hydrosulphuric acid, an ingredient so palpable as always to attract attention, it is considered necessary to class them under the head of sulphur. The general rule is to attempt to class a water under the head of its predominant element; but if the amount of that be extremely small, this leads to such waters as those of Mont Dore being classified as alkaline or arseniated, because they contain a very little soda and arsenic. The classification in the following table, which is that usually adopted in Germany, has the merit of comparative simplicity, and of freedom from theoretical considerations which in this matter influence the French much more than the German writers. The more important constituents only are given. The amount of solid constituents is the number of parts to one thousand parts of the water; the temperature of thermal springs is added. The waters are classified as indifferent, earthy, salt, sulphuretted, iron, alkaline, alkaline saline—with subvarieties of table waters and purging waters.

Hydrosulphuric acid.....					trace					

In addition to their solid constituents, gas is present in many waters in considerable quantity. There is a little oxygen and a good deal of nitrogen in some of them; the quantity of hydrosulphuric acid, even in strong sulphuric waters, is wonderfully small; but the volume of carbonic acid present is often very large,—for instance, in the case of Kissingen, Schwalbach, and Selters. Carbonic acid is so generally diffused that it is practically a very important agent in the therapeutics of mineral waters. Springs that contain it are far the most agreeable to the taste, and consequently most popular with patients. The immediate effect of the carbonic acid which they contain is that of pleasant stimulation to the stomach and system, although it can scarcely be said to approach, as some have thought, the slighter forms of stimulation from alcoholic drinks. Extremely little appears to be known of its actual operation on the system: a part of what is swallowed is returned by eructation, and a part passes on to the intestines; whether any appreciable quantity reaches the blood is doubtful. There is no question that carbonic acid increases diuresis. Practically it is found to aid digestion, helping the functions of the stomach, and in a slight degree the peristaltic action of the intestines. The increased flow of urine may be caused by its favouring the absorption of water by the stomach. In some baths carbonic acid is so abundant that precautions have to be taken to prevent its tendency to accumulate on account of its heavy specific gravity. Carbonic acid gas, used as a bath, proves stimulating to the skin and to the general system; but its employment has not answered the expectations formed of it.

Indifferent Waters scarcely vary in chemical qualities from ordinary drinking water; but they are usually of higher temperature. Their therapeutic action, which is mainly exercised through baths, has been explained on the theory of peculiarities of their electric or thermal condition, about which we know nothing definite, and on the presence in some of them of a large quantity of nitrogen. It has also been ascribed to the various organic substances in some of them, such as glairin, which when collected is sometimes useful as a cataplasm. These waters are not often much drunk, but any efficiency they may have in dyspepsia and perhaps in neuralgic diarrhœas must be attributed to the favourable action of hot water on the digestion. The waters of this class, especially the hotter ones in the form of baths, are extremely useful in resolving the effects of inflammation, in thickenings of the joints, and in chronic rheumatism and gout. They also are often effective, especially the cooler ones, in neuralgia and in some hysterical affections. They are sometimes prescribed in urinary affections, in which case they probably assist by dilution. The effects of many of these waters are aided by the baths often being situated at considerable elevations and in out-of-the-way spots, whence the Germans called them *Wildbäder*. They are very widely diffused, being found in all quarters of the globe, especially in volcanic districts. There are many in New Zealand; in America the hottest are in the West and in California.

Earthy Waters.—These differ chiefly from the indifferent waters in containing an appreciable quantity of salts, among which sulphate or carbonate of lime or of magnesia predominates. The great majority of them are of high temperature. They produce the same effects as the indifferent waters, but are perhaps less efficacious in neuralgic affections, while they are more employed in some of the chronic scaly eruptions. There was formerly a tendency to consider these waters useful in urinary affections; but at the present day it is only the colder ones that have come into repute for the expulsion of gravel and biliary calculi and in the treatment of affections of the bladder generally. Some of them have also of late years been considered to exercise a favourable influence on scrofula, and to be useful in the early stages of pulmonary phthisis. This has been attributed to the salts of lime present in them, although it is known that most of its salts pass through the system unaltered. Many of these baths, such as Leuk and Bormio, enjoy the advantages of great elevation, but Bath, otherwise one of the best of them, lies low.

[1] In this and the following tables a selection is given of some of the best-known mineral waters in various European countries that possess establishments. Their chief peculiarities of elevation, of temperature, and constituents are briefly noted. The curative effects, necessarily alluded to very generally, are those usually attributed to them.

Salt Waters are so called from containing a predominant amount of chloride of sodium. They also generally contain chlorides of magnesia and of lime, and occasionally small amounts of lithium, bromine, and iodine. They further often contain a little iron, which is an important addition. The great majority of the drinking wells have a large supply of carbonic acid. There are cold and hot salt springs. Sometimes they are used for drinking, sometimes for bathing; and the double use of them is often resorted to.

The normal quantity of common salt consumed daily by man is usually set down at about 300 grains. The maximum quantity likely to be taken at any well may be 225 grains, but commonly not more than half of that amount is taken. The increase to the usual daily amount is therefore probably not much more than one-third. Still it may be presumed that the action of a solution of salt on an empty stomach is different from that of the same amount of salt taken with food. Salt introduced into the stomach excites the secretion of gastric juice, and favours the peristaltic actions, and when taken in considerable quantity is distinctly aperient. We thus see how it is useful in dyspepsia, in atony of the stomach and intestines, and sometimes in chronic intestinal catarrh. Salt when absorbed by the stomach appears again in the urine, of which it increases the amount both of fluid and of solid constituents, especially of the urea. It seems therefore to be pretty certain that considerable quantities of salt taken into the circulation increase the excretion of nitrogenous products through the urine, and on the whole accelerate the transformation of tissue. Salt is thus useful in scrofula by stimulating the system, and also in anæmia, especially when iron is also present. In some German stations, as at Soden, carbonated salt waters are considered to be useful in chronic laryngitis or granular pharyngitis.

Baths of salt water, as usually given, rarely contain more than 3 per cent. of chloride of sodium, some of the strongest perhaps from 8 to 10 per cent. Their primary action is as a stimulant to the skin, in which action it is probable that the other chlorides, especially that of calcium, and still more the carbonic acid often present, co-operate. In this way, and when aided by various processes of what may be termed water poultices and packing, they are often useful in removing exudations, in chronic metritis and in some tumours of the uterus, and generally in scrofula and rachitis, and occasionally in some chronic skin affections.

The French accord high praise to some of their thermal salt waters in paralysis, and some German ones are used in a similar way in spinal affections. The salt waters are sometimes so strong that they must be diluted for bathing. In other cases concentrated solutions of salt are added to make them sufficiently strong. These waters are widely diffused, but on the whole Germany is richest in them, especially in such as are highly charged with salt. The Kissingen springs may be considered as typical of the drinking wells, and sea-water of bathing waters. The air of salt-works and pulverization of the water are employed in German baths as remedial agents.

Salt springs are found in many quarters of the world, but the chief carbonated groups for drinking purposes occur in Germany, and at Saratoga in America, where very remarkable wells indeed are to be found. France and England have no springs of this class. The stronger wells, used chiefly for bathing, occur where

TABLE IV.—*Salt Springs.*

	Locality.	Temp. ° Fahr.	Therapeutic Action.
Cold.	Soden, near Frankfort	...	Dyspepsia, anæmia, scrofula, special for throat and phthisis.
	Homburg, do.	...	Dyspepsia, slighter hepatic affections, chlorosis, gout.
	Kissingen, Bavaria	...	In all essentials the same.
	Pyrmont, North Germany	...	Better known for its iron; has a good salt drinking spring.
	Kreuznach, near Bingen	...	A salt well without carbonic acid used in scrofula and anæmia; bathing more important.
Warm.	Wiesbaden, Nassau	155	Used in dyspepsia and gout; the bathing is most important.
	Baden-Baden	156	Still milder water; uses similar; gout.
	Bourbonne, Haute-Marne	114–149	Rheumatism, neuralgia, effects of malaria.
	Balaruc, South France	116·6	Do.; special for treatment of paralysis.
	Salins, Moutiers, Savoy (1450 ft.)	96	Scrofula, anæmia, loss of power, sexual disorders.
	Brides, Savoy (1700 ft.)	95	Act on liver and digestive canal; used for obesity.
	Acqui, North Italy	169	Rheumatism; special treatment with the bath deposit.
	Abano, do.	185	Chiefly as baths; mud of bath used for poultice.
	Caldas de Mombuy, near Barcelona	153–158	Rheumatism, sciatica, old injuries.
	Cestona, Guipuzcoa, Spain	88–94	Rheumatism, indigestion, bronchitis.

Almost all the above stations have several springs of various strengths: the cold may be said to vary from 14 to 5·8 per cent. of chloride of sodium; the warm are generally weaker, perhaps varying from 6·8 to 1·6.

there are salt-bearing strata, as in Germany, Galicia, Italy, Switzerland, France, and England. Very powerful waters of this class are those of St Catherines in Canada.

The presence of minute portions of *iodine* or *bromine* in salt waters is by no means infrequent, and they appear in considerable quantity in some few. It is, however, extremely doubtful whether any known spring contains a sufficient quantity of iodine, still more of bromine, to act specially on the system, even if that action were not necessarily superseded by the presence of the large quantity of other salts with which they are associated. Some of the best known springs of the kind are:—Challes, Wildegg, Castrocaro, Hall, Adelheid's Quelle, Krankenheil, Kreuznach, Woodhall Spa.

Iron or Chalybeate Waters.—Iron usually exists in waters in the state of protoxide or its carbonate, less frequently as sulphate or crenate, and very rarely if at all as chloride. The quantity present is usually extremely small. It may be said to vary from ·12 to ·03 in the 1000 parts of water. Some wells considered distinct chalybeates contain less than ·03. Many wells, especially in Germany, have a rich supply of carbonic acid, which is unfortunately wanting in French and English ones.

It has long been the prevalent idea that want of iron in the blood is the main cause of chlorosis and of other anæmic conditions, and that these conditions are best relieved by a supply of that metal. Since the detection of it in hæmoglobuline this view has been still more popular. It is pretty certain that the blood contains 37 to 47 grains and the whole system 70 to 74 grains of iron; and it has been calculated that in normal conditions of the system somewhat more than one grain of iron is taken daily in articles of food, and that the same amount is passed in the fæces; for although the stomach takes the iron up it is excreted by the alimentary canal mainly, it being doubtful whether any is excreted in the urine. It is possible by drinking several glasses to take in more than a grain of carbonate of iron in the day, equivalent to half that amount of metallic iron. It has further been ingeniously reckoned from practice that 10 to 15 grains of metallic iron suffice to supply the deficiency in the system in a case of chlorosis. It is thought probable that a portion of the iron taken up in water is in certain pathological states not excreted, but retained in the system, and goes towards making up the want of that metal. But, whether this or any other explanation be satisfactory, there is no question as to the excellent effects often produced by drinking chalybeate waters (especially when they are carbonated), and by bathing in those which are rich in carbonic acid after they have been artificially heated. As regards the drinking cure we must not, however, forget that carbonate and chloride of sodium, and also the sulphate, are often present and must be ascribed a share in the cure. Thus chloride of sodium is a power-

ful adjuvant in the strong Stahl Quelle of Homburg and in the Putnam Well at Saratoga. A whole category of female complaints is treated successfully with these waters. Indeed anæmia from any source, as after fever or through loss of blood, and enlargements of the spleen, are benefited by them. The stimulating action of the copious supply of carbonic acid in steel baths is a very important adjuvant; no one now believes in direct absorption of iron from the bath. Iron waters are scarcely ever thermal. They are extremely common in all countries,—frequently along with sulphuretted hydrogen in bogs, and near coal-measures. But such springs and non-carbonated wells generally are weak, and not now held in much esteem.

It may be added that some of the strongest known iron wells are *sulphated* or *aluminated*. They are styptic and astringent, and can only be used diluted. They are sometimes useful as an application to ulcers and sores. Such springs have often been brought into notice, but never retain their popularity. They are known in the Isle of Wight, in Wales, in Scotland, as well as in Elba, &c.; and of late years the Bedford Alum and Oak Orchard Springs, U.S., have been brought into notice, the latter containing 10 grains of free sulphuric acid in the pint. All such springs have been considered useful in scrofula, anæmia, and chronic diarrhœas.

Sulphur Springs.—Waters having the odour of hydrosulphuric acid, however slightly, are usually called sulphur ones. They owe their smell sometimes to the presence of the free acid, sometimes to sulphides of sodium, calcium, or magnesia, and sometimes to both. Hydrosulphuric acid is absorbed more freely by cold than by hot water, and is therefore most abundant in cold springs. The sulphides decompose and give off the gas. Most of these springs occur near coal or shale measures, or strata containing fossils, or in moors and in places generally where organic matter is present in the soil or strata. Many of them contain so little mineral impregnation that they might as well be classed among the indifferent or earthy waters. One group contains a considerable amount of chloride of sodium, another of sulphate of lime, while a third has little mineral impregnation, but contains sulphides.

Hydrosulphuric acid is a strong poison, and its action on the system has been pretty well ascertained. It has been assumed that the gas in mineral waters acts similarly, though in a modified degree; but there is next to nothing absolutely known of the action of the small quantities of the gas that are present in mineral waters, and which certainly have no toxic effect. It has been assumed that this gas has some special action on the portal system and so on the liver. On the connexion of metallic poisoning with the liver has been founded the idea that sulphur waters are useful in metallic intoxication. Drinking large quantities of these waters, especially of such as contain sulphates or chlorides of sodium or magnesia, combined with hot baths and exercise, may help to break up albuminates, but there is no proof of the action of the sulphur.

For similar reasons, and primarily to counteract mercurial poison, sulphur waters have been considered useful in syphilis. But it may be well to remember that at most baths mercury is used along with them. No doubt they are frequently, like other warm waters, useful in bringing out old eruptions, acting in this way as a test for syphilitic poison, and in indicating the treatment that may be required. Sulphur waters, both hot and cold, are used in gout and rheumatism, in dyspepsia, in hepatic and cutaneous affections; and of late years inhalation of them has been popular in phthisis and in laryngeal affections. They have long been popular remedies in cutaneous affections. While so much doubt has been cast on the action of the sulphur of these waters, it may be admitted that the sulphides are probably decomposed in the stomach and hydrosulphuric acid generated. That gas is probably a slight stimulant to the intestine. What hydrosulphuric acid reaches the blood is eliminated by the lungs. There seems to be no doubt that the gas is absorbed in small quantities by the skin.

It is in sulphur waters chiefly that glairin and baregin occur. This peculiar organic substance has been found both in American and in European springs. Cold sulphur springs are very widely diffused throughout the world. Thermal ones are not so common. Perhaps the largest though not the strongest group of the latter is to be found in the Pyrenees. We may remark again how very little hydrosulphuric acid there is in many of the most favourite sulphur springs, including the very popular White Sulphur ones of Virginia. There seems to be something peculiarly unsatisfactory in the analysis of sulphur waters, and there has been difficulty in constructing the following imperfect tables.

Some of the most powerful cold wells are those of Challes (with its very peculiar water), Leuk, and Harrogate. Uriage has a very large amount of chloride of sodium in its springs. Cold sulphur waters are on the whole more used in liver and indigestion than warm ones. The general effects of warm sulphur waters differ so little at the various baths as to make it difficult to mention anything special to particular localities. Schinznach has a reputation in skin complaints, Cauterets, Eaux Bonnes, and Challes in laryngeal affections, the two Aixes, Luchon, and Archena in syphilis.

Alkaline Waters are such as contain carbonate (chiefly bicarbonate) of soda, along with an excess of carbonic acid. Of the action of those carbonates it is known that when taken into the stomach they are neutralized by the gastric juice, and converted into chloride of sodium. On their introduction into the stomach they produce an increased flow of gastric juice. If given during or immediately after meals in any quantity, they impede digestion. They slightly increase peristaltic action, but only feebly, unless assisted by other salts. They act slightly as diuretics. Of the connexion between the biliary system and alkalies, which undoubtedly exists, not much is known with certainty. The alkalization of the blood by them is assumed by many, but not proved. It is very doubtful whether they reduce the quantity of fibrine in the blood, and thus induce a

lowered state of the system, or whether they have any direct tendency to combine with fat and carry off a portion of superfluous adipose tissue. Their excess of carbonic acid, through its action on the stomach, favours the operation of alkaline waters. They have been classed as follows:—(I.) simple alkalines, where carbonate of soda is the main agent; (II.) waters containing in addition some chloride of sodium; (III.) waters containing sulphates of soda or of magnesia. All these classes may be said to be used in gout, lithiasis, affections of the liver, catarrh, and obstructions of the gall ducts, in dyspepsia, chronic catarrh of the stomach, and diarrhœa, in obesity, and in diabetes. Some of the waters of the second class are supposed to influence bronchial catarrhs and incipient phthisis, while the more powerful sulphated waters of the third class are especially useful in catarrh of the stomach, and in affections of the biliary organs; of these only one of importance (Carlsbad) is thermal. The rival cold waters of Tarasp contain twice as much carbonate of soda. The cold ones are chiefly used internally, the thermal ones both internally and externally. The latter, besides acting as warm water, slightly stimulate the skin when the carbonic acid is abundant, and the carbonate of soda has some slight detergent effect on the cutaneous surface like soap. These waters are unknown in England. They are most abundant in countries of extinct volcanoes.

Classes I. and II. of alkaline waters may be said to have a subvariety in *acidulated* springs or carbonated waters, in which the quantity of salts is very small, that of carbonic acid large. These table waters are readily drunk at meals. They have of late years been so widely exported as to be within the reach almost of every one. Their practical importance in aiding digestion is in reality much greater than one could expect from their scanty mineralization. They are drunk by the country people, and also largely exported and imitated. They are very abundant on the Continent, and, although some of the best-known ones enumerated below are German and French, they are common in Italy and elsewhere:—Heppingen, Roisdorf, Landskro, Apollinaris, Selters, Brückenau, Gieshübel, all German; St Galmier, Pougues, Chateldon, French.

Associated with Class III. is that of the strongly *sulphated* waters known in Germany as bitter or purging waters, which have of late deservedly come into use as purgative agents. They are almost wanting in France and in America, and there are no very good ones in England. The chief supply is from Bohemia and Hungary. The numerous waters of Ofen are the best-known, and some of them are stronger than the Hunyadi, of which an analysis has been given in Table I. They are easily imitated. Some of the best-known are Ofen, Püllna, Saidschütz, Friedrichshall, Birmerstorff, Kissingen.

Two other classes of waters demand a few words of notice. The French have much faith in the presence of minute quantities of arsenic in some of their springs, and trace arsenical effects in those who drink them, and some French authors have established a class of *arsenical* waters. Bourboule in Auvergne is the strongest of them, and is said to contain $\frac{1}{12}$th of a grain of arseniate of soda in 7 ounces of water. Baden-Baden, according to Bunsen's latest analysis, has a right to be considered an arsenical water. It is, however, extremely doubtful whether the small amounts of arseniate of soda which have been detected, accompanied as they are by preponderating amounts of other salts, have any actual operation on the system. The following are among the most noted springs:—Bourboule, Mont Dore, Royat, Salies (Bigorres), Plombières, Baden-Baden.

Of late years *lithium* has been discovered in the waters of Baden-Baden; and various other places boast of the amount of that substance in their springs. Indeed a new bath has been established at Assmannshausen on the Rhine in consequence of the discovery of a weak alkaline spring containing some lithium. Not very much is known of the action of lithium in ordinary medicine, and it undoubtedly does not exist in medicinal doses even in the strongest springs. Among these springs are those of Baden-Baden, Assmannshausen, Elster, Royat, Ballston Spa, and Saratoga (U.S.).

American Mineral Waters.—The number of springs in the United States and Canada to which public attention has been called on account of their supposed therapeutic virtues is very large, amounting in all to more than three hundred. Of this number comparatively few are in Canada, and of these not more than six (St Catharines, Caledonia, Plantagenet, Caxton, Charlottesville, and Sandwich) have attained general celebrity. The first three belong to the saline class, the Caxton is alkaline-saline, and the last two are sulphur waters. The St Catherines is remarkable for the very large amounts of sodium, calcium, and magnesium chlorides which it contains, its total salts (450 grains in the pint) being more than three times the quantity contained in the brine-baths of Kreuznach in Prussia. The Charlottesville and Sandwich springs likewise surpass the noted sulphur-waters of Europe in their excessive percentages of sulphuretted hydrogen, the former containing more than 3 and the latter 4·72 cubic inches of this gas in the pint.

The mineral springs in the United States are very unequally distributed, by far the larger number of those which are in high medical repute occurring along the Appalachian chain of mountains, and more especially on or near this chain where it passes through the States of Virginia, West Virginia, and New York. The Devonian and Silurian formations which overlie the Eozoic rocks along the course of the Appalachian chain have been greatly fissured—the faulting of the strata being in some places of enormous magnitude—by the series of upheavals which gave rise to the many parallel mountain ridges of the Appalachians. In many places the springs occur directly along the lines of fault. The various classes of mineral waters are likewise very unequally represented, the alkaline springs, and those containing Glauber and Epsom salts, being much inferior to their European representatives. On the other hand, the very numerous and abundant springs of Saratoga compare very favourably with the Selters and similar saline waters, and among the many American chalybeate springs the subclass represented by the Rockbridge Alum is unequalled in regard to the very large percentages of alumina and sulphuric acid which it contains. Besides its greater amount of mineral constituents (135 grains per pint), the Ballston spring surpasses the similar saline waters of Homburg, Kissingen, Wiesbaden, and Selters in its percentage of carbonic acid (53 cubic inches). It is also remarkable for the very large proportion of carbonate of lithia, amounting to 0·701 grains. Thermal springs are specially numerous in the territories west of the Mississippi and in California. Those in the east mostly occur in Virginia along the southern portion of the Appalachian chain; in the middle and New England States Lebanon is the only important thermal spring. Subjoined is a list of thirty American springs, the design being to represent as many of the more noted spas as possible, while at the same time enumerating the best representatives of the classes and subclasses into which mineral waters are divided according to the German method of classification.

	Designation and Locality.	Therapeutic Application
Indifferent (Thermal).	Lebanon, Columbia Co., N.Y. (73° F.)	
	Healing, Bath Co., Va. (88° F.)	Scrofulous ulcers and ophthalmia, ozæna, chronic diarrhœa and dysentery, secondary and tertiary syphilis.
	Warm, Bath Co., Va. (98° F.)	Chronic and subacute rheumatism, gout, neuralgia, nephritic and calculous diseases.
	Hot, Bath Co., Va. (110° F.)	Chronic rheumatism, gout, diseases of liver, neuralgia, contractions of joints.
	Paso Robles, San Luis, Obispo Co., Cal. (122° F.)	
	Hot, Garland Co., Ark. (93°–150° F.)	Dartrous diseases of skin, functional diseases of uterus, chronic mercurial and lead poisoning.
Calcareous and Earthy.	Gettysburg, Adams Co., Penn.	Calculus, gravel, catarrh of stomach or bladder, dyspepsia.
	Sweet, Monroe Co., W. Va. (74° F.)	Gravel, dyspepsia (diuretic, diaphoretic).
	Berkeley, Morgan Co., W. Va. (74° F.)	Neuralgia (restorative).
	Alleghany, Montgomery Co., Va.	Purgative, diuretic.
	Bethesda, Waukesha Co., Wis.	Diabetes mellitus, gravel, inflammation of bladder, dropsy, albuminuria (diuretic).
Sulphur.	Lower Blue Lick, Nicholas Co., Ky.	Aperient and alterative.
	Sharon, Schoharie Co., N. Y.	Do. do.
	White Sulphur, Greenbrier Co., Va.	Dartrous skin diseases, diseases of the bladder, jaundice, dyspepsia.
	Salt Sulphur, Monroe Co., W. Va.	Do.; scrofula and syphilis.
Epsom Salt.	Bedford, Bedford Co., Penn.	Anæmia, gravel, calculus (strongly diuretic).
Common Salt.	St Catherines, Ontario, Canada	Rheumatism, gout, scrofula, neuralgia.
	Caledonia, Ontario, Canada	Rheumatism, gout.
	Hathorne, Saratoga, N.Y.	Dyspepsia, jaundice, abdominal plethora.
	Ballston, Saratoga Co., N.Y.	Do. do. do.
Iron.	Oak-Orchard Acid, Genesee Co., N.Y.	Ulcers, diseases of the skin, passive hæmorrhages, atonic diarrhœa (has 10 grains of free sulphuric acid in the pint).
	Rawley, Rockingham Co., Va.	Chlorosis and anæmia generally; tonic.
	Sweet Chalybeate, Alleghany Co., Va.	Do. do. do.
	Rockbridge Alum, Rockbridge Co., Va.	Scrofula, chronic diarrhœa.
	Cooper's Well, Hinds Co., Miss.	Anæmia, chlorosis, chronic diarrhœa, dropsy.
Glauber Salt.	Crab Orchard, Lincoln Co., Ky.	
	Midland, Midland Co., Mich.	
Alkaline.	Bladon, Choctaw Co., Ala. (carbonated alkaline).	
	Congress, Santa Clara Co., Cal. (saline alkaline)	
	St Louis, Gratiot Co., Mich. (simple alkaline)	Dyspepsia, neuralgia, chronic and subacute rheumatism.

MINERVA (*i.e.*, *menes-va*, endowed with mind) was the Roman goddess who presided over all handicrafts, inventions, arts, and sciences. She was probably an Etruscan deity, but her character was modified on Roman soil through her identification with the Greek Pallas Athena (see ATHENA). No legend of her birth is recorded; the Roman deities were abstractions, not distinct persons with an individual history. Her chief worship in Rome was in the temple built by Tarquin on the Capitol, where she was worshipped side by side with Jupiter and Juno. This foundation may be assigned to Etruscan influence. She had also an old temple on the Aventine, which was a regular meeting-place for dramatic poets and actors. The dedication day of the temple and birthday of the goddess was March 19, and this day was the great festival of Minerva, called *quinquatrus* because it fell on the fifth day after the Ides. The number five was sacred to the goddess. All the schools had holidays at this time, and the pupils on reassembling brought a fee (*minerval*) to the teachers. In every house also the *quinquatrus* was a holiday, for Minerva was patron of the women's weaving and spinning and the workmen's craft. At a later time the festival was extended over five days, and games were celebrated. This feature is evidently due to the Græcizing conception of Minerva as the goddess of war. To this same Græcizing tendency we must attribute the *lectisternium* to Minerva and Neptune conjointly after the battle of the Trasimene Lake. The 23d had always been the day of the *tubilustrium*, or purification of the trumpets, so that the ceremony came to be on the last day of Minerva's festival. Trumpets were used in many religious ceremonies; and it is very doubtful whether the *tubilustrium* was really connected with Minerva. There was another temple of Minerva on the Cælian Hill, and a festival called the lesser *quinquatrus* was celebrated there on June 13–15, chiefly by the flute-players.

Minerva of the Cælian temple was called Capta; June 19 was the foundation day of this temple and the birthday of the goddess. The *palladium*, an archaic image of Pallas, was brought from Troy to Lavinium, and thence to Rome by the family of the Nautii; it was preserved in the temple of Vesta as a pledge of the safety of the city. There are some traces of an identification of Minerva with the Italian goddess Nerio, wife of Mars; it is probable that March 19 was originally a feast of Mars.

MINGRELIA, a former principality of Transcaucasia, which became subject to Russia in 1804, and since 1867 has constituted three circles of the government of Kutais—Letchgum, Senakh, and Zugdidi. The country corresponds to the ancient Colchis; and Izgaur or Iskuriah on the Black Sea coast, which was the capital during the period of Mingrelian independence under the Dadian dynasty, is to be identified with the ancient Dioscurias, a colony of Miletus. The Mingrelians (still almost exclusively confined to the Mingrelian territory, and numbering 197,000) are closely akin to the Georgians. See CAUCASUS, vol. v. p. 257, and GEORGIA.

MINIATURE is a term which by common usage has come to be applied to two different branches of painting. Derived from the Latin word *minium*, the red pigment used in the primitive decoration of MSS., in the first place it is the technical word employed to describe a painting in a MS.; and, from the fact of such pictures being executed on a reduced scale, it has its secondary and modern signification of a small, or miniature, portrait. In the latter sense it belongs to the general subject of painting. Here it is proposed to trace the development of the miniature in MSS. of the different schools of Europe.

The rise of the art of ILLUMINATION, in which the miniature plays so important a part, has been described under that heading; and something has been said in that place about the earliest extant specimens of miniature painting. Unfortunately we cannot with any certainty reach farther back than the 4th century for the most ancient of them; and all remaining examples between that period and the 7th century in Greek and Latin MSS. can be counted on the fingers. The two famous codices of Virgil in the Vatican Library stand pre-eminent as the most ancient Latin MSS. decorated with paintings. The miniatures in the first of them, the *Codex Romanus*, are large and roughly yet boldly executed paintings, which have no pretension to beauty, and are simply illustrations; but they are as old as the 4th century, and are of the highest value in enabling us to appreciate the debased style to which classical art had descended, and which no doubt was more largely employed than we might think. The second MS., the *Schedæ Vaticanæ*, which may also be assigned to the 4th century, is far more artistic and retains a good deal of the grace of classic art. Of the same kind, but of rather later date, are the fragments of the *Iliad* in the Ambrosian Library at Milan, the miniatures of which are generally of excellent design. Next comes the Dioscorides of the Imperial Library at Vienna, with its semiclassical portrait-miniatures executed at the beginning of the 6th century. Of a rather later period are the paintings which illustrate the Greek MS. of Genesis in the same library. A far finer and older MS. of the same book of the Pentateuch once existed in the Cottonian Library, but was almost totally destroyed by fire. The few fragments of the miniatures which once filled this volume, and which were of the 5th century, are sufficient to show what excellent work could be done in the capital of the eastern empire, from whence the MSS. most probably came. The late interesting discovery of an illustrated MS. of the Gospels in Greek, of the latter part of the 6th century, at Rossano in southern Italy, adds another number to our scanty list of early volumes of this class, which is closed by the Latin Pentateuch in the library of the earl of Ashburnham. This last MS., however, is not older than the 7th century. It was executed in Italy, and is adorned with many large miniatures, not of high artistic merit, but of great interest for the history of painting and of costume.

Coeval with the MSS. which have just been enumerated are the beautiful mosaics and wall-paintings which are seen at Rome, Ravenna, and in other parts of Italy, serving as standards of comparison and carrying on the history of art where MSS. fail us. The strong and ever-increasing Byzantine element which appears in these works prepares us to find the predominance of the same influence when we again pick up the broken thread of the history of miniature painting. We may then, at this point, turn for a moment to the east of Europe and state briefly what remains of Greek art in MSS. Of Greek miniatures there are still many fine examples extant, but, excepting those which have been noticed above, there are few which are earlier than the 11th century. At this period the miniature appears in the set form which it retained for the next two or three hundred years; and the connexion between its

style and that of the mosaics is too evident for us to be at a loss to explain the course of development. The figure drawing is delicate, but rather exaggerated in length; the colours are brilliant; and the whole effect is heightened by glittering backgrounds of gold. In some few instances, however, the Greek artist breaks away from conventionalism, and, especially when pourtraying the divine features of the Saviour or some subject which deeply stirs his feelings, he surprises us with the noble dignity with which he invests his figures. Minuteness also caught the fancy of these Byzantine miniaturists; and there still remain MSS., such as Psalters and saints' lives, adorned throughout with delicate little drawings of great symmetry and beauty. The ornamentation which was employed in Greek MSS. in the period of which we are speaking, either as frames for miniatures or as borders or head-pieces, is designed evidently after Eastern types, and has more than an accidental likeness to the patterns which are seen in the tapestries and prayer-carpets of Persia. After the 13th century decadence sets in, and we need not follow the course of Byzantine art in MSS. farther than to notice that immediately from it sprang such national styles as those of Russia, Bulgaria, and modern Greece.

Meanwhile, in the West, under the fostering care of Charlemagne, arose a great school of decoration in MSS., which at the close of the 8th and beginning of the 9th century were multiplied and enriched with all the splendour that colours and gilding could give to them. But the books thus ornamented were almost always copies of the Gospels, or Bibles, or church service books, which afforded little scope for invention. Hence among the miniatures of this period we have an endless repetition of portraits of the evangelists, drawn, for the most part, in a lifeless way after Byzantine traditions, and degenerating, as time passes, into positive ugliness. The few miniatures of other descriptions, such as Biblical illustrations, show no great merit, and a half-barbaric splendour was generally preferred to artistic effect. But an exception must be made in regard to the style of drawing found in the MS. known, on account of its present resting-place, as the Utrecht Psalter. This volume is filled from beginning to end with delicately drawn pen illustrations, designed and executed with a facility which, compared with the mechanical and clumsy drawing of other Continental MSS. of the period, is astonishing. And these drawings are of particular interest for us, as they are of the style which was adopted in England and which gives to Anglo-Saxon art its distinctive aspect. Executed about the year 800 or early in the 9th century, and probably in the north of France, the volume was soon brought to England, where, however, MSS. of the same kind, it may be assumed, had long before been introduced. The light "fluttering" outlines of the drapery and other details of the drawings seem to suggest that the original models were derived directly from Roman life, and perhaps partly copied from sculpture; but those models must have gone through many modifications before passing into the style of the drawings of the Psalter. That the MS. was copied from an older one there can be scarcely a doubt; and it is not impossible that the original archetype may date back some centuries earlier. May not MSS. which St Augustine and his successors brought from Rome have contained drawings of the same kind? This style of drawing was, at all events, adopted and became nationalized in England; but it had there a rival in the Irish school of ornamentation, introduced from the north of the island. The early civilization of Ireland placed her in the van of art development in these islands. The wonderfully intricate interlaced designs which render Irish MSS. of the 7th and 8th centuries such marvels of exact workmanship derive their origin, in all probability, from the metal-work of earlier ages. But, apart from ornamentation, the Irish miniatures of saints and evangelists are extraordinary and grotesque instances of purely mechanical drawing, which cause us to wonder how the same eyes and hands which assisted in the creation of such beautiful specimens of pure ornament could tolerate such caricatures of the human shape. The explanation is perhaps to be found in superstitious regard for tradition. This style of art was carried by the monks to Iona and thence to Lindisfarne, where was founded the school which produced, in the 8th and 9th centuries, the richly ornamented codices of Durham. While, then, Byzantine models were copied on the Continent, the free drawing introduced from the south and the intricate ornamentation brought in from the north were practised in England; but the free drawing, with its accompanying decoration copied from foliage, and gradually developing into beautiful borders harmoniously coloured, gained the day, and lasted down to the time of the Norman Conquest. The one great fault of this latter style of drawing strikes the eye at the first glance. This is the inordinate length of limb with which the human figures are endowed. But this blemish is forgotten when one comes to appreciate the many points of merit in the designs.

In Italy, after a long period of inactivity, two very different styles of decoration of MSS. sprang into existence. The first of these was that of the Lombardic school, which is distinguished by intricate patterns and bright colouring. The large initial letters which are found in the MSS. of the 11th and 12th centuries, the best period of this style, are often a perfect maze of interlaced bands and animal forms, and are extremely handsome and effective. Figure drawing, however, seems to have been but little practised by the Lombardic artists, but such as there is appears on a broad scale and well executed. In the collections of Monte Cassino are some of the best examples of this school. In the second style which developed in Italy the Byzantine influence is at first most marked. Indeed, among its early specimens of the 13th century are some which might pass for the work of Greek artists. But the genius of the Italians soon assimilated the foreign element, and produced a national school which spread throughout the peninsula and afterwards extended its influence to southern France and Spain. It is, however, remarkable that in a country which produced such fine pictures and wall-paintings at an early date there is comparatively little miniature painting in contemporary MSS. A curious and early instance of this kind of art occurs in a MS. in the British Museum, written and ornamented with a series of miniatures at Winchester, in the 12th century, in which are two paintings which are purely Italian and of more than ordinary excellence.

In the majority of the extant Italian miniatures of the 14th century the influence of the great artists of the Florentine school is manifest. The peculiar treatment of flesh tints, painted in body colour over a foundation of olive-green, and the peculiar vermilion and other colours which need be but once seen to be ever afterwards recognized as belonging to this school, are constantly present. The figures are generally rather shortened and the drapery carried in straight folds, very different characteristics from the swaying figures and flowing drapery of the English and French artists of the same period. The ornamentation which accompanied this style of miniature generally consists of heavy scrolls and foliated or feather-like pendants from the initial letters, with spots of gold set here and there in the border. There are also extant some examples of a most beautiful kind of ornamentation which appears to have originated in central Italy, and which seems to partake of the qualities of both the styles of Italian art of which we have been speaking, combining

the drawing of the Florentine school with a lighter colouring which may have been suggested by the Lombardic.

Of native Spanish miniature art little can be said. In the Visigothic MSS. of the early Middle Ages there is no ornament beyond roughly coloured initial letters and some barbaric figure drawing. A little later, however, we get some indication of national peculiarities in the MSS. of the 10th, 11th, and 12th centuries. Here there appear miniatures, stiff and rude in their drawing, but exhibiting the unmistakable Spanish predilection for sombre colours,—dusky reds and yellows and even black entering largely into the compositions.

The materials at our disposal of the 10th, 11th, and 12th centuries show the gradual development in France and western Germany of a fine free-hand drawing which was encouraged by the proportionately increasing size of books. Both in outline and colour the fully developed miniatures of the 12th century are on a grand scale; and initial letters formed of scrolls and interlacings assume the same proportions. The figure drawing of this time is frequently of great excellence, the limbs being well-proportioned; care is also bestowed upon the arrangement of the drapery, which is made to follow the shape and, as it were, to cling to the body.

But the great revulsion from the broad effects and bold grandeur of the 12th century to the exact details and careful finish of the 13th century is nowhere more striking than in miniature painting in MSS. With the opening of the new period we enter on a new world of ideas. Large books generally disappear to give place to smaller ones; minute writing supersedes the large hand; and miniatures appear in circumscribed spaces in the interior of initial letters. The combination of the miniature with the initial brings it into close connexion with the ornamental border, which develops *pari passu* with the growth of the miniature and by degrees assumes the same national and distinctive characteristics. Burnished gold was now also freely used, tending to give the miniature a more decorative character than formerly. In England, northern France, and the Netherlands the style of miniature painting of this period was much the same in character; and it is often difficult to decide from which of these countries a MS. is derived. English work, however, may be often distinguished by its lighter colouring, while deeper and more brilliant hues and a peculiar reddish or copper tinge in the gold marks French origin. The drawing of the Flemish artists was scarcely so good, the outlines being frequently heavy and the colours rather dull. Of the Rhenish or Cologne school examples are more scarce; but they generally show greater contrasts in the colours, which, though brilliant, are not so pleasing. As the century advanced, and particularly at its close, national distinctions became more defined. English artists paid more attention to graceful drawing and depended less upon colour. In some of their best productions they are satisfied with slightly tinting the figures, finding room in the backgrounds for display of brilliant colours and gilding. In France the drawing, though exact, is hardly so graceful, and colour plays a more important part. From the 13th to the middle of the 15th century great decorative effect is obtained by the introduction of diapered or other highly ornamented backgrounds. Of landscape, properly so called, there is but little, a conventional hill or tree being often taken as sufficient indication. Borders begin in the 13th century in the form of simple pendants from the initial letters, terminating in simple buds or cusps. But once arrived fairly in the 14th century, a rapid development in all parts of the decoration of MSS. takes place. There is greater freedom in the drawing; the borders begin to throw out branches and the bud expands into leaf. This is the best period of English miniature painting, many of the fine MSS. of this century which are preserved in the public libraries bearing witness to the skill and delicate touch of native artists. In France the decoration of MSS. received a great impetus from the patronage of King John and Charles V., of whose famous libraries many handsome volumes are still to be seen; and later in the century the duke of Berri carried on the same good work.

With regard to miniature art in Germany there are so few examples to guide us that little can be said. Most of them are rough in both drawing and colouring; and in the few remaining specimens of really good work foreign influence is distinctly seen. In the west the art of France and Flanders, and in the south that of Italy, are predominant. Perhaps the finest MS. of this southern style to be seen in England is a Psalter belonging to Lord Ashburnham, which was probably executed in the 14th century at Prague, and is full of miniatures which in drawing and colouring follow the Italian school.

When we enter the 15th century we find great changes in both the great English and French schools. In England the graceful drawing of the previous century has disappeared. At first, however, some beautiful examples of purely native work were produced, and still remain to excite our admiration. Probably the most perfect of these MSS. are the Sherborne Missal belonging to the duke of Northumberland, and a very beautiful volume, a Book of Hours, in the library of Lord Ashburnham. The care bestowed upon the modelling of the features is particularly noticeable in English work of this period. In decoration the border of the 14th century had by this time grown to a solid frame surrounding the page; but now another form of most effective ornament was also used, consisting of twisted feather-like scrolls brightly coloured and gilt. As the century advanced native English work died out, and French and then Flemish influence stepped in.

In France immense activity was shown all through the 15th century in the illumination and illustration of books of all kinds, sacred and profane; and it is in the MSS. of that country, and, a little later, in those of the Low Countries, that we can most exactly watch the transition from mediæval to modern painting. Early in the century there were executed in France some of the most famous MSS. which have descended to us. In these the colouring is most brilliant, the figure drawing fairly exact; and the landscape begins to develop. The border has grown from the branching pendant to a framework of golden sprays or of conventional and realistic leafage and flowers. Towards the middle of the century the diaper disappears for ever, and the landscape is a recognized part of the miniature; but perspective is still at fault, and the mystery of the horizon is not solved until the century is well advanced. And now Flemish art, which had long lain dormant, sprang into rivalry with its French sister, under the stimulus given to it by the Van Eycks, and the struggle was carried on, but unequally, through the rest of the century. French art gradually deteriorates; the miniatures become flat and hard; nor are these defects compensated for by the meretricious practice of heightening the colours by profusely touching them with gold. The Flemish artists, on the other hand, went on improving in depth and softness of colouring, and brought miniature painting to rare perfection. The borders also which they introduced gave scope for the study of natural objects. Flowers, insects, birds, and jewels were painted in detached groups on a solid framework of colour surrounding the page.

But if, as the 15th century drew to its close, the Flemings had outstripped their French rivals, they had now more powerful antagonists to contend with. The Italians had been advancing with rapid strides towards the glories of

the Renaissance. Early in the century there arose a taste for older models. As, for their writing and afterwards for their printing, they went back to the 11th and 12th centuries for their standards, so they adopted again the interlacing designs of the Lombardic school for their ornament, and produced beautiful borders of twining patterns relieved by colour; or they took natural objects for their models, and painted borders of delicate flowers made still more brilliant with clustering stars of gold. Later, they drew from the ancient classical designs inspiration for the wonderful borders of arabesques, medallions, griffins, human forms, antique objects, &c., which they brought to such perfection early in the next century. Their miniatures rose to the rank of exquisitely finished pictures, and were executed by some of the best artists working under the patronage of such great houses as those of Sforza and Medici.

Here then, having advanced to the threshold of the domain of modern painting, we leave these two great schools of miniaturists in possession of the west of Europe. The Flemings had the wider field; they were wanderers from home; and their works are scattered through many lands, from England in the north to Spain in the south. But Italian art had greater inherent strength, and will always hold the first rank. To instance a few of the more famous MSS. of this closing period of miniature painting: the Breviary of Isabella the Catholic, in the British Museum, is a masterpiece of Flemish art produced in Spain; the Grimani Breviary at Venice is another fine example of the same school. Some beautiful Italian miniatures (executed for Leo X. and others) were in the collection lately sold by the duke of Hamilton. The earl of Ashburnham possesses a most delicately illuminated Book of Hours written for Lorenzo dei Medici by the famous scribe Sinibaldo in 1485, as well as a MS. to which Perugino and his contemporaries contributed paintings. And in one MS., a Book of Hours belonging to Mr Malcolm of Poltalloch, are gathered some of the best miniatures of both schools, viz., a series of exquisite paintings by Milanese artists supplemented by later ones of the finest Flemish type. (E. M. T.)

MINIMS. See FRANCIS (ST) OF PAOLA, vol. ix. p. 695.

MINING

THE art of mining consists of those processes by which useful minerals are obtained from the earth's crust. This definition is wider than what is popularly known as mining, for it includes not only underground excavations but also open workings; at the same time it excludes underground workings which are simply used for passages, such as railway tunnels and sewers, and galleries for military purposes. We must remark also that the word "mine," or its equivalent in other languages, varies in signification in different countries on account of legal enactments or decisions which define it. Thus, in France and Belgium, the workings for mineral are classified by the law of 1810, according to the nature of the substance wrought, into *mines, minières, et carrières*. In the United Kingdom, on the contrary, it is the nature of the excavation which decides the question for certain legislative purposes, and the term mine is restricted to workings which are carried on underground by artificial light. The consequence is that what is merely an underground stone quarry in France becomes a true mine in England, whilst the open workings for iron ore, such as exist in Northamptonshire, would be true mines under the French law. It is necessary, therefore, in an article on mining, to go beyond the English legal definition of a mine, and include the methods of working minerals in excavations open to daylight as well as in those which are purely subterranean. Furthermore, as it is customary for the miner to cleanse his ore to a greater or less extent before selling it to the smelter, we shall treat, under the head of mining, those processes which are commonly known as the dressing or mechanical preparation of ores; and, finally, a few remarks will be made concerning legislation affecting mines in the United Kingdom, accidents in mines, and the production of the useful minerals in various parts of the globe.

The subject therefore will be dealt with as follows:—

1. Manner in which the useful minerals occur in the earth's crust, viz., tabular deposits and masses; faults or dislocations.
2. Prospecting, or search for mineral.
3. Boring with rods and ropes; diamond drill.
4. Breaking ground; tools employed; blasting by various methods; machine drills; driving levels and sinking shafts.
5. Principles of employment of mining labour.
6. Means of securing excavations by timber or masonry.
7. Exploitation, or the working away of strata or veins.
8. Carriage or transport of minerals through underground roads.
9. Winding, or raising in the shafts, with the machinery and apparatus required.
10. Drainage of mines, adit-levels, pumps, pumping engines.
11. Ventilation and lighting of mines.
12. Means of descending into and ascending from mines.
13. Dressing or mechanical preparation of minerals.
14. Recent legislation affecting mines in the United Kingdom.
15. Accidents in mines.
16. Useful minerals produced in various parts of the globe.

1. *Manner in which the Useful Minerals Occur.*—The repositories of the useful minerals may be classified according to their shape as (A) tabular deposits, and (B) masses.

A. *Tabular Deposits.*—These are deposits which have a more or less flattened or sheet-like form. They may be divided, according to their origin, into (1) beds or strata, and (2) mineral veins or lodes.

(1) *Beds.*—Geology teaches us that a large proportion of the rocks met with at the surface of the earth consist of substances arranged in distinct layers, owing to the fact that these rocks have been formed at the bottom of seas, lakes, or rivers by the gradual deposition of sediment, by precipitation from solutions, and by the growth or accumulation of animal and vegetable organisms. If any one of these layers consists of a useful mineral, or contains enough to make it valuable, we say that we have a deposit in the form of a bed, stratum, or seam. Of course the most important of all bedded or stratified deposits is coal, but, in addition, we have beds of anthracite, lignite, iron ore, especially in the Oolitic rocks, cupriferous shale, lead-bearing sandstone, silver-bearing sandstone, diamond-, gold-, and tin-bearing gravels, to say nothing of sulphur, rock-salt, clays, various kinds of stone, such as limestone and gypsum, oil-shale, alum-shale, and slate.

The characteristic feature of a bed is that it is a member of a series of stratified rocks; the layer above it is called the *roof* of the deposit, and the one below it is the *floor*. Its *thickness* is the distance from the roof to the floor at right angles to the planes of stratification; its *dip* is the

inclination downwards measured from the horizontal; its *strike* is the direction of a horizontal line drawn in the middle plane.

The thickness of beds that are worked varies within very wide limits. Whilst the thickness of certain workable beds of coal is only 1 foot, and that of the Mansfeld cupriferous shale only 10 to 20 inches, we find on the other hand one of the beds of lead-bearing sandstone at Mechernich no less than 85 feet thick, and beds of slate far exceeding that thickness. It must not be supposed, however, that the thickness of a bed necessarily remains uniform. Occasionally this is the case over a very large area; but frequently the thickness varies, and the bed may dwindle away gradually, or increase in size, or become divided into two owing to the appearance of a parting of valueless rock. Fig. 1 shows beds of shale, limestone, iron ore, and sandstone. Any one of these beds may be valuable enough to be worked.

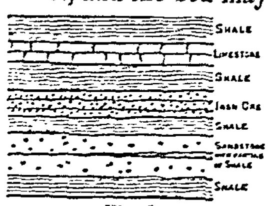

Fig. 1.

Mineral veins. (2) *Mineral Veins or Lodes.*—Veins or lodes are tabular or sheet-like deposits of mineral which have been formed since the rocks by which they are surrounded; they differ, therefore, by their subsequent origin from beds, which, as just stated, are of contemporaneous origin with the enclosing rocks (although of course cases occur in which the deposit is lying unconformably upon very much older strata, or is covered unconformably by very much younger strata). It is necessary to explain that the term "vein" in this definition is used in a more restricted sense than is sometimes customary among miners, who speak of *veins* of coal, clay-ironstone, and slate, which geologically are true beds. They see a band of valuable mineral or rock, and, careless of its origin, call it metaphorically a vein or seam. On the other hand, the definition is broader than that which prevails among some geologists, who would confine the term vein to deposits occupying spaces formed by fissures.

The term "lode" was defined in 1877 by Mr Justice Field in the celebrated Eureka *v.* Richmond case as follows:—"We are of opinion, therefore, that the term, as used in the Acts of Congress, is applicable to any zone or belt of mineralized rock lying within boundaries clearly separating it from the neighbouring rocks." This interpretation seems suitable for the peculiar mining tenure of the United States, where the discoverer of a vein or lode can obtain a mining claim of 500 yards in length along the lode. It protects the prospector, whose object is to obtain a secure title, the mode of origin of the deposit being a matter of small importance to him so long as it is worth working. In many cases also it would be impossible to decide upon the mode of origin until workings had progressed considerably, and even then there would be room for disputes.

No doubt a very large number of mineral veins are simply the contents of fissures; others are bands of rock impregnated with ore adjacent to fissures or planes of separation; others, again, have been formed by the more or less complete replacement of the constituents of the original rock by particles of ore.

Veins may occur in igneous or in sedimentary rocks, and in the latter they frequently cut across the planes of stratification.

Like a bed, a vein has its dip and strike; but, as the dip of veins is generally great, the inclination is usually measured from the vertical, and is then spoken of as the *underlie* or *hade*. The bounding planes of a vein are called the *walls* or *cheeks*, and they are frequently smooth and striated, showing that one side must have slid against the other. The upper wall is known as the *hanging wall*, the lower one as the *foot wall*. The width of a vein is measured at right angles to the walls.

A typical example of a fissure-vein is shown in fig. 2, representing a lead lode in slate at Wheal Mary Ann mine[1] in Cornwall. It is evident that a fissure in the surrounding slate has here been filled up by the successive deposition of bands of mineral on both sides.

A large proportion of the contents of a lode may consist of fragments of the walls that have fallen into the original fissure, and these are often tightly cemented together by minerals that have been introduced subsequently. The horizontal section of part of the Comstock lode[2] (Plate IV.) shows much "country" rock enclosed within the walls.

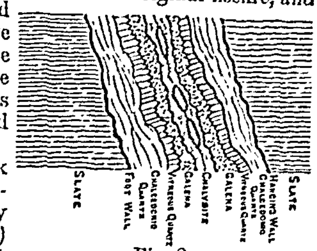

Fig. 2.

Where a lode consists of rock impregnated with ore, the mineralized part may fade away gradually into the surrounding rock (*country*) without there being any distinct wall, as shown in *fig.* 3, which is an illustration taken from the Great Flat Lode[3] near Redruth in Cornwall.

The celebrated Ruby Hill deposit in the Eureka district, Nevada, is a mineralized zone of dolomitic limestone varying in width from a few inches to 450 feet, and having a mean width of 250 feet. It contains numerous irregular ore-bodies, which consist mainly of highly ferruginous carbonate of lead, rich in silver and gold. This mineralized limestone band, long called a lode by miners, has been determined by the decision just mentioned to be a lode in the eyes of the law.

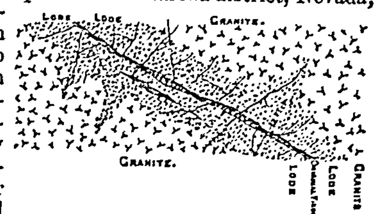

Fig. 3.

Veins often continue for a great distance along their strike. The Van lode in Montgomeryshire is known for a length of 9 miles, whilst the Great Quartz Vein in California has been traced for a distance of no less than 80 miles. Veins are of less uniform productiveness than beds, and are rarely worth working throughout. Rich portions alternate with poor or worthless portions. The rich parts have received various names according to the forms they assume: *fig.* 4 represents a longitudinal section along the strike (*course*) of a lode, and the stippled parts are ore-bodies; B, B, B are *bunches*; A is a large bunch or *course of ore*; when an ore-body forms a sort of continuous column we have a *shoot*, and ore-bodies which on being excavated leave chimney-like openings are called *pipes* (fig. 4, C). In the United States the Spanish word *bonanza*, literally meaning "fair weather" or "prosperity," is frequently used for a rich body of ore.

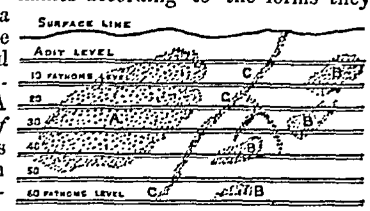

Fig. 4.

The richness of veins is dependent in many cases upon the nature of the adjacent rock (*country*), upon the underlie, and upon the strike, variations in any one of these three elements being often sufficient to cause a decided change of productiveness.

Various theories have been formed concerning the origin of mineral veins. Some geologists suppose that the minerals now constituting the veins have been dissolved out of the adjacent rocks and re-deposited in the vein cavity; others, on the contrary, believe that the ores have been brought up from great depths by mineral springs. In all probability both theories are correct, some lodes having been formed by the former process and some by the latter; and, furthermore, other lodes appear to owe their origin to a gradual substitution of valuable minerals in the place of some of the constituents of a worthless rock. One of the most important contributions to the science of ore-deposits of late years has been the discovery by Professor F. Sandberger of small quantities of silver, lead, copper, nickel, cobalt, bismuth, arsenic, antimony, and tin in silicates, such as olivine, augite, hornblende, and mica, which are constituents of igneous rocks. He therefore regards these rocks as the sources from which lodes have derived their riches.

Masses. B. *Masses.*—These are deposits of mineral, often of irregular shapes, which cannot be distinctly recognized as beds or veins. Such, for instance, are the red hæmatite

[1] C. Le Neve Foster, "Remarks on the Lode at Wheal Mary Ann, Menheniot," *Trans. Roy. Geol. Soc. Cornwall*, vol. ix. p. 153.

deposits of the Ulverston district (fig. 5[1]) and the brown hæmatite deposits (*churns*) of the Forest of Dean, which

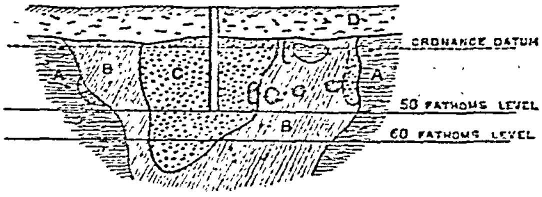

Fig. 5.—Vertical Section, Roanhead Mine. A, Mountain Limestone; B, red hæmatite; C, sand and clay; D, gravel. Scale $\frac{1}{3000}$.

occupy irregular cavities in the Mountain Limestone. These may have been formed by the percolation of water bringing down iron in solution from overlying Triassic rocks. Other examples of masses are the calamine deposits of Altenberg[2] (fig. 6), Sardinia, and Lombardy, the iron ore deposits in Missouri, such as Iron Mountain and Pilot Knob, the huge upright "necks" or "pipes" of diamantiferous rock in South Africa, and the granite decomposed *in situ* worked for china clay in Cornwall.

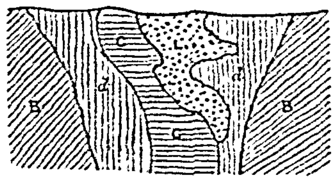

Fig. 6.—Vertical Section, Altenberg. B, slate; *d*, dolomite; C, calamine; L, clay.

Under this head also are included by most authors the so-called "stockworks" or "reticulated masses," names applied to masses of sedimentary or igneous rock which are penetrated by so many little mineral veins as to make the whole worth excavating.

It must be understood that we cannot expect nature to make distinct lines of demarcation between the different kinds of deposits. Though we may be able to see clearly that a seam of coal is contemporaneous with the enclosing rocks, and that a vein intersecting beds of shale and sandstone was formed subsequently, cases frequently occur where the origin of the mineral is uncertain. For example, we have the lead-bearing sandstone of Mechernich and the silver-bearing sandstone of Utah. The grains of sand are of sedimentary origin; but opinions differ as to whether the lead and silver respectively were deposited with the sand or were introduced subsequently by solutions percolating through the beds. In the case of the well-known bed of Cleveland ironstone, Dr Sorby considers that the iron was "derived partly from mechanical deposition and partly from subsequent chemical replacement of the originally deposited carbonate of lime."[3] Furthermore, a bed may be so folded and contracted as to lose its original sheet-like form in places and assume the shape of an irregular mass. This may happen even with a coal seam.[4]

Faults. All kinds of deposits are subject not only to irregularities of origin dependent upon their mode of formation but also to dislocations or shiftings known as faults, heaves, or throws.

We will take the case of a bed (fig. 7). AB is a seam which ends off suddenly at B, whilst the continuation is found at a lower level at CD. The bed was evidently once continuous; but a fracture took place along the line XY followed by a displacement. As a rule

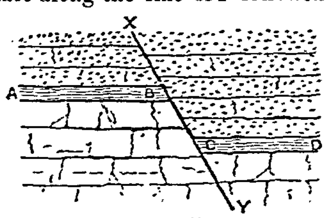

Fig. 7.

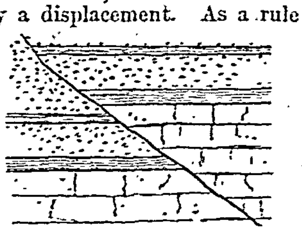

Fig. 8.

the portion of rock on the hanging-wall side of a fault appears to have slid downwards, but occasionally this is not so, and we have a reversed fault (fig. 8). It is very evident, in some cases, that the motion took place, not along the line of greatest dip, but in a diagonal direction, causing a displacement sideways as well as downwards. Nevertheless, where beds or veins are not horizontal, a mere shift along the line of dip is sufficient to cause an apparent heave sideways. This will be understood from fig. 9. Let AB and CD represent two portions of a lode dislocated by the fault EF. The point B′ corresponded originally with B, and the dislocation was caused by a simple sliding of B′ along the line of dip BB′. An instance of the complication caused by a succession of faults is shown in fig. 10.[5]

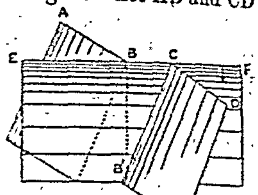

Fig. 9.

2. *Prospecting, or Search for Mineral.*—The object of the prospector is to discover valuable deposits of mineral. This search is beset with many difficulties: the outcrops of Prospecting.

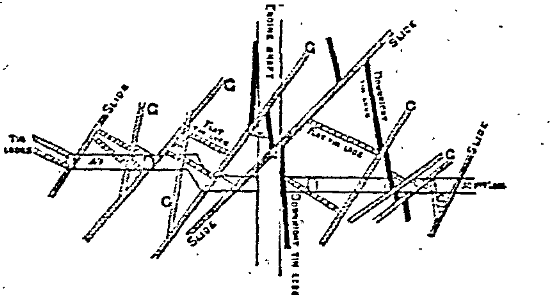

Fig. 10.—Vertical Section, Penhalls Mine, Cornwall. G, G, G, small veins called *gossans* in the St Agnes district.

mineral deposits are frequently hidden by soil; the nature of the deposit itself is generally entirely changed near the surface; and, in addition to this, the explorer may have to pursue his work in trackless forests far away from any settlements.

The prospector seeks for natural sections of the rocks, such as occur in cliffs or in river valleys and their tributary gullies and gorges; he examines the materials constituting the river-beds, often digging up and washing portions in a pan, in order to ascertain whether they contain traces of the heavy ores or metals. If, while prospecting in a valley, he discovers stones that have the appearance of having once belonged to veins, he endeavours to trace them to their source, and is perhaps rewarded by finding similar fragments, but less water-worn, as he goes up the stream; further on he may come upon large blocks of veinstuff lying about, and finally find the vein itself laid bare in a gorge, or at the bottom of a brook, or possibly projecting above the soil in the form of huge crags of quartz. Thus at the Great Western quicksilver mine in California the outcrop of the vein appears as a dike over 100 feet wide, and having precipitous sides in places 75 feet high.[6] Loose pieces of veinstuff found lying about are known in Cornwall as shoad-stones, and *shoading* is the term given to the process of tracking them to the parent lode.

The upper portion of a deposit is frequently much altered by atmospheric agencies, and bears little resemblance to the undecomposed bed or vein which will eventually be met with at a greater or lesser depth. The principal difference consists in the change of sulphides into oxides or oxidized compounds. Thus iron pyrites, which is such a common constituent of mineral veins, is converted into hydrated oxide of iron, and a vein originally consisting largely of iron pyrites and quartz now becomes a cindery mixture of quartz and ochre, known in Cornwall as *gossan*. This gossan, or *iron hat*, may often furnish important indications concerning the nature of the lode itself, because such minerals as pyromorphite or cerussite point to the existence of galena, whilst melaconite, cuprite, malachite, and azurite are the forerunners of chalcopyrite or copper glance. The gossan itself may contain a sufficient quantity of valuable ores to be worth working.

The seams containing native sulphur in Sicily often show no trace of that element immediately at the surface, as the sulphur-bearing limestone weathers into a soft white granular or pulverulent

variety of gypsum, called *briscale* by the miners, and considered by them as affording important indications concerning the bed itself.[1]

Other signs of mineral deposits are given by springs and by certain plants dependent upon the deposit or its associated minerals for part of their nourishment. The appearance of the so-called lode-lights may be explained by the production of phosphoretted hydrogen from the action of organic matter and water upon phosphates, which are so common in the upper parts of mineral veins; and one hears also of differences in the appearance of the vegetation along the line of the deposit, of places where snow will not lie in winter, and of vapours hanging over the ground. Though some writers refuse to put any value upon these indications, they should not be entirely overlooked, because the outcrop of a lode, of different nature and texture to the surrounding rocks, and which is generally a channel for water, may readily cause the phenomena just mentioned. Where the surface is cultivated and the natural springs are tapped by adit-levels or other mine-workings, these appearances cannot be looked for to any great extent. With one special mineral, magnetic iron, the position of the deposit may be traced out with some degree of accuracy with a dipping needle; this is used in Sweden.

After having acquired an idea of the position of a vein or seam by some of the surface indications just mentioned, it is necessary, before attacking it by shafts or levels, to obtain more certain data concerning it. In the case of mineral veins, trenches are dug at right angles to the supposed strike; and, when the upper part of the deposit has been cut in several places, its general course and dip can be determined sufficiently for the purpose of arranging the future workings. These trenches are called "costean pits"; in some cases, instead of a trench, a pit is sunk a short distance and a little tunnel driven out.

Where the mineral to be wrought occurs as a bed or mass, the process of boring is resorted to, and indeed this method is also applied in the case of veins, especially in the United States. Boring is a work of such importance that it deserves to be treated under a separate heading.

Boring.

3. *Boring with Rods and Ropes—Diamond Drills.*—The object of boring is to reach a deposit by a small hole and ascertain its nature, its depth from the surface, thickness, dip, and strike. Bore-holes are also used for obtaining water, brine, and petroleum, which either rise to the surface or have to be pumped up from a certain depth, and finally for tapping water in old workings or for effecting ventilation. The methods of boring may be classified as follows:—(1) boring with the rod; (2) boring with the rope; (3) boring with the diamond drill.

Boring with rods.

In the first method tools for cutting and removing the rock are fixed to rods, which are lengthened as the hole increases in depth, and which are worked by hand or by machinery at the surface. Where the ground is soft, such as sand or clay, tools like augers can be employed; but in harder ground it becomes necessary to have recourse to percussion; various forms of chisel are used, the simplest being made of the shape shown in fig. 11.[2] The rods generally consist of bars of square iron, from 1 inch to 2 inches on the side. The length of each rod depends upon the height of the tower, derrick, or shears erected above the bore-hole, which should be an exact multiple of the individual parts. These are made in lengths of 15 to 30 or rarely 40 feet, and with a suitable tower it is possible to detach or attach two or three lengths at a time, instead of having to make or unmake every joint. The mode of connexion usually preferred is by a screw joint as shown in fig. 12; care is taken to have all the joints exactly alike, so that any two bars can be screwed together. In order to

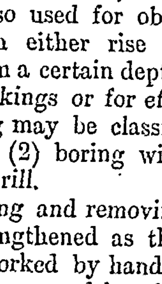

Fig. 11.—Chisels.

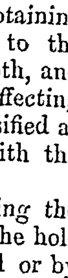

Fig. 12.

diminish the weight of the rods, which becomes considerable in deep holes, wood has sometimes been employed. The rods are connected by male and female screws attached to the rods by sockets of sheet iron, or by a fork-like arrangement. At the surface a head is screwed to the uppermost rod by which the rods can be lifted, and they are turned by means of cross-bars called tillers.

When the depth is small the rods are lifted by hand and then allowed to drop, being turned slightly at each lift so that the cutting chisel may strike a new place each time. For greater depths a lever has to be employed, the rods being suspended at one end, whilst the other end can be pressed down by men using their hands or feet. The spring pole is another arrangement, in which the elasticity of a long pole is made use of for lifting the rod at each stroke. The length of the stroke can be maintained the same while the bore-hole is deepened by means of a screw in a swivel-head at the top of the rod.

With deep holes, and especially those of large diameter, steam machinery has to be employed for working the rod; the engine may be direct-acting and stand immediately above the bore-hole, but a commoner arrangement is to employ a single-acting cylinder working a beam. Occasionally also the beam is actuated by a connecting-rod worked by a crank.

The actual boring machinery has now been described, and the mere boring appears to be a very simple matter, consisting only in lifting the rod a little and allowing it to drop, the rod being turned slightly before each stroke. Nevertheless the process of putting down a bore-hole is not so simple as it seems, for there are numerous indispensable accessory operations which take up much time. In the first place the débris have to be removed, and in order to effect this the rods must be drawn up, the swivel-head is disconnected and a cap screwed on. A length of rods is now drawn up by a hand or steam windlass and disconnected. It is well to have as many caps as there are lengths to be drawn up, and then each length can be suspended in the house. Sometimes a *grip* which catches the rod at the bulging joint is used instead of a cap. The next operation consists in lowering by means of a rope the *shell-pump* or *sludger*, which is a hollow cylinder with a clack or a ball-valve (fig. 13). It is worked up and down a little till it is filled, and it is then drawn up and emptied at the surface. The operation is repeated, if necessary, and the boring is resumed with the rod.

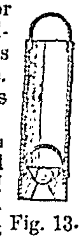

Fig. 13.

Occasionally a bore-hole has to be widened slightly with a tool called a *reamer*. Soft beds may have to be bored through with a *wimble*; and, unless the rocks are hard and firm, the hole has to be lined with a tube, generally of sheet-iron. Accidents may occur, causing an immense amount of trouble, such as the breaking of rods or chisel, and many ingenious implements have been devised for seizing the broken rod or the fragments of tools which prevent further progress with the work.

In boring at considerable depths, the weight of the rod becomes so great that much vibration ensues when the mass is suddenly arrested by the chisel striking against the bottom of the hole. Various devices have been contrived for overcoming this difficulty and producing a tool which will act independently of the rod. One of the best-known arrangements is the free-falling tool invented by Kind (fig. 14).[3] The head of the actual boring-rod is held by a click or grapple; when the main rod descends, the resistance of the water in the hole slightly stops the sliding disk D, the jaws J, J open, the head is disengaged, and the boring part falls and strikes the bottom without any injurious vibrations being communicated to the main rod. When this descends farther the head is caught again by the click. Special tools also are used for cutting an annular groove at the bottom of a bore-hole and breaking off the core, which is then brought up, with certain precautions, so as to show the nature and dip of the strata traversed.

Fig. 14.

Boring with rope.

In order to obviate the great loss of time which ensues from connecting and disconnecting long lengths of rods, recourse may be had to boring *with the rope*. In this method, known as the Chinese method, the chisel is worked by a rope in the same manner as the sludger already described. Messrs Mather and Platt of Manchester have long used with success, in many parts of England and various other countries, a system of boring by means of a flat hempen rope.

The most important modification of late years in the

[3] J. Callon, *Lectures on Mining*, vol. i., Atlas, plate ix. fig. 52.

Diamond drill.

process of making bore-holes is the introduction of the diamond drill. The working part of the drill consists of the so-called crown, which is a short piece of tube made of cast steel, at one end of which a number of black diamonds are fastened into small cavities (fig. 15). The crown is screwed on to wrought-iron pipes, which constitute the boring rod. Machinery at the surface causes the rod to rotate, and the result is the cutting of an annular groove at the bottom of the hole, leaving a core, which, breaking off from time to time, is caught by a little shoulder, and brought up to the surface with the rod. In places where it is not necessary to make any verification of the rocks traversed, the crown is arranged with diamonds in the centre also. The débris, in either case, are washed away by a stream of water, which is forced down the tube and flows up the sides of the hole. With this system a bore-hole can be deepened continuously at a speed altogether unattainable by the other methods, which require stoppages for cleaning out. It has the further advantage of making it possible to drill holes in any direction; and prospecting diamond drills are constantly used with much success inside many metal mines, especially in the United States.

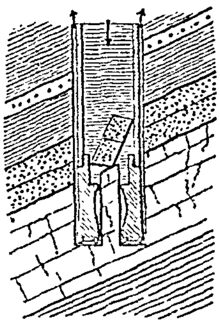

FIG. 15.—Diamond Drill.

Fig. 16[1] shows the Little Champion Rock-Drill, which is largely employed in the Lake Superior district for prospecting. It can be used above or below ground. Two inclined cylinders drive a horizontal crank shaft, which works bevel gear, causing the drill to revolve. At the same time a countershaft is likewise set in motion, and this effects the advance of the drill by gearing driving the feed-screw; as there are three kinds of gearing, the speed can be varied at pleasure. The feed-screw and its connexions are carried by a swivel-head, and this can be turned so as to drill holes at an angle. The drum shown above the cylinders is used for hoisting out the drill-rods by a rope. The rods are lap-welded iron tubes $1\frac{5}{8}$ inches in diameter, fitted with a bayonet joint.

Another light portable prospecting drill for underground work is

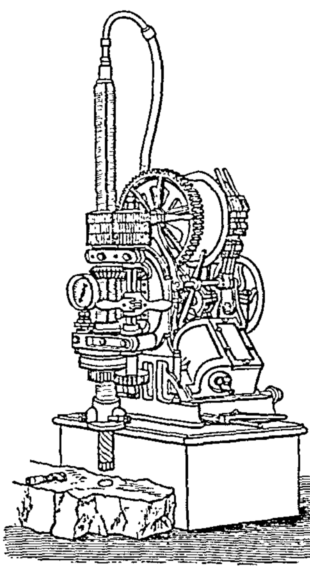

FIG. 16.—Little Champion Rock-Drill.

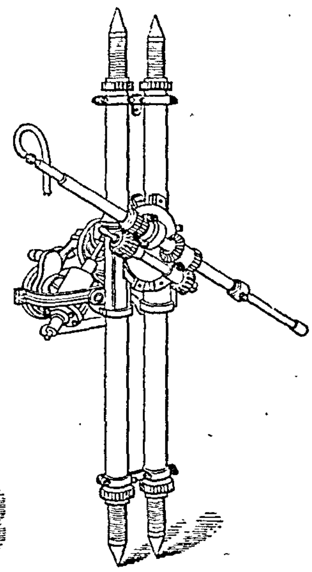

Fig. 17.

represented in fig. 17.[2] It is intended for drilling holes $1\frac{1}{4}$ inches in diameter to a depth of 150 feet. The cores which it yields are $\frac{7}{8}$ inch in diameter. It has double oscillating cylinders $3\frac{1}{2}$ inches in diameter with $3\frac{1}{2}$ inches stroke, which are run up to a speed of 800 revolutions. The drill can be set to bore in any direction by turning the swivel-head on which it is carried.

The larger rock-drill used by the American Diamond Rock Boring Company for putting down holes to a depth of 2000 feet consists of a 20 horse-power boiler with two oscillating 6-inch cylinders and the necessary gearing for working the drill, all mounted upon a carriage, so that the whole machine is readily moved from place to place. The feed is effected by gearing or by hydraulic pressure; a $2\frac{3}{4}$-inch crown is employed, leaving a 2-inch core. Each separate drill-rod is 10 feet long. The total weight of the machine is about 4 tons.

1 *Engineering and Mining Jour.*, vol. xxxiii. p. 119.
2 *Ibid.*, vol. xxxiii. p. 273.

4. *Breaking Ground—Tools Employed—Blasting by Various Methods—Machine Drills—Driving Levels and Sinking Shafts.*—The kind of ground in which mining excavations have to be carried on varies within the widest limits, from loose quicksands to rocks which are so hard that the best steel tools will scarcely touch them.

Tools.

Loose ground can be removed with the shovel; but in the special case of peat sharp spades are employed, which cut through the fibres and furnish lumps or sods of convenient form for drying and subsequent use as fuel. What is called *fair*, *soft*, or easy ground, such as clay, shale, decomposed clay-slate, and chalk, requires the use of the pick and the shovel. The pick is a tool of very variable form, according to the material operated on. Thus there are the navvy's pick, the single-pointed pick with a striking head at the other end called the poll-pick (fig. 18), and numerous varieties of the double-pointed pick (fig. 19), the special tool of the collier, but also largely used in metal mining. When the ground, though harder, is nevertheless "jointy," or traversed by many natural fissures, the wedge comes into play. The Cornish tool known as a *gad* is a pointed wedge (fig. 20). The so-called "pick and gad" work consists in breaking away the easy ground with the point of the pick, wedging off pieces with the gad driven in by a sledge or the poll of the pick, or prizing them off with the pick after they have been loosened by the gad. The Saxon gad is held on a little handle, and is struck with a hammer. It is used for wedging off pieces of jointy ground, and in former days even hard rocks were excavated by its aid. The process consisted in chipping out a series of parallel grooves and then chipping away the ridges left between the grooves. As a method of working this process is obsolete; but it is useful on a small scale for cutting recesses (*hitches*) for timber, for dressing the sides of levels or shafts before putting in dams, and for doing work in places where blasting might injure pumps or other machinery.

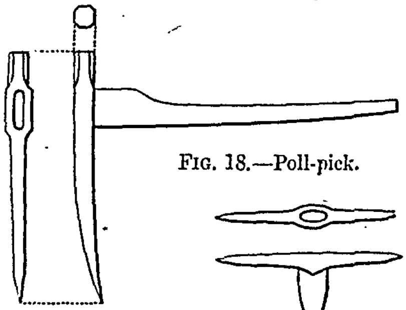

FIG. 18.—Poll-pick.

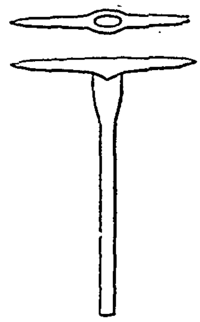

FIG. 19.—Double-pointed Pick.

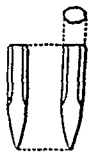

FIG. 20.—Gad.

We now come to hard ground; and in this class we have a large proportion of the rocks met with by the miner, such as slate of various kinds, hard grits and sandstone, limestone, the metamorphic schists, granite, and the contents of many mineral veins. Rocks of this kind are attacked by boring and blasting. The tools employed are the jumper, the borer or drill, the hammer, the sledge (*mallet*, Cornwall), the scraper and charger, the tamping bar or stemmer, in some places the pricker or needle, the claying bar, the crowbar, and finally the shovel for clearing away the broken rock.

Fig. 21.

The jumper (fig. 21) is merely a long bar of iron terminating in two chisel-like edges made of steel; generally there is a swelling in the middle, and sometimes the jumper tapers all the way from the middle to the edge or bit. The jumper is most commonly used when it is necessary to bore holes downwards, and is

largely employed in quarries; occasionally it is used in boring holes horizontally, as for instance in the salt mines of Cheshire. The jumper is held in the desired direction, lifted up, and thrust down; it is turned a little after each stroke.

However, the miner's tool is generally the borer proper, or drill (fig. 22), which is a bar of round or octagonal steel, usually from $\frac{7}{8}$ inch to $1\frac{1}{2}$ inches in diameter, with one end forged into a chisel-shaped edge, the exact shape and degree of sharpness varying according to the hardness of the rock. The hole is bored by striking the drill with a hammer or sledge and turning it after each blow. Boring is said to be single-handed if the miner holds the drill in one hand and strikes with the hammer in the other, whilst it is called double-handed when one man turns and another strikes. The hammers for single-handed boring usually vary in weight from 2 to 6 or 7 lb. The double-handed boring hammer, or sledge (fig. 23), weighs from 6 to 10 lb or more. If a hole is directed downwards, the miner pours in a little water and bores the hole wet. From time to time he draws out the sludge with the scraper, a little disk at the end of a metal rod, and he takes a fresh borer when the tool he is using has become blunt. The depth bored varies with the rock and the nature of the excavation; but in driving levels in the ordinary way the depth is commonly from 18 inches to 3 feet.

Fig. 22.

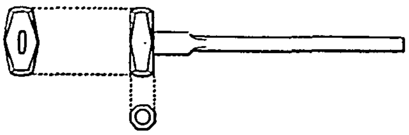

Fig. 23.—Sledge-Hammer.

Holes for blasting are sometimes bored by tools like carpenters' augers. One of the simplest, which is used in some French slate-mines, is very like a brace and bit, and the tool is kept pressed against the rock by means of a screw fixed in a frame resting on the ground.

The pricker, or needle, is a slender tapering rod of copper or bronze, with a ring at the large end. It is used for maintaining a hole in the *tamping* through which the charge can be fired. The use of needles made of iron is prohibited in many countries, on account of the danger of their striking sparks which might fire the charge. The tamping bar, or *stemmer*, is a rod of iron, copper, or bronze, or iron shod with copper, and it is used for ramming in dried clay, slate pounded up, or other fine material, upon the powder, and so creating a resistance sufficient to make the gases generated by the explosion of the charge rend the rock in the manner required. The claying bar is used for lining wet holes with clay, and so rendering them temporarily watertight.

Shovels vary much in different districts. In the south-west of England the long-handled shovel is preferred to the common one with a short handle; in Germany the ore or rubbish is frequently scraped into a tray with a sort of hoe.

Explosives.

In addition to these tools the miner requires an explosive, and a means of firing the charge at the bottom of the hole which will give him time to escape. Twenty years ago gunpowder was the only explosive in common use in mines, but at the present day its place has been taken to a very large extent by mixtures containing nitro-glycerin or gun-cotton. The powder used for blasting in mines usually contains less saltpetre than that which is employed for sporting or military purposes. The following is an analysis of mining powder by Captain Noble and Sir F. Abel:[1]—

Saltpetre	61·66	Oxygen	2·23
Potassium sulphate	0·12	Ash	0·59
,, chloride	0·14	Water	1·61
Sulphur	15·06		
Carbon	17·93		100·00
Hydrogen	0·66		

1 "On Fired Gunpowder," *Phil. Trans.*, 1880, p. 225.

Gunpowder compressed into cylinders of diameters suitable for bore-holes, and provided with a central hole for the insertion of the fuse, has lately been brought forward with some success.

Nitro-glycerin or glyceryl nitrate is a light-yellow oily liquid which is very sensitive to shocks; under the action of a fulminating cap it explodes with great violence. Its chemical composition is expressed by the formula $C_3H_5(NO_2)_3O_3$ or $(C_3H_5)3NO_3$; its specific gravity is 1·6. It has been found so dangerous that its use by itself has been given up; but on the other hand the mixture of nitro-glycerin and infusorial earth (*Kieselguhr*) called dynamite or giant powder is now one of the commonest explosives met with. It has the advantage over powder that it is far more powerful, that it may be used in wet holes or under water, that it is very effective even in ground full of "vughs" or cavities, and that it requires no hard tamping, which is always a source of danger. Its plasticity too enables it to fill the space at the bottom of a bore-hole, which is rarely a true cylinder, more completely than any solid cartridge can do. One disadvantage is that it has to be thawed in cold weather, and there is also the fact that occasionally the whole of a charge of dynamite fails to go off, and unnoticed remnants have exploded and caused serious and even fatal accidents when struck with the pick or borer. The danger is enhanced when the remnants have been left in contact with water, which causes a separation of the sensitive nitro-glycerin, so that even a blow upon the adjacent rock may lead to an accident if any of the explosive oil has leaked into cracks. The strongest dynamite contains about 75 per cent. of nitro-glycerin, the rest being kieselguhr. A newer explosive is blasting gelatin; it is made by mixing nitro-cotton with nitro-glycerin, until enough nitro-cotton has been dissolved to convert the nitro-glycerin into a jelly-like mass. The blasting gelatin in ordinary use contains no less than 93 per cent. of nitro-glycerin, with 7 per cent. of nitro-cotton, and its strength is very great.

Gun-cotton *per se* is not much in favour in ordinary mining; but mixed with some nitrate or mixture of nitrates, such as the nitrates of barium and potassium, and known as cotton powder, tonite, and potentite, it is employed extensively. Though not quite so powerful as dynamite, nitrated gun-cotton possesses the important advantage of not requiring to be thawed in cold weather. As in the case of dynamite, accidents have been caused by remnants of charges; and with both explosives it is necessary to examine carefully the bottoms of all holes after blasting, and to destroy any possible remnants by firing off a detonator in any bottom or "socket" which cannot with certainty be pronounced free from danger.

Safety-fuse.

The commonest method of firing a charge is by means of the *safety-fuse*, a cord containing a core of gunpowder introduced during the process of manufacture; it may be rendered waterproof by tar or gutta-percha.

In blasting in the ordinary way the charge of gunpowder is put in either loose or enclosed in a paper bag, and it is pressed down to the bottom of the hole with a wooden stick, whilst a piece of fuse also is inserted extending from the charge well beyond the hole. If the powder is loose the miner carefully wipes down the sides of the hole with a wet *swab stick* (a wooden rod with the fibres frayed at one end), or with a wisp of hay twisted round the scraper, in order to remove any loose grains adhering to the fuse or the sides of the hole, and then presses in a wad of hay or paper. A little fine tamping, often the dust from boring a dry hole, is now thrown in and rammed down with the wooden charging stick, and the same process is repeated, and when harder tamping is required the metal bar is brought into operation, until the hole is completely filled.

As the safety-fuse burns slowly, at the rate of about 2 or 3 feet a minute, the miner can secure ample time for retreat by taking a sufficient length. It is usual to ignite the fuse by a candle-end fixed under it by a piece of clay, and it takes a little time for the candle to burn through the fuse.

The old plan of firing a charge, which is still in use in many

places, consists in inserting the needle into the charge and then tamping up the hole. Care is taken to draw out the needle a little as the tamping proceeds, so as to prevent too much force being required for its final withdrawal. The small hole left in this way serves for the insertion of a straw, rush, or series of small quills, filled with fine powder, which like the fuse reaches from the charge to the outside. A short squib which shoots a stream of sparks down the needle hole is also used occasionally. The straw or squib is lighted by some kind of slow match, made either by dipping a cotton strand in melted sulphur or soaking a piece of paper or a lucifer in the tallow of a candle; touch-paper also is used.

Dynamite, blasting gelatin, gun-cotton, and cotton-powder are fired by the detonation of a fulminating cap. A long copper cap containing fulminate of mercury is fastened into the safety-fuse by squeezing with a pair of nippers, and is then inserted into a small cartridge of the explosive (*primer*), and placed above the rest of the charge. Fig. 24 shows a hole charged with two dynamite cartridges, a primer with cap, and filled up with water as tamping. Sometimes gun-cotton is fired by a small charge of powder above it.

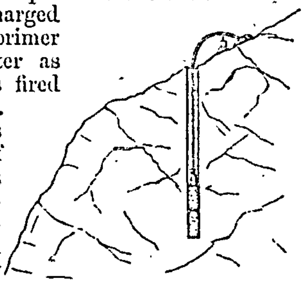

Fig. 24

Several substitutes for explosives have been tried with the object of getting rid of the flame, which is dangerous in collieries giving off fire-damp. Among these may be mentioned plugs of dry wood which swell when wetted, wedges worked by hydraulic pressure, cartridges containing compressed air at extremely high pressures, and lastly cartridges of compressed lime which expands when water is brought into it.

For the purpose of firing several holes simultaneously, Messrs Bickford, Smith, & Co., the original inventors and makers of the safety-fuse, have brought out a new fuse (fig. 25), the action of which will be easily understood from the figure. An ordinary fuse is fixed into a metal case called the igniter, from which a number of instantaneous fuses convey fire to as many separate holes. It is found in practice that this fuse answers very well.

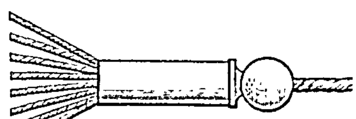

Fig. 25.

Blasting by electricity.

Charges may be readily fired singly or simultaneously with the aid of electricity, either of high tension obtained from a frictional, magneto-electric, or dynamo-electric machine, or of low tension from a galvanic battery. The former is preferred.

Fig. 26 shows a section of one of Brain's high-tension fuses. A is a cylindrical wooden case containing a paper cartridge B,

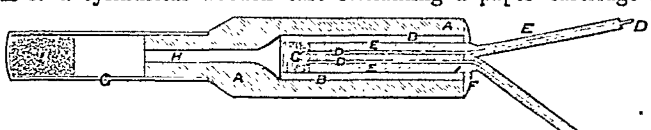

Fig. 26.

with an electric igniting composition C at the bottom. Two copper wires D, D enclosed in gutta-percha E, E reach down to the composition, where they are about $\frac{1}{10}$ inch apart. A copper cap or detonator G is fixed on to the small end of the wooden case. The insulated wires D, D are long enough to reach beyond the bore-hole. The ends of the wires are scraped bare, and one wire of the first hole is twisted together with a wire of the next hole, and so on, and finally the two odd wires of the first and last hole are connected to the two wires of a single cable, or to two separate cables, extending to some place of safety to which the men can retreat. Here the two cable wires are connected by binding screws to a frictional electrical machine or dynamo exploder. A few turns of the handle charge a condenser, and by pressing a knob or by some other device the circuit is completed and the discharge effected. The electricity passes through the fuse wires making a spark at each break, and so firing the electric igniting composition. The flame flashes through the hole H, and ignites the fulminating mercury I, the detonation of which causes the explosion of the dynamite, blasting gelatin, or tonite surrounding the cap.

One great advantage of electric firing is that the miner can retire to a perfectly safe place before attempting to explode the charge. This is important in sinking shafts, where the means of escape are less easy than in levels. A second advantage is that there is no danger of a "hang fire," an occasional source of accidents with the ordinary safety-fuse.

Machine drills.

One of the greatest improvements in the art of mining during the last few years has been the introduction of machinery for boring holes for blasting; most of the machines imitate percussive boring by hand, but a few rotary machines are also in use. A percussive drill or perforator consists of a cylinder with a piston to which the drill is fastened. Compressed air is made to act alternately on each side of the piston, and in this manner the drill receives its reciprocating motion. Various arrangements have been adopted for securing the automatic rotation of the drill. In some cases also the advance forward of the machine, as the hole is deepened, is also effected automatically; but in many of the best drills this work is left to the man in charge. It is impossible within the limits of this article to describe the various drills now in use, or even to make a complete enumeration of them.

The following, in alphabetical order, are the names of some of the best-known drills:—Barrow, Beaumont, Burleigh, Champion, Cornish, Cranston, Darlington, Desideratum, Dœring, Dubois and François, Dynamic, Eclipse, Excelsior, Ferroux, Fröhlich, Ingersoll, Laxey, Mackean, Osterkampf, Rand, Roanhead, Sandycroft, Schram. An account of two of the simplest, the Barrow and the Darlington drills, will be sufficient to give a general idea of the construction of these machines.

Barrow drill.

"The Barrow drill (fig. 27) consists essentially of a gun-metal

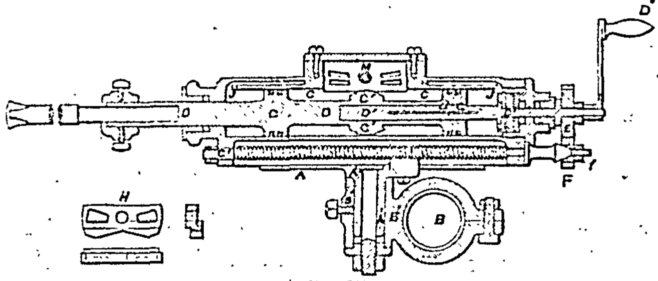

Fig. 27.

cylinder C about 2 feet in length and 4 inches in diameter, in which works a cast-steel piston-rod D, fitted with two pistons G, about 12 inches apart, mid-way between which is the tappet, or boss, G'. In a valve-box on the top of the cylinder is placed the oscillating slide-valve H (shown separately), hinged at M, which is worked by the reciprocation of the tappet G' coming in contact with its lower edges, which for this purpose are formed with two slopes at each end, as shown. It has ports corresponding with openings in the slide-valve face for admitting the fresh steam or compressed air from the inlet pipe I (fig. 28) to the

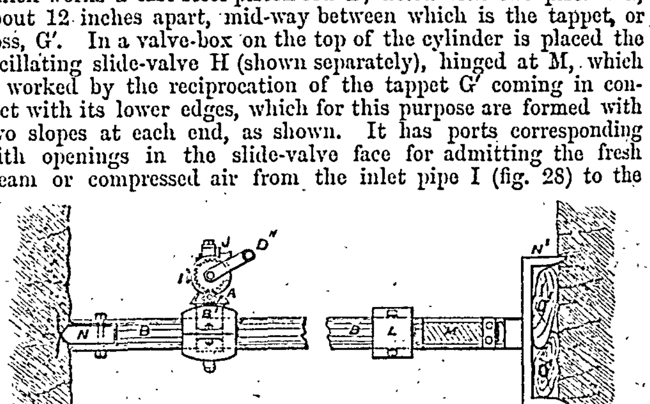

Fig 28.

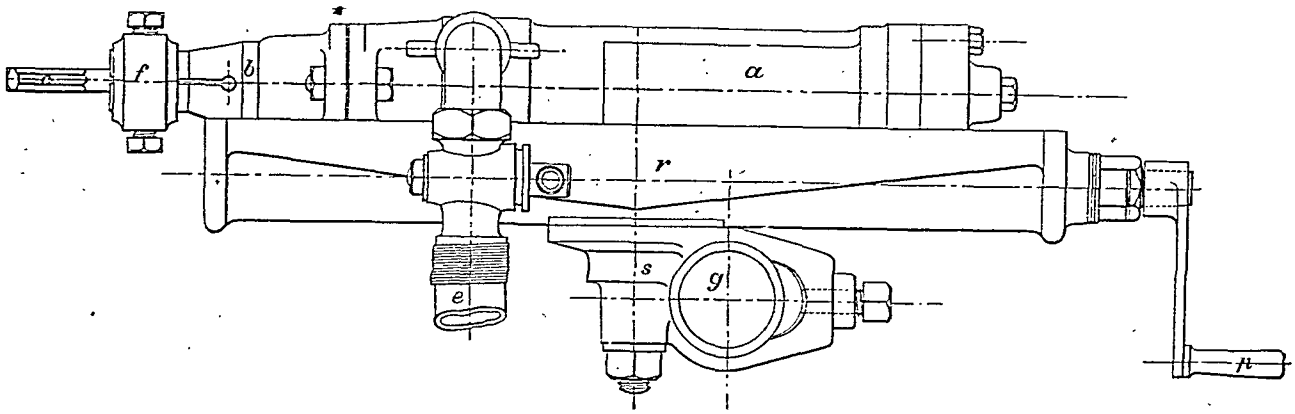
ports j at each end of the cylinder, and for letting the spent or exhaust air or steam escape by the exhaust pipe J. This simple arrangement constitutes the whole valve gear of the machine.

"The borer is inserted into a hole formed in the fore end of the piston rod, and is fixed therein by means of a screw. Its rotation is effected by hand, by means of the handle D'', turning a spindle D', which is so fitted by means of the cotter d, made fast in the piston DG, and fitting in a slot in the spindle D', that the latter can slide in the piston DG, but when turned by the handle causes the piston to turn with it. The spindle D' has a pinion E gearing into the pinion F, on the adjusting and feeding screw C', so that when the piston D is turned by means of the handle D'' the cylinder C is simultaneously pushed along the bed-plate A. These pinions can be easily disconnected by loosening the nut f, and thus the piston and the adjusting screw can be turned independently of one another when required.

"The borers used are respectively $1\frac{1}{4}$ inches, $1\frac{1}{8}$ inches, and 1 inch in diameter, the length of the stroke 4 inches, and the maximum number of blows about three hundred per minute. The air is

brought down about 400 fathoms from surface, at a pressure of 50 to 55 lb to the square inch, in wrought-iron pipes 2 inches in diameter in the shaft, and $1\frac{1}{2}$ inches in the level, and admitted through a flexible tube into the inlet I on the left-hand side of the cylinder. The cost of the pipes is rather under 7d. a foot, or about 3s. 3d. per fathom. The air is compressed at the surface by a 14-inch compressor, worked by a 12-inch horizontal engine, capable, however, of working two machine drills. The gross weight of the machine, including the bed-plate and gudgeon, is about 115 lb."

The method of fixing the machine for work is as follows:—"The bed-plate A of the machine is formed with a gudgeon A′ which fits into, and can be adjusted to any position in, a socket formed in or on a clamp B′, which can be fixed on any part of the wrought-iron bar or column B, thus forming a universal joint. This bar or column



Scale, figs. 29, 30.

Inches 12 9 6 3 0 1 2 Feet.

FIG. 29.—Side Elevation of Darlington's Rock-Drill.—Scale $\frac{14}{100}$.

can be placed in position either horizontally or vertically, as may be most convenient, but is generally placed across the level, against the sides of which it is secured by means of the clamp L, and adjusting screw M, and claws N and N′. If necessary, wooden wedges O, O′ are driven in between the claws and the wall to make it still firmer. The weight of the bar is about 120 lb."[1]

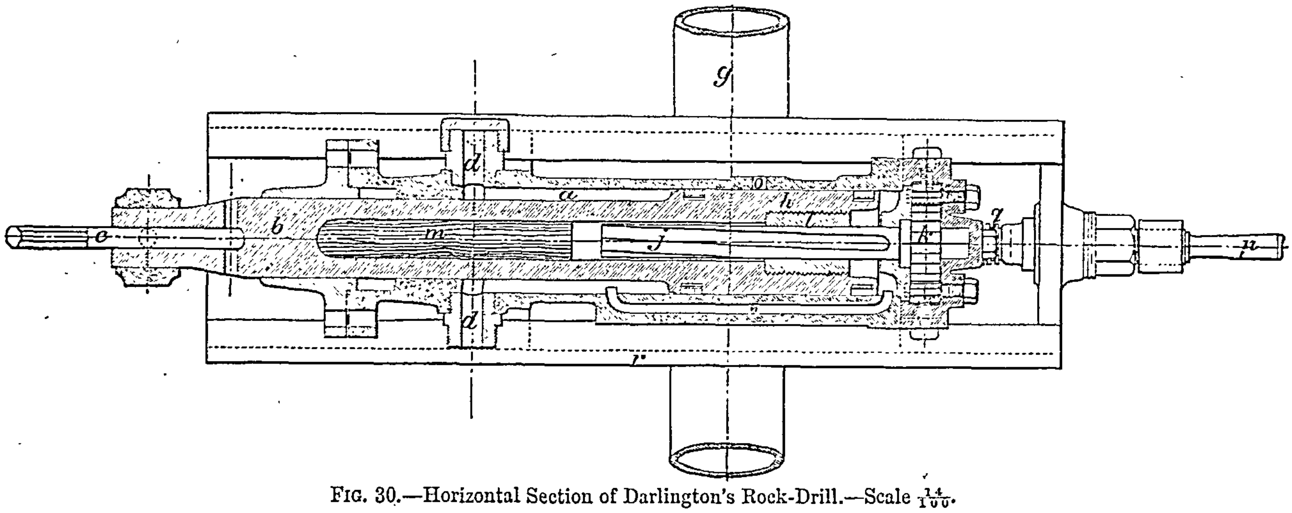


FIG. 30.—Horizontal Section of Darlington's Rock-Drill.—Scale $\frac{14}{100}$.

Air-compressing plant of greater size has now been erected at Dolcoath mine, to which the above description refers. At Snailbeach mine in Shropshire they have two air-compressors of 18 inches

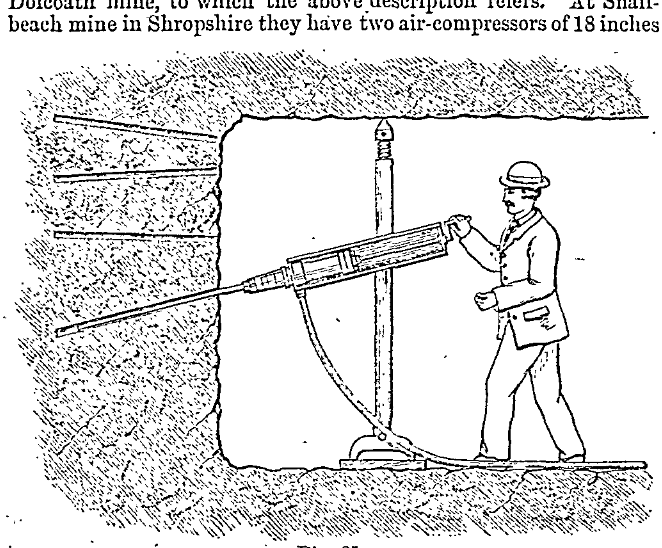

Fig. 31.

diameter and 5 feet stroke; the air-main is at first 9 inches in diameter, then 6 inches, whilst 2-inch gas-pipe is used in the levels.

A rock-drill which has done, and is doing, excellent work is that of Mr John Darlington. Its construction will be understood by referring to figs. 29, 30, and 31; *a* is the cylinder, *b* the piston rod, *c* the borer; *d*, *d* are two openings for bringing in compressed air, either of which may be used according to the position of the drill; *e* is the inlet hose with a stopcock, *f* drill-holder, *g* stretcher bar, *h* piston, *j* rifled bar for turning piston and drill, *k* ratchet wheel attached to rifled bar, *l* rifled nut fixed in the piston head, *m* wood for lessening weight of piston rod and blocking space, *n* portway for allowing the compressed air to pass to the top of the piston and give the blow, *o* exhaust portway. The action of the drill is as follows. The compressed air is always acting on the underside of the piston, and when the upper side of the piston communicates with the outer atmosphere the piston moves rapidly backwards and uncovers the portway *n*. The compressed air rushes through and presses against the upper side of the piston, which has a greater area than the lower side, the difference being equal to the area of the piston rod. The piston is driven rapidly downwards and the drill strikes its blow. At the same time it uncovers the exhaust port *o* and then the constant pressure on the annular area on the underside of the piston produces the return stroke. The number of blows per minute is from six hundred to eight hundred. The rotation of the drill is effected by the rifled bar. On the down-stroke of the piston the bar with its ratchet wheel is free to turn under a couple of pawls, and consequently the piston moves straight whilst the bar and ratchet wheel turn. When the up-stroke is being made the ratchet wheel is held by the pawls and the piston is forced to make part of a revolution. As the hole is deepened the cylinder is advanced forwards by turning the handle *p*; this works an endless screw *q*

Darlington drill.

[1] *Proc. Mining Institute of Cornwall*, vol. i., 1877, p. 12.

passing through a nut attached to the cylinder; *r* is the cradle carrying the feed-screw and supporting the cylinder. It is centred on the clamp *s*. As this clamp can be fixed in any position on the bar, and as the cradle can be turned on the clamp, it is evident that holes can be bored in any direction.

In driving a level with the Darlington drill it is usual to fix the stretcher bar horizontally across the level so as to command the upper part of the face; holes can then be bored with the cradle above the bar or below it. The bar is then shifted low enough to bore the bottom holes. It is found that all the necessary holes can be bored from two positions of the bar. The bar therefore has simply to be fixed twice; the alterations in position for boring holes in various directions are managed by shifting the clamp on the bar and turning the cradle on the clamp. Fig. 31 shows the stretcher bar fixed in a vertical position, which is sometimes convenient.

In order to clear out the sludge from holes that are "looking downwards," a jet of water, supplied from a hose attached to a half-inch gas-pipe leading from a cistern at a higher level, is made to play into the holes during the process of boring.

For sinking shafts Mr Darlington has the drill fixed in a cylindrical case with a large external thread which works in a nut on the clamp. The drill is fed forwards by turning a hand-wheel attached to the case.

Rotating drills.

Rotating machine drills are also used in mines as well as those with percussive action. Stapff pointed out some years ago that, if a rock may be chipped off by power communicated by a blow, it may also be chipped off by a similar amount of power communicated by pressure. Brandt's rotatory boring-machine consists of a hollow borer which has a steel crown with cutting edges screwed on. The tool is kept tight against the rock by the pressure of a column of water, and is at the same time made to rotate by two little water-pressure engines, whilst a stream of water passing down through the borer washes away the débris and keeps the cutting edges cool. In principle, therefore, this drill resembles the original diamond boring machine of De la Roche-Tolay and Perret, save that the crown is made of steel and not of diamonds. During the last few years it has been tried with success in railway tunnels and in mines. Jarolimek's drill[1] acts also by rotation, but the borer is fed forwards and pressed against the rock by a differential screw arrangement. The machine can be worked by hand, or by a little water-pressure or compressed-air engine or an electro-motor. In working certain minerals occurring in seams the undercutting may be performed by machines similar to those used in coal mines (see vol. vi. p. 68).

We now come to the application of the tools and machine drills to the purpose of breaking ground for driving levels and sinking shafts.

Driving levels.

A level or drift is a more or less horizontal passage or tunnel, whilst a shaft is a pit either vertical or inclined. In driving a level by hand labour in hard ground, the first thing the miner has to do is to take out a cut, *i.e.*, blast out a preliminary opening in the "end" or "forebreast." The position of this cut is determined by the joints, which the miner studies carefully so as to obtain the greatest advantage from these natural planes of division. Thus fig. 32 shows a case in which, owing to joints, it was

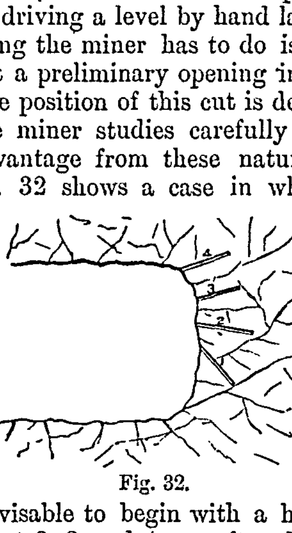

Fig. 32.

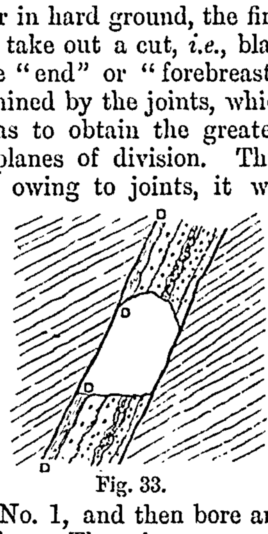

Fig. 33.

advisable to begin with a hole No. 1, and then bore and blast 2, 3, and 4 one after the other. The miner as a rule does not plan the position of any hole until the previous one has done its work; in fact he regulates the position and depth of each hole by the particular circumstances of the case. Though a vein and its walls may be hard, there is occasionally a soft layer of clay (DD, DD, fig. 33) along one wall (*dig*, Cornwall; *gouge*, United States). The miner then works this away with the pick, and, having excavated a groove as deep as possible, he can now blast down the lode by side holes and so push the level forward.

Sinking shafts.

In sinking a shaft a similar method of proceeding is observed. A little pit (*sink*) is blasted out in the most convenient part, and the excavation is widened to the full size by a succession of blasts, each hole being planned according to circumstances. This series of operations is repeated, and the shaft is thus gradually deepened.

Where boring machinery is employed, less attention, and sometimes no attention, is paid to natural joints, because when once the drill is in its place it is very little trouble to bore a few more holes, and the work can then be carried on according to a system which is certain of effecting the desired result.

Driving levels with machine drills.

A common method of procedure for hard ground is shown in figs. 34 and 35. Four centre holes are bored about a foot apart at first, but converging till at a depth of 3 feet they are within 6 inches, or less, of each other. Other holes are then bored around them until the end is pierced by twenty or thirty holes in all. The four centre holes are then charged and fired simultaneously, either by electricity or by Bickford's instantaneous fuse, and the result is the removal of a large core of rock. The holes round the opening are then charged and fired, generally in volleys of several holes at a time, and the level is thus carried forward for a distance of 3 feet. If the ground is more favourable fewer holes are required, and they may be bored deeper,—in fact as much as 6 feet in some instances. Occasionally the four centre holes are directed so that they meet at the apex of an acute pyramid, and then, after all have been charged with blasting gelatin, only one of them receives a primer and cap; the shock of the explosion of one charge fires the other three adjacent charges simultaneously. The preliminary opening is not necessarily made in the centre of a level, and sometimes it is blasted out in the bottom or one side.

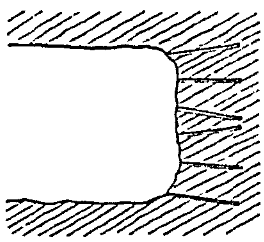

Fig. 34.

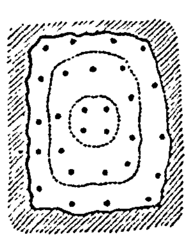

Fig. 35.

Sinking shafts with machine drills

In sinking shafts by boring machinery operations are conducted much in the same way as in levels, save of course that the holes are directed downwards. Figs. 36 and 37 are a section and plan of a shaft which is now being sunk at the Foxdale mines in the Isle of Man. About forty-five holes are bored in the bottom of the shaft before the drills are removed; two of the holes A, B, and occasionally four, are bored only 4 feet deep, and are blasted with ordinary fuse. They serve simply to smash up and weaken the core; then the six holes nearest the centre, which are 8 feet deep, are blasted all together with Bickford's instantaneous fuse, and the result is the removal of a large core leaving a deep *sink*. The remaining holes are fired in volleys of four at a time in the ordinary way. In this manner the shaft, which is in hard granite, is being deepened at the rate of 3½ or 4 fathoms a month. Tonite is the explosive used.

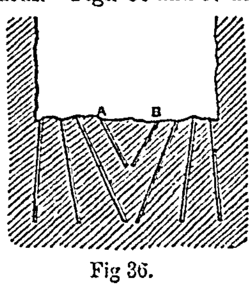

Fig 36.

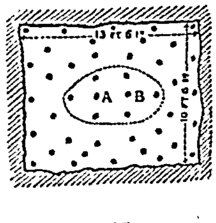

Fig. 37.

Sundry machines have been invented and used for driving levels without blasting. Some cut up the face into small chips which can

[1] *Oesterreichische Zeitschrift für Berg- und Hüttenwesen*, 1881.

easily be removed, but they have not made their way at present into ordinary mining. The Bosseyeuse of MM. Dubois and François acts on a different principle. It is a strong machine worked by compressed air. It first of all drills holes 4 inches in diameter by percussion; a striking head is then substituted for the drill, and wedges, on the principle of the plug and feathers, are inserted into the holes; and powerful blows with the striking head wedge off the rock in lumps. This machine is being used with success in Belgium for driving levels and crosscuts in fiery mines.

Some comparative experiments between hand-labour, a percussive drill, and a rotatory drill have lately been made in one of the Freiberg mines,[1] and the results are of much interest and importance. The actual figures are as follows, the cost including, in the case of the machines, interest, depreciation, and cost of repairs, and cost of steam-power, supposing water-power not available:—

	Hand-boring.	Schram's Drill.	Brandt's Drill.
Distance driven per week (in metres)	0·95	4·5	5·0
Cost in marks per metre driven	120 to 123·5	77·4 to 85·25	74·34
Wages realized by the miners, in marks, per 8 hours shift	1·85 to 2·05	3·48 to 3·66	3·76

The advantages of machine work are very marked indeed both as regards rate and cost of driving, and wages earned by the men. Brandt's rotatory drill did its work cheaper and faster than Schram's machine; but nothing is said in the original notice of the advantage of a machine driven by compressed air for ventilating workings such as advanced headings in which these drills are employed.

Brandt's machine was worked with water at a pressure of 83½ atmospheres, of which 56·6 atmospheres were obtained by pressure pumps provided with an accumulator, and 26·9 atmospheres by natural fall, owing to the working level being 277 metres below the pumps. The water was conveyed to the machine in iron pipes of 1½ inches diameter inside. The diameter of the holes bored was 2¾ inches, and they could be bored in gneiss at the rate of 1½ inches per minute. The stretcher bar on which the machine is carried is hollow, and has a piston which can be forced out by hydraulic pressure so as to fix the bar firmly. A similar bar is sometimes used with percussive drills.[2]

As a method of breaking ground the ancient process of fire-setting requires to be mentioned. Before blasting was known it was largely employed, but its use is now confined to a few places on the Continent where the rocks are exceedingly hard and where wood is abundant and cheap. Piles of wood are heaped up against the face of the workings and set on fire. On returning to the working place two or three days afterwards, when the rocks have cooled a little, it is found that the ground has split and flaked off, and that much has been loosened which can be removed by the pick and wedge.

We finally come to water as an agent for removing rocks. Streams of water were formerly used in South Wales for working beds of clay ironstone at the outcrop. The water washed away the clay and shale and left the clean nodules of ironstone. The china clay of Cornwall is also worked by water: a stream of water is turned on to the soft mass, and the workman loosens the ground with a pick; the water carries off the particles of decomposed rock in suspension to regular settling pits. Water under pressure has rendered vast services to the miner in working auriferous alluvia. The system is described and figured at p. 746 of vol. x., so it is unnecessary here to enter into details. In the special case of salt-mines recourse may be had to the solvent action of water, directed by suitable jets, for making excavations.

Modes of paying miners.

5. *Principles of Employment of Mining Labour.*—As a large proportion of the expenditure in mining is for actual manual labour, it is very important that means should be taken to prevent any waste in this department. Three principles are in vogue—payment by time, by work done either measured or weighed, and by the value of the ore extracted.

The overseers, called captains in many metal mines, are naturally paid by the month, and where strict supervision can be exercised, such as is possible at the surface, on the dressing-floors for instance, the same principle may be adopted; but when men are working underground, and often in small gangs of only two or three persons at some distance apart, piecework of some kind is more economical and satisfactory in every way.

In driving levels and sinking shafts it is usual for the men to work at a certain price per running yard or fathom. The agents have to see that the excavation, whether shaft or level, is maintained of the full dimensions agreed upon, and preserved in the proper direction. At the end of a certain time, generally a month, the work is measured by the agent. From the gross amount obtained by multiplying the price by the number of fathoms driven or sunk it is necessary to deduct the cost of the materials supplied to the men by the mining company, such as explosives, steel, candles, &c., and the remainder is divided among the persons who took the contract. When the useful mineral is being obtained the men may be paid at so much per cubic yard or fathom excavated, or at so much per ton of mineral extracted; the overseer of course has to see, in this latter case, that worthless rock is not sent to the surface. Payment by the number of inches bored is a method in use in some countries, where the men are not experienced or enterprising enough to undertake the work in any other way. A foreman points out to the men the position and direction in which the holes must be bored, measures them when completed, and subsequently charges and fires them.

The third method is that which is known as the tribute system. The miner working on tribute is allowed to speculate upon the value of the ore in a certain working area assigned to him and called his *pitch*. He gives the mining company all the ore he extracts at a certain proportion of its value, after he has paid all the cost of breaking it, hoisting it to the surface, and dressing it. Thus, supposing he takes a pitch at 5s. in the £, and produces marketable copper ore of the value of £50, his share will be 50 × 5s. = £12, 10s., less the cost of the materials he has been supplied with, and all expenses for winding, dressing, sampling, &c.

6. *Means of Securing Excavations by Timber, Iron, and Masonry.*—The following kinds of timber are those most frequently employed for securing excavations underground: oak, larch, pitch pine, spruce fir, and acacia. In many mines the timber is attacked by dry rot, which gradually renders it useless, and when the timber has often to be renewed the expense may be very considerable. Various methods of preventing dry rot have been tried with more or less success, such as letting water trickle over the timber in the mine or treating it with preservative solutions beforehand. Brine, creosote, and solutions of chloride of zinc, sulphate of zinc, sulphate of copper, and sulphate of iron increase the duration of timber. It was found by experiments carried on at Commentry during a long series of years that one of the best plans was to soak the timber for twenty-four hours in a strong solution of sulphate of iron. The total cost was only ½d. per yard of prop, whilst the timber lasted eleven times as long as when this simple treatment was omitted. Timbering.

Timber is used in various forms—either whole and merely sawn into lengths, or squared up, or sawn in half, or sawn into planks of various thicknesses.

Where the roof of a bed is weak it may be kept up by simple props; but in some coal-mines and clay-mines a better support is obtained by logs (*chocks*) laid two by two crosswise (fig. 38).

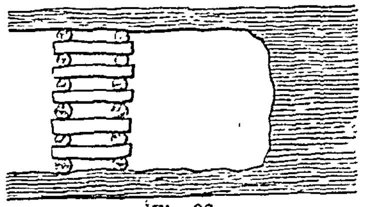

Fig. 38.

Though a level is an excavation of a very simple nature, the methods of timbering it vary considerably, because the parts requiring support may either be the roof alone, or the roof and one or two sides, or the roof, sides, and bottom.

If the roof only is weak, as is the case with a soft lode between two hard walls, a *cap* with a few boards resting on it (fig. 39) is sufficient to prevent falls. If one side is weak the cap must be

[1] *Jahrbuch für das Berg- und Hüttenwesen im Königreiche Sachsen auf das Jahr* 1882, p. 18, and abstract in *Proc. Inst. Civ. Eng.*, vol. lxix., 1881–82, part iii. p. 51.

[2] *Annales des Mines*, ser. 8, ii., pl. 1, fig. 6, 1882.

supported by a side prop or *leg* (fig. 40), and very often by two legs. The forms of joint between the cap and leg are numerous

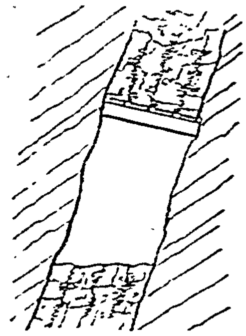

Fig. 39.

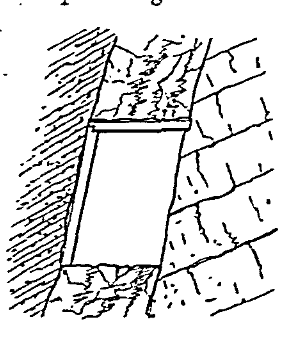

Fig. 40.

(fig. 41), depending to a great extent upon the nature of the pressure, whether coming upon the top or sides. With round timber the top of the leg is sometimes hollowed as shown in fig. 42 A, but occasionally the joint is flat and a thick nail, or *nog*, is put in (fig. 42 B) to prevent the effects of side pressure, or, better, a piece of thick plank is nailed under the cap (fig. 43). Where the floor of a level is soft and weak, a sole-piece or *sill* becomes necessary, and, if the sides or roof are likely to fall in, a lining of poles or planks is used (fig. 43).

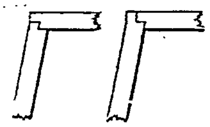

Fig. 41.

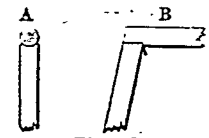

Fig. 42.

In some very heavy ground in the Comstock lode a special system of timbering is adopted (fig. 44).

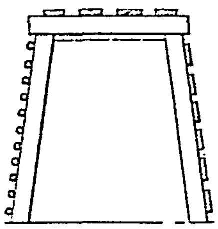

Fig. 43.

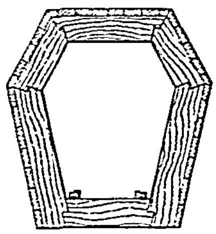

Fig. 44.

If the ground is loose, so that the roof or sides, or both, will run in unless immediately supported, the method of working called *spilling* or *poling* is pursued. It consists in supporting the weak parts by boards or poles kept in advance of the last frame set up. The poles or boards (*laths*) are driven forward by blows from a sledge, and the ground is then worked away with the pick; as soon as a sufficient advance has been made a new frame is set up to support the ends of the poles or boards and the process is repeated (figs. 45 and 46). In running ground it is necessary to have the laths fitting closely together, and the working face also must be supported by *breast-boards* kept in place by little struts resting against the frame. These are removed and advanced one by one after the laths in the roof and side have been driven beyond them.

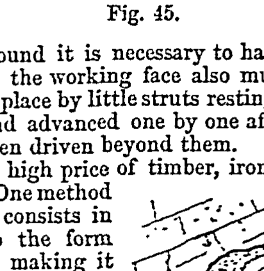

Fig. 45.

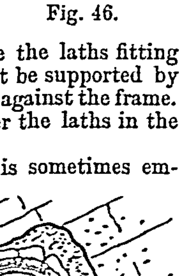

Fig. 46.

Iron supports. On account of the high price of timber, iron is sometimes employed in its place. One method in use in the Harz consists in bending a rail into the form shown in fig. 47 and making it support other rails laid longitudinally, against which flattish stones are placed; the vacant spaces are then filled with rubbish.

Masonry. Masonry has long been used for supporting the sides of mining excavations. The materials necessary are stone, ordinary bricks, or slag-bricks, and they may be built up alone (*dry walling*) or with the aid of mortar or hydraulic cement. The bottom of a level is occasionally lined with concrete to carry a large stream of water, which otherwise might run into lower workings through cracks and crevices. Dry walling is not uncommon, and it may be combined with the use of timber (or iron) as shown in fig. 69, in which a level is maintained between two walls keeping back a mass of rubbish.

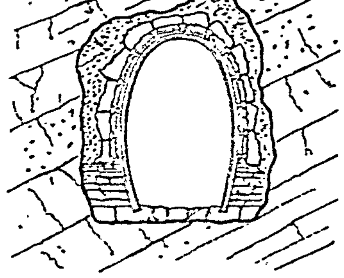

Fig. 47.

Figs. 48 and 49 show methods of securing a drift by arches when a lode has been removed.

Timbering for shafts. The timbering required for shafts varies according to the nature of the ground and the size of the excavation. A mere lining of planks set on their edges (fig. 50) suffices for small shafts, corner pieces being nailed to keep the successive frames together. In some of the salt-mines of Cheshire the shafts are lined with 4-inch planks united by mortice and tenon joints.

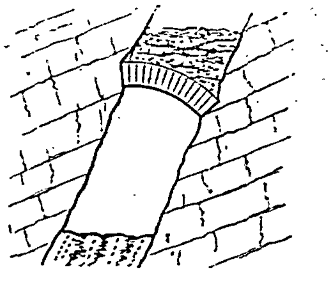

Fig. 48.

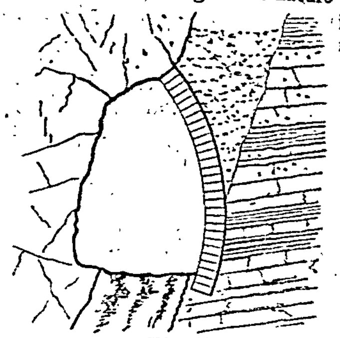

Fig. 49.

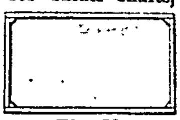

Fig. 50.

The usual method of securing shafts is by *sets* or *frames*. Each set consists of four pieces, two longer ones called *wall-plates* and two shorter ones called *end-pieces*. They are joined by simply halving the timber as shown in fig. 51. A more complicated joint (fig. 52) is often preferred. The separate frames are kept apart by corner pieces (*studdles*, Cornwall; *jogs*, Flintshire), and loose ground is prevented from falling in by boards or poles outside the frames.

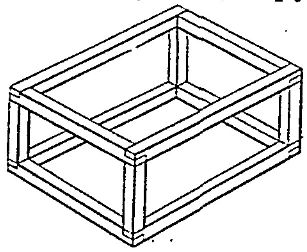

Fig. 51.

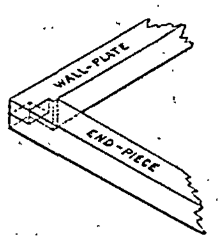

Fig. 52.

As shafts are frequently used for the several purposes of pumping, hoisting, and affording means of ingress and egress by ladders, it becomes necessary in such cases to divide them into compartments. Pieces of timber parallel to the end-pieces (*buntons* or *dividings*) are fixed across the shaft, and serve to stay the wall-plates and carry the guides as well as to support planks (*casing boards*) which are nailed to them so as to form a continuous partition or brattice. The magnificent timbering of some of the shafts on the Comstock lode is described by Mr James D. Hague as follows:[1]—"The timbering consists of framed sets or cribs of square timber, placed horizontally, 4 feet apart, and separated by uprights or posts introduced between them. Cross-timbers for the partitions between the compartments form a part of every set. The whole is covered on the outside by a lagging of 3-inch plank placed vertically." Figs. 53, 54, and 55, copied from Mr Hague's plates, illustrate this method

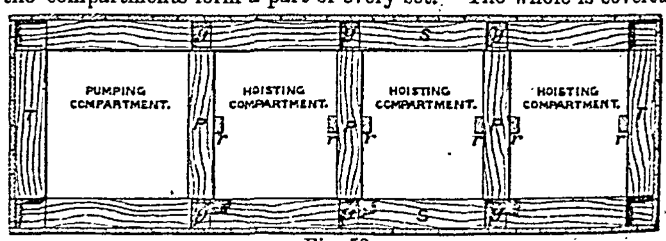

Fig. 53.

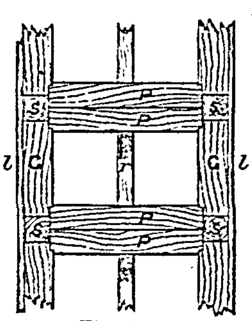

Fig. 54.

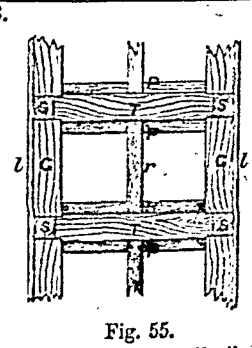

Fig. 55.

[1] *United States Geological Exploration of the Fortieth Parallel*, vol. iii., "Mining Industry," p. 103.

of timbering: Fig. 53 is a plan of the shaft: "S, S are the longitudinal or sill-timbers, T, T the transverse end-timbers, P partition-timbers, r guide-rods between which the cage moves, g gains cut in the sill-timbers, to receive the ends of the posts. The sheathing or lagging is seen enclosing the whole frame." Fig. 54 is a transverse section through the partition P of fig. 53, "between the pumping compartment and the adjoining hoisting compartment, looking towards the latter. In this figure, G, G are the posts, S the sill-timbers, P the partition-timbers, the ends of which are framed with short tenons that are received in gains cut in the sill-timbers and the ends of the posts, r guide-rod, l lagging or sheathing." Fig. 55 is an end view of the frame shown in fig. 53. "The single piece T forms the end, while the double pieces P forming the partitions are seen beyond." "The outer timbers of each set, that is, the two sides and ends of the main frame, are 14 inches square; the posts, ten in number, four at the corners and two at each end of the three partitions, are of the same size. The dividing timbers, forming the partitions, are 12 inches square."

When ground is loose or running, recourse must be had to a *spilling* process like that described for levels. Strong balks of timber are fixed at the surface or in solid ground, and then the first frame is hung from these *bearers*, and each successive frame from the one above it. Iron bars with cotters may be used for suspending the sets; but on the Comstock lode each bolt is made in two parts with a tightening screw in the middle, and the sets can thus be kept very firmly together. The laths are driven in advance, in the manner explained in the case of levels, and a new frame is put in as soon as the excavation has been sufficiently deepened within the protecting sheath of boards. In very unstable ground it may be necessary to put in the frames touching each other, so that the shaft becomes encased in a solid box of timber, occasionally 14 inches thick.

Masonry for shafts.

Like levels, shafts may be lined with masonry or brickwork, and these have the advantage of being far more permanent than timber, and of requiring fewer repairs. This kind of shaft-lining is especially desirable in the loose ground near the surface; because, if the working is discontinued temporarily, the shaft still remains secure and available for use at any future time, whereas if timber is put in it often decays, the top of the shaft collapses, and much expense is incurred in the process of reopening it. The section of the shafts that are walled is generally circular as affording the best resistance to pressure; but elliptical walling is also met with. Another shape is like a rectangle, save that the sides, instead of being straight, form curves of large radius. The walling may be dry or with mortar, according to circumstances.

The masonry is put in either in one length or in successive portions in descending order, and this is the usual plan. The shaft is sunk a certain depth, with temporary timbering if necessary, and when firm ground has been reached a bed is cut out round the shaft, and on this is placed a crib or curb AB (fig. 56)[1] consisting of segments of timber which form a ring. This serves for a foundation for the brickwork, which is built up to the surface; the temporary timbering is removed, and the space filled up with earth or concrete. Sinking is then resumed below the curb, and for a certain distance of a smaller diameter, so as to leave a bracket, or ledge, to support the first curb. On arriving, after a certain depth of sinking, at another firm bed, a second curb CD is put in and a portion of brickwork built up. When the ledge of rock is reached, it is carefully removed in small sections and the brickwork brought up to the first curb. This process is repeated till the shaft is completed, or reaches rock in which no masonry is requisite. If, owing to the nature of the ground, it is impossible at first to find a firm seat for the curbs, it becomes necessary to hang them by iron bolts from a strong bearing frame at the surface.

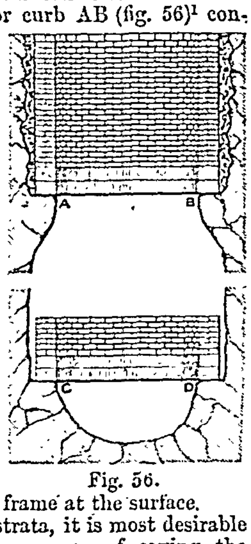

Fig. 56.

When shafts pass through very watery strata, it is most desirable to stop all influx into the mine for the purpose of saving the heavy expense of pumping. The manner in which this is effected by a watertight lining, known as tubbing, is described in the article COAL, vol. vi. p. 62, where will also be found an account of Triger's plan of sinking shafts with compressed air, and the very successful method of boring shafts through water-bearing ground invented by Messrs Kind & Chaudron.

Exploitation.

7. *Exploitation, or Working Away of Veins, Beds, and Masses.*—We have described how shafts are sunk and levels driven, and we now come to the processes employed in removing the mineral.

[1] J. Callon, *Lectures on Mining*, vol. i., Atlas, plate xxviii.

The deposit must first of all be reached by a shaft, or, where the contour of the country permits it, by a level. In the case of a vein an exploratory shaft is often sunk on the course of the lode for 20 or 30 fathoms, and, if the indications found in a level driven out from this shaft warrant further prosecution of the mine, a first working shaft is sunk to intersect the lode at a depth of 100 fathoms or more from the surface. Crosscuts are then driven out at intervals of 10, 15, or 20 fathoms to reach the lode, as shown in fig. 57, which represents a section at right angles to the line of strike. Sometimes the main shafts are carried down all the way along the dip of the deposit, though perpendicular shafts have the advantages of quicker and cheaper winding and cheaper pumping, to say nothing of the possibility of utilizing the cages for the rapid descent and ascent of the miners. If an inclined shaft appears to be advisable, great care should be taken to sink it in a straight line. In either case levels are driven out along the strike of the lode as shown in the longitudinal section fig. 58, in the hopes of meeting with valuable ore-bodies such as are represented by the stippled portions of the figure. For the purpose of affording ventilation, and still further exploring the ground and working it, intermediate shafts, called *winzes* (Cornwall) or *sumps* (North Wales), are sunk in the lode.

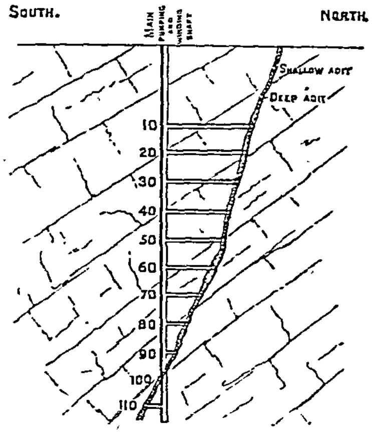

Fig. 57.

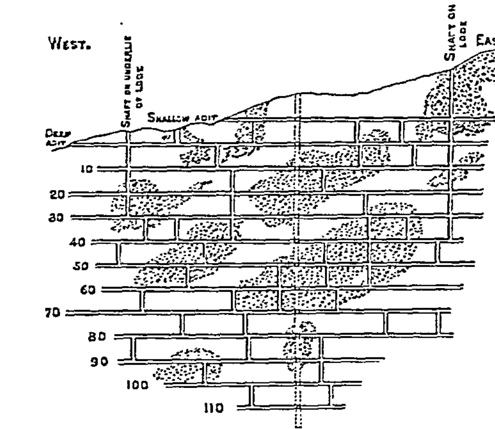

Fig. 58.

The actual mode of removing the lode itself depends a good deal upon circumstances, viz., its width, the nature of its contents, and the walls that enclose it; but the methods of working may generally be brought under one of two heads, viz., underhand stoping or overhand stoping. The word *stope* is equivalent to step, and the term stoping means working away any deposit in a series of steps. *Underhand* or *bottom stopes* are workings arranged like the steps of a staircase seen from above, whilst *overhand* or *back stopes* are like similar steps seen from underneath. Both methods have their advantages and disadvantages, and both are largely used.

Underhand stoping.

We will first take underhand stoping, as this is the older method. In the old days the miner began in the floor of the level (fig. 59), and sank down a few feet, removing the part 1; he followed with 2, 3, 4, &c., until the excavation finally presented the appearance shown in fig. 60. Any valueless rock or mineral was deposited upon platforms of timber (*stulls*), and the ore was drawn up into the level

Fig. 59.

by a windlass. One great disadvantage of this method is that the ore and water have to be drawn up some distance by hand labour; much timber is required for the stulls if there is a large quantity of worthless stuff in the vein, or if the sides are weak. The advantages are that ore can be worked away as soon as the level is driven, that the men are always boring downwards, and, lastly, that the ore can be carefully picked after it is broken, without fear of any valuable particles being lost.

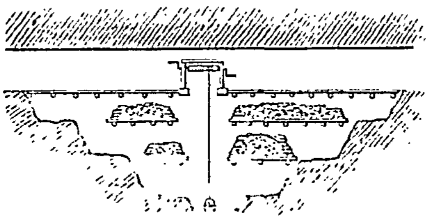

Fig. 60.

A more economical method of working by underhand stopes, and one largely employed in Cornwall at the present day, consists in reserving any attack upon the ore-ground until a lower level has been driven. An intermediate shaft (*winze*) between the two levels is then made, either by sinking from the upper level or rising from the lower one. The work of stoping is commenced at the two upper ends of the winze, and the lode is removed in a succession of steps, the workings assuming the appearance exhibited in fig. 61. The steps are generally made steep, so that the ore may readily roll into the winze, and so that the bore-holes may do better execution; but these steep stopes are dangerous if a man happens to slip and fall. The huge open chasms left by the removal of a large lode in this way are also a source of danger; for there is always a risk of falls of rock, and from places which cannot easily be examined.

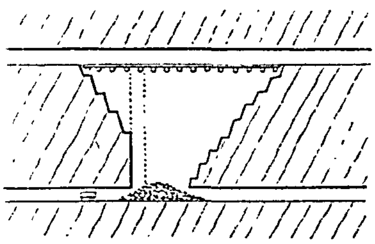

Fig. 61.

Figs. 62 and 63, kindly supplied by Captain Josiah Thomas,[1] explain the general arrangement of the workings of the largest tin mine in Cornwall. The lode after producing copper ores to a considerable depth changed its character and became rich in tin. The workings for tin ore are confined almost entirely to the granite. The section fig. 62 shows that the main shaft of the mine is at first vertical and then carried down on the dip of the lode.

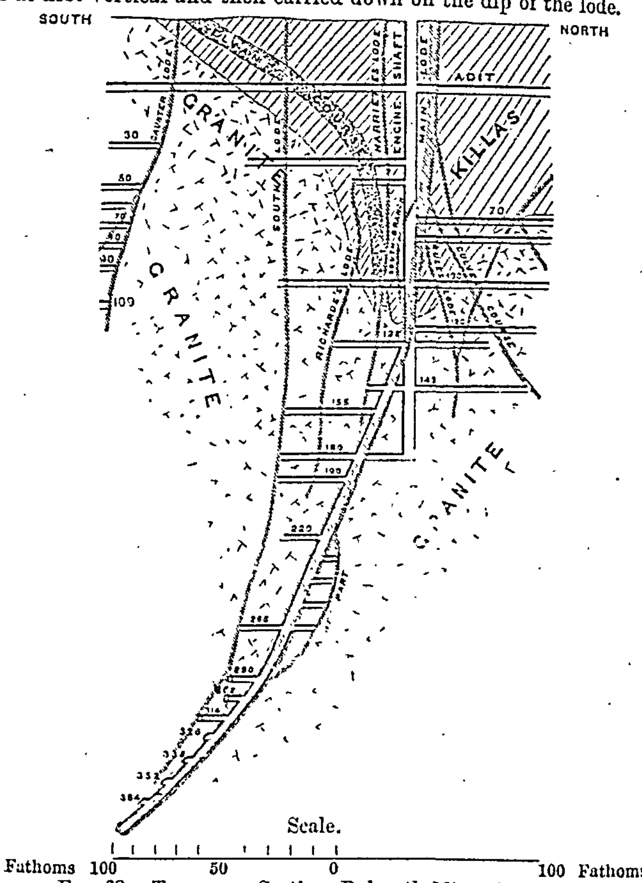

FIG. 62.—Transverse Section, Dolcoath Mine, Cornwall.

The process of overhand stoping is precisely the reverse of that

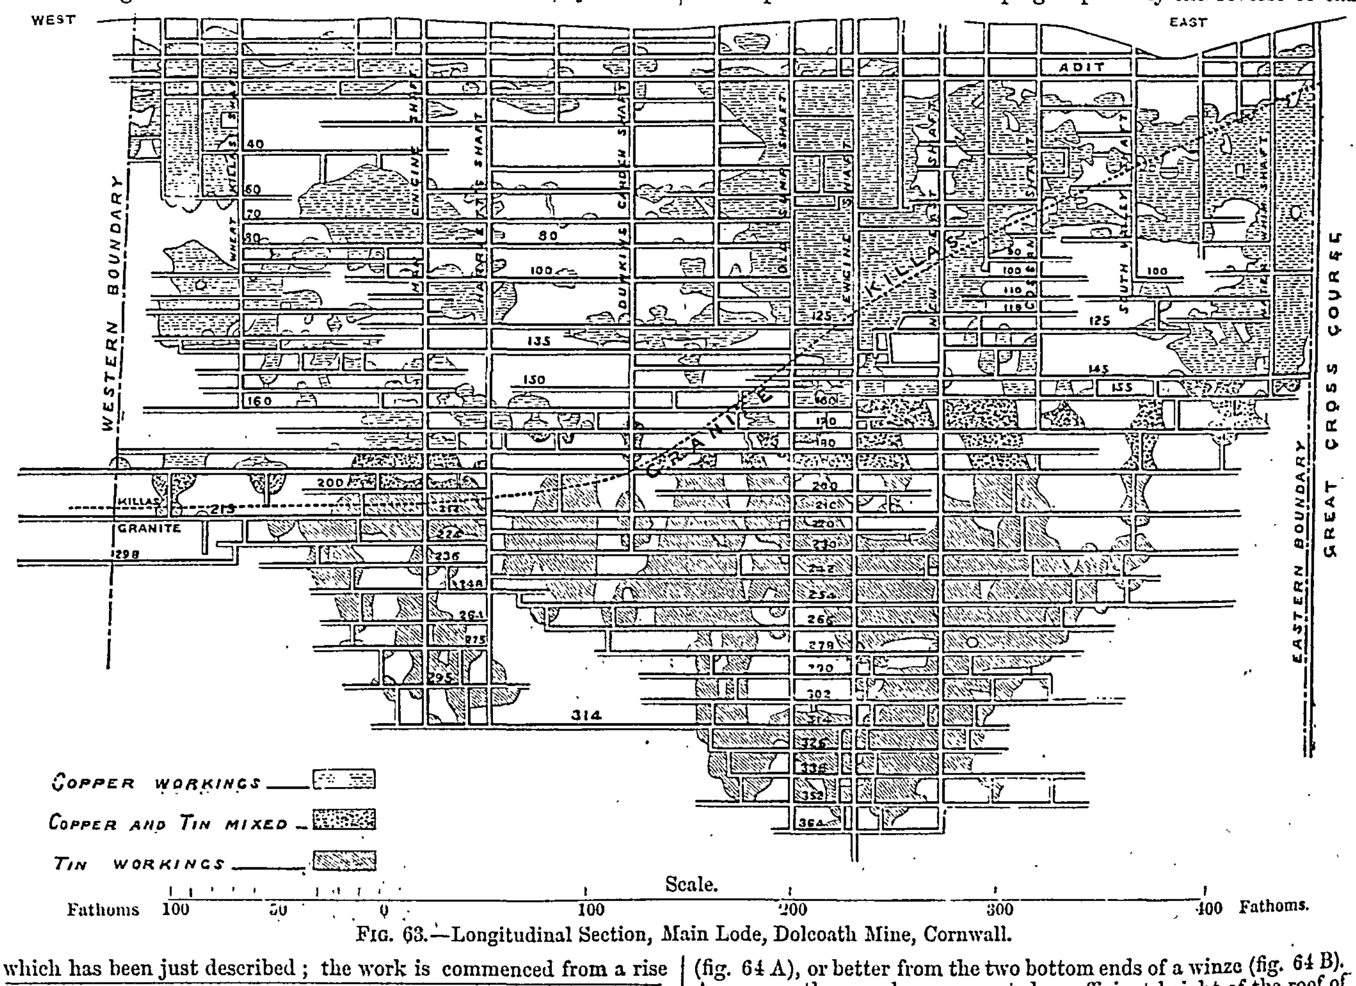

FIG. 63.—Longitudinal Section, Main Lode, Dolcoath Mine, Cornwall.

which has been just described; the work is commenced from a rise (fig. 64 A), or better from the two bottom ends of a winze (fig. 64 B). As soon as the men have excavated a sufficient height of the roof of the level, they put in strong pieces of timber from wall to wall, and

[1] See *Report of Miners' Association of Devon and Cornwall for* 1882, and R. J. Frecheville, *Trans. Roy. Geol. Soc. Cornwall*, vol. x. part v.

cover these cross-pieces (*stempels, stull-pieces*) with boards or poles, and throw down the rubbish upon the platform (*stull, bunning*) thus formed. In the midst of the rubbish chimney-like openings (*mills, passes*) are reserved, lined with boards or dry-walling, and

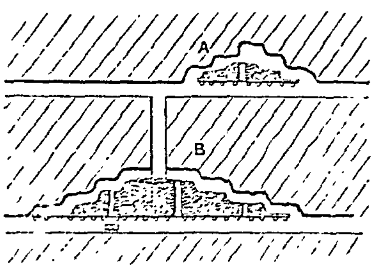

Fig. 64.

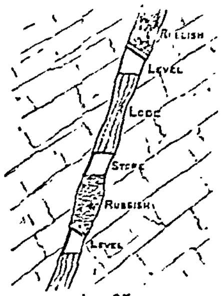

Fig. 65.

closed at the bottom with shoots provided with doors. The ore is thrown into these passes, which are tapped when necessary; the ore falls into the tram-waggon placed ready to receive it.

Fig. 65 gives a transverse section showing the rubbish resting on the stull. This is what may be called the typical method of stoping, when the lode affords rubbish enough for the men to stand on and to keep them close to the rock they are attacking. Very often such is not the case, and the whole of the lode has to be sent to the surface for treatment. If the walls are firm, the lode is sometimes stoped away, a stull put in, and a sufficient heap of broken ore is left upon the stull to give the men good standing ground; the excess is thrown over the ends of the stull, or the great heap is tapped by cutting a hole in the stull-covering, and allowing a quantity to run down into the level.

Another method consists in putting in temporary stages upon which the men stand to do their work, whilst the excavation is left as an open space (fig. 66).

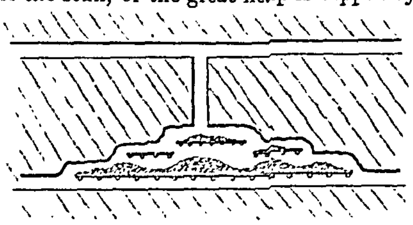

Fig. 66.

This mode of working is incompatible with weak walls. If a lode does not afford rubbish enough for completely filling up the excavated space, or if it is too narrow for men to do their work comfortably, one of the walls may be cut into and blasted down (fig. 67), so that the men always stand upon a firm bed of rubbish while at work, and there is no fear of a collapse of the mine. In certain special cases rubbish is sent down from the surface to fill up the excavations.

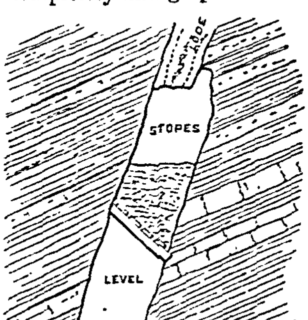

Fig. 67.

The advantages of overhand stoping are—that the miner is assisted by gravity in his work, that no ore or rock has to be drawn up by hand labour, and that less timber is required. On the other hand, the miner is always menaced by falls, but as he is close by he can constantly test the solidity of the roof and sides by sounding them with his sledge; there is the further disadvantage that particles of ore may be lost in the rubbish, but this loss is often prevented by laying down boards or sheets of iron while the lode is being broken down.

Working wide lodes.

When very wide lodes come to be worked, recourse is often had to special methods. The great lode at the famous Van mine, in Montgomeryshire, is sometimes 40 feet in width, and the hanging wall is weak. The lode is stoped away overhand, and the cavities packed with rubbish, part of which is derived from the lode itself, whilst the greater portion is supplied from a special quarry at the surface. Fig. 68[1] explains the details of the case. A is the original cross-

Van mine.

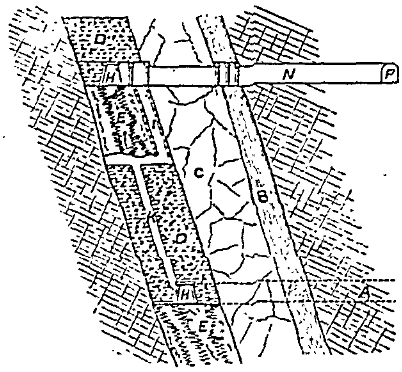

Fig. 68.

cut (not in the line of section) by which the lode was reached, B is the *flucan*, C the bastard lode, generally worthless, E the main lode, H permanent levels, and K *ore-pass* reserved amidst the rubbish (*deads*) D, I *pass* down which rubbish is shot, N crosscut connecting the level H with P the permanent level in the *country*.

If the lode is not firm enough to allow of the stopes being carried for its full width, the crosscut method is adopted; the workings in this case, instead of proceeding along the strike, are carried across the deposit from one wall to another.

The lode is removed in successive horizontal slices A, B, C, D, E, and for each slice a level (L, fig. 69) is driven, either in the lode,

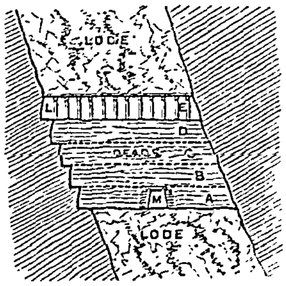

Fig 69.

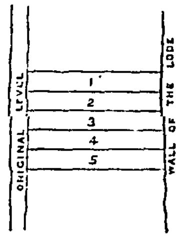

Fig. 70.

or partly or entirely in the country; from this level crosscuts are put out 6 or 8 feet wide, as shown in the plan (fig. 70). These are regularly timbered according to the necessities of the case, and, when No. 1 is completed, No. 2 is begun, and the rubbish from No. 2 thrown into the empty space of No. 1 crosscut. If the quantity is insufficient, deads are brought in from the surface or from exploratory workings in worthless rock in the neighbourhood. Sometimes the crosscuts are not driven side by side, but 1 and 5 would be driven first, leaving 2, 3, and 4 as a solid pillar; then 3 would be worked away, and finally 2 and 4 between the timber and rubbish on each side. The greater part of the timber can be recovered when the next slice above is taken off, as the props are put in with the small ends downwards, and can be drawn up with levers. M (fig. 69) is a level reserved in the deads for traffic and ventilation. This method of working is applicable not only to lodes but also to irregular masses.

In working away the soft "bonanzas" or ore-bodies of the great Comstock lode, which are from 10 to 30 or even 40 or 50 feet wide, and which are enclosed in very unstable ground, a special method of timbering is employed (figs. 71 and 72).[2] "It consists in framing timbers together in rectangular sets, each set being composed of a square base placed horizontally, formed of four timbers, sills, and cross-pieces, 4 to 6 feet long, framed together, surmounted by four posts 6 to 7 feet high, at each corner, and capped by a frame-work, similar to that of the base. These cap-pieces, forming the top of any set, are at the same time the sills or base of the next set above, the posts, as the sets rise one above the other in the stope, being generally placed in position directly over those below." "The timbers are usually of 12-inch stuff square-hewn or sawn." Each post has a tenon 9 inches long at the upper end, and a tenon of 2 inches at the lower end, which fit into mortices in the cap and sill respectively; and "the sills and caps have short tenons on each end and shoulders cut to receive the ends of the post and the horizontal cross-pieces." The walls of the excavation are sustained by a lagging of 3-inch or 4-inch plank. The whole width of the ore-body is stoped away at once, and its place supplied by timbering, and finally the vacant space is filled with waste rock derived from dead work in the mine or from special excavations,—underground quarries in fact,—in barren ground. The stoping is carried on overhand, starting from an intermediate shaft or winze, and fig. 73 will explain how the different frames are built up one above the other.

Comstock lode.

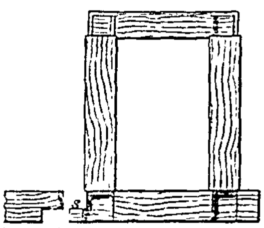

Fig. 71.

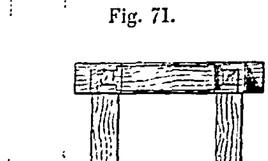

Fig. 72.

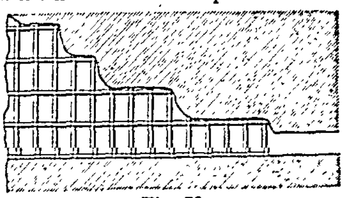

Fig. 73.

Another method of working a wide lode is to attack it in slices

[1] C. Le Neve Foster, "Notes on the Van Mine," *Trans. Roy. Geol. Soc. Cornwall*, vol. x. p. 41.

[2] James D. Hague, *United States Geological Exploration of the Fortieth Parallel*, vol. iii. "Mining Industry," p. 112.

parallel to the dip, working away each slice separately as if it were a lode of ordinary dimensions, and filling up with rubbish (fig. 74).

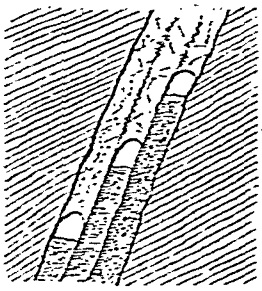

Fig. 74.

Working of beds. We now come to beds or seams. The mode of working the most important beds that occur in the earth's crust, viz., coal seams, has already been described in the article COAL (vol. vi. p. 64 *sq.*), and details have been given concerning the removal of the mineral by pillar working and long-wall working. Both these methods are applicable in the case of seams of other minerals. Such for instance are the beds of fire-clay and clay-ironstone which are wrought by both the processes just mentioned, and often in connexion with coal.

Next in importance to coal is ironstone, and a brief account of the workings in the Cleveland district will explain the manner in which more than one-third of the iron ore raised in the British Isles is obtained by mining. It resembles the "bord and pillar" system used for working coal in Durham.

Cleveland ironstone workings. The Cleveland ore occurs in the form of a bed from 6 to 16 feet thick in the Middle Lias, lying pretty level. A mainway (*fig. 75*) is driven about 12 feet wide for a considerable distance, and at right angles to it *bords* are driven 5 yards wide for a length of 30 yards, and then at right angles a *wall* 7 or 8 feet wide and 20 yards long. By drivages of this kind the bed is cut up into pillars or blocks 30 yards long by 20 yards wide. The pillars are subsequently removed in the following way. A *place*, or drift, *ab*, 6 feet wide, is driven across the pillar 10 yards from the corner, and portions (*lifts*) about 6 yards wide are worked away in the order 1, 2, 3. After No. 1 lift has been removed, the timber put in to support the roof temporarily is withdrawn, and the roof is allowed to fall; No. 2 is then taken, and No. 3 in the same way. While these lifts are being taken out, another place *cd* is being driven across the pillar 10 yards from the first, and the pillar removed entirely by a series of fresh lifts.

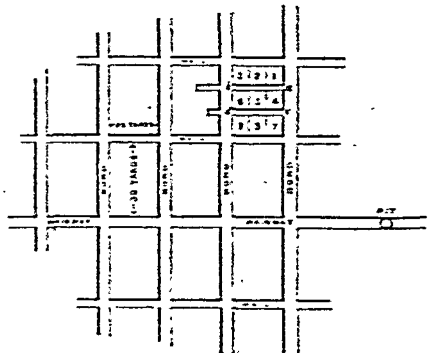

Fig. 75.

Gypsum quarries. Fig. 76 represents in section and plan the chambers and pillars of the underground gypsum quarries which supply the well-known plaster of Paris to all the world.[1] The principal bed is from 50 to 60 feet in thickness; pillars are left 10 feet square at the base, and the *stalls* between them are 16 feet wide. The workings are slightly arched, and are not carried up to the roof, for the purpose of better maintaining the security of the chambers, because heavy damages would have to be paid if they "caved in" and rendered the surface useless. A similar layer left for the floor prevents *creep* (see COAL, vol. vi. p. 64), and enables the underground roads to be kept in good repair.

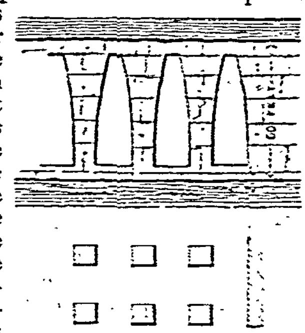

Fig. 76.

Slate quarries. Underground slate quarries afford examples of very various methods of removing thick beds of mineral of comparatively little intrinsic value. At Angers in France, where the beds dip at a high angle, the underground workings are carried on like an open quarry

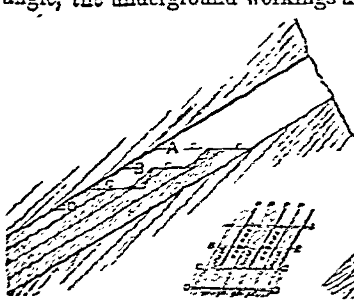

Fig. 77. Fig. 78.

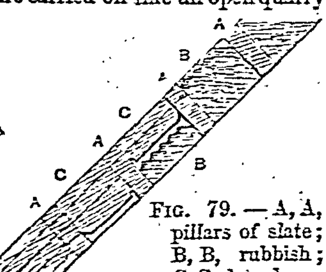

Fig. 79.—A, A, pillars of slate; B, B, rubbish; C, C, slate chambers. Scale $\frac{1}{2000}$.

under a strong roof of slate; the floor is continually being worked away in steps, and an immense open chamber is left. In the Festiniog district in North Wales the principal bed, or *vein* as it is called, is more than 100 feet thick in places, and the method of working consists in making alternate pillars and chambers each 30 feet to 50 feet wide along the strike (cross-section and plan, figs. 77 and 78). The pillars follow lines of natural cross-rending PP', which commonly make an angle of 25° to 35° with the direction of the dip. The excavations are arranged in regular lines, and form continuous chambers extending very often from the surface to the very lowest workings. A, B, C, D are the original working levels. The slate of the supporting pillars is entirely lost, as these cannot be removed with safety. This method of working requires a strong roof. In the Ardennes, on the contrary, the pillars are carried along indefinitely along the strike (fig. 79, cross-section). The slate in each longitudinal chamber is removed in slices parallel to the bedding, and the men stand upon the rubbish, which finally fills up the chambers completely.

Rock-salt constitutes another important mineral which occurs in the form of stratified deposits. The principal source of the Cheshire salt is a bed 84 feet thick lying horizontally; but only the bottom part, 15 feet to 18 feet thick, is mined. Pillars 10 yards square are left promiscuously about 25 yards apart, as shown in fig. 80, which represents part of Marston Hall rock-salt mine.[2] The workings Salt mines.

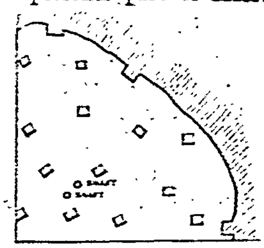

Fig. 80.

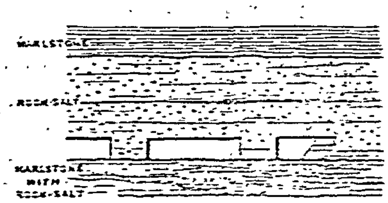

Fig. 81.

are advanced by making in the upper part an excavation 5 feet 9 inches high, called the *roofing* (*a*, fig. 81); and then the lower two-thirds of the part worked are removed by blasting slanting holes. Many of the old salt mines have collapsed from weakness of the roof or insufficiency of the pillars, and have become inundated; the brine is then extracted by pumping and evaporated for salt.

In some countries, especially when the beds of salt are impure or much mixed with clay or shale, the formation of brine is conducted regularly by making a network of drivages within a rectangular, elliptical, or circular area in thick beds of saliferous marl, and then introducing fresh water by pipes, so as to form underground ponds which gradually dissolve the roof and sides. The brine is drawn off and either pumped up or conveyed by adits to the surface.

A few words remain to be said about open workings. Some minerals are always obtained in this way; others are worked open before regular underground mining begins; and, thirdly, it often happens that underground and surface work are both carried on simultaneously on the same deposit. Among deposits worked opencast are peat, numerous kinds of stone, iron ore, cupreous pyrites, lead ore, gold- and tin-bearing alluvia, and diamantiferous rock. Open workings.

Owing to its soft, spongy, and fibrous texture, and the fact of its often lying below the water-level, peat has to be worked in a special manner. Trenches are dug about a foot deep with a sharp spade, which cuts out sods of convenient size for drying and burning. When one layer has been removed in this way, another is taken off, and so on. If water is reached the working can still be pursued by using the long spade (*grand louchet*, France) with a handle of 16 or 20 feet. It cuts out a sod 3 or 4 feet long at each thrust.

When a deposit is more or less solid the workings are frequently arranged in steps, the height and breadth of each depending upon the firmness of the rock.

In many cases the first work consists in removing worthless rock at the surface (*overburden*), and where the underlying deposit is thick or very valuable it will pay to remove a very great thickness of overburden, on account of the advantages of working a deposit open. These advantages are—entire removal of the deposit without loss in pillars, no expense for timbering or for packing with rubbish or for ventilating or lighting the workings, better ventilation, easier supervision, longer working hours, less danger.

As an example of a large open working may be mentioned the great Penrhyn slate quarry near Bangor, employing about 3000 hands, and worked by a succession of terraces on an average 60 feet high by 30 feet wide (fig. 82). Reference has already been made to the thick lead-bearing sandstone of Mechernich, which is in part worked as an open quarry. Mokta-el-Hadid, near Bona in Algeria, and the Rio Tinto mines in Spain, afford instances of extensive combined open and underground workings for iron ore and cupriferous pyrites respectively.

[2] Joseph Dickinson, "Report on the Salt Districts," *Reports of the Inspectors of Mines for the year* 1881, p. 63.

Diamond mines. owned by separate individuals or companies, considerably affect the methods of working. This is especially the case with the diamond deposits of South Africa. The diamantiferous rock at the celebrated Kimberley mine (formerly called Colesberg Kopje) occurs in the shape of an elliptical upright mass, the greatest length being about 330 yards and the greatest breadth about 200 yards. The superficial area is about 9 acres; the mass extends downwards within almost perpendicular walls of shale, and is worked in places to a depth of about 400 feet. The claims are only 31 feet square, and are more than four hundred in number, and these have in some instances been subdivided into portions as small as the sixteenth of a claim; but, as at the present time one company may own very many claims, the number of individual holdings is less numerous than formerly when the limit was two claims. The working is carried on vertically downwards, and, as the claims are not all worked at the same rate, those that progress most rapidly are surrounded by perpendicular walls of neighbouring claims. The shale, or *reef*, enclosing the deposit is constantly falling into the huge open pit, and has to be cut away to a slope, the expense of this work being charged to the claim-holders generally by the mining board. The diamantiferous rock is extracted by innumerable wire-rope inclines.

Evils attending hydraulic mining. We have already referred to the method of working gold-bearing alluvia by the hydraulic process, which has rendered such services in the United States (GOLD, vol. x. p. 746). At the same time one must not be blind to the evils of this method of working, which have at last necessitated legislative interference. Some idea of the extent of the mischievous results of hydraulic mining will be gathered from the statement that one working alone, the Gold Run Ditch and Mining Company, for the last eight years has been discharging 4000 to 5000 cubic yards of sand, gravel, and boulders daily, for a period of five months each year, into a tributary of the Sacramento. As a natural consequence deposits are formed lower down the river, obstructing the navigable channels, rendering overflows more frequent and destructive, and causing valuable land to be destroyed by deposits of sand. The superior court of Sacramento county, California, has recently decided that the hydraulic mining companies must build dams to impound the coarse and heavy débris, or take other efficacious means to prevent their being washed down the rivers.

Underground transport. 8. *Carriage or Transport of Minerals along the Underground Roads.*—After the mineral has been broken down in a deposit it is necessary to pick out any barren rock and then convey to the surface all that is of value.

Carriage by workers. The simplest and oldest method of transport along underground roads is carriage on the back, and this method may still be seen at the present day even in countries where the art of mining is generally highly advanced. Thus, for instance, in the little slate mines near Cochem on the Moselle men and lads carry up all the blocks of slate upon their backs, walking upon steps cut in the rock; they come up with their hands upon the ground bent almost double under the weight of the block, which rests upon a thick pad. Again, the blocks of slate are still carried on the back from the actual working place to the nearest tram-road, in the slate mines of the Ardennes. In the Sicilian sulphur mines the same method is common, and it is found also in parts of Spain and China, where baskets are used, whilst bags are employed in Mexico and also in Japan. Even in England the system still survives in the Forest of Dean, where boys carry iron ore in wooden trays from the very irregular ore-producing cavities either to the surface or to the nearest shaft.

Sledges. Sledges, or *sleds*, enable greater loads to be transported; but they are not available unless the conveyance is along roads sloping downwards. They have been largely employed in coal mines, and are still resorted to in some collieries for conveying the coal from the working place to the nearest tram-road.

Wheel carriages. We next come to wheeled carriages. The simplest is the wheelbarrow. The barrow used in Cornwall at the present day is not unlike that figured more than three centuries ago by Agricola. The navvy's barrow is more advantageous, but it requires a wider and higher level. The barrow runs upon the natural floor of the level, upon boards, or upon thin strips of iron. Carts drawn by horses may be used in large underground quarries. Excepting in special cases it is advisable to replace barrows by waggons running upon rails. The oldest form is the German *Hund.* It consists of a rectangular wooden body, with four wheels, resting upon two boards as rails, and it is kept on the track by a pin which runs between the boards.

Cast-iron tram-plates were introduced in the last century, and were finally succeeded by iron rails, which are now in general use, though steel threatens to displace iron in this as in other departments of mining. Various forms of rail are employed. The simplest is a bar of iron set on its edge in transverse sleepers, or flat iron nailed to longitudinal sleepers. Small T-headed and bridge rails are not uncommon. In the Harz the rails sometimes lie on stone sleepers; a hole is bored in the stone, plugged with wood, and the rail is nailed on. The gauge varies from 14 inches to 3 feet or more; 20 inches to 22 inches is a common gauge in metal mines. Arrangements of course have to be made for passing from one line to another by *points*; but the transference is frequently best effected by putting down flat plates of cast iron, upon the smooth surface of which the waggons can be handled with ease and turned in any direction; raised ledges guide the wheels into any particular track.

The form and size of the waggons running upon the rails necessarily vary according to the size of the underground roads and the manner in which the mineral is raised in the shaft. In some mines the practice exists of loading the mineral in the level into an iron bucket (*kibble*) standing upon a *trolley*, which is merely a small platform upon wheels. This trolley is pushed (*trammed*) to the shaft; the full kibble is hooked on to the winding-rope and drawn up, whilst an empty kibble is placed upon the trolley and trammed back along the level, where it is again loaded from a shoot (*mill, pass*) or by the shovel. The usual plan, however, is to have a waggon, which is tipped on coming to an enlargement of the shaft (*plat, lodge*) where the level joins it. These waggons may be made of wood or sheet-iron, and of late years sheet-steel for the body and cast-steel for the wheels have been coming into favour.

The most modern system in metal mines is to imitate collieries, and use waggons which are drawn up in cages. Fig. 83 represents the plain but strong waggon of the Van mines, consisting of a rectangular body of sheet-iron resting on an oak frame, and provided with cast-steel wheels. The wheels are loose upon the axles, which themselves run loose in the pedestals. The waggon is emptied by being run on to a "tippler," which enables it to be completely overturned with great ease. A commoner plan is to construct the waggon with a hinged door at one end, and the contents are discharged by opening this door and raising the body.

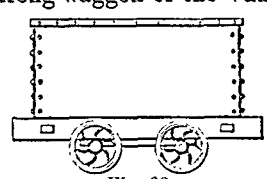

Fig. 83.

The motive power for tramming waggons along the levels of metal mines is generally supplied by men or boys, though, where large quantities have to be extracted, and where the roads are favourable, recourse may be had to ponies and horses and the various kinds of mechanical haulage described in COAL, vol. vi. p. 69.

Trains of cars are sometimes drawn along underground railways by locomotives; they have the great disadvantage of polluting the air with the products of combustion, and consequently they are not available unless the ventilation is very good. A small locomotive of 2 horse-power nominal is used on an 18½-inch track in the adit-level of the Great Laxey mine (Isle of Man), now approaching a mile in length, and full-sized locomotives ply along the adit of the Rio Tinto mines. Locomotives worked by compressed air improve the ventilation instead of injuring it, and are not a source of danger in cases where fire-damp may be present; but, except in special cases, they cannot be worked so cheaply as engines fired with coal. Conveyance by electric railroads underground has hardly gone beyond the experimental stage, but the results obtained at the Zaukeroda colliery in Saxony[1] show that electricity can be applied with profit in this department of mining.

A few instances of transport by boats may still be met with. Boats. The boats used in the underground canal at Klausthal are 31 feet

[1] *Jahrbuch für das Berg- und Hüttenwesen im Königreiche Sachsen auf das Jahr* 1883, p. 50.

long by 4 feet 6 inches wide, and 2 feet 11 inches deep. Each boat carries 5 or 6 tons.

Where roads have a strong gradient, inclined planes are employed, either self-acting if the mineral has to be lowered, or worked by stationary engines if the mineral has to be raised (see COAL, vol. vi. p. 69).

Winding. 9. *Winding, or Raising in the Shafts, with the Machinery and Apparatus required.*—In speaking of the transport by underground roads, we mentioned that the mineral is occasionally brought to the surface on the backs of men or boys. In other cases daylight is reached by adit-levels provided with railroads; but in by far the greater number of mines it is necessary to hoist the mineral, and often much rubbish, up vertical or inclined pits generally known as shafts.

In beginning to sink a shaft from the surface, or in sinking a winze, hand-power applied by a windlass is sufficient. The broken rock at the bottom of the shaft is shovelled into a wooden or iron bucket (*kibble*), which is drawn up by a rope passing round the barrel of the windlass. When a depth of 20 or 30 yards has been reached it is more advantageous to introduce horse-power, and the usual machine by which this power is applied, called a *gin* or *horse-whim*, is a common sight in many metalliferous districts. It consists of a vertical axis carrying a barrel or drum 8 to 12 feet in diameter, round which is coiled the rope, which after passing over a pulley hangs down the shaft. The axis carries an iron pin at each end, the lower one working in a stone and the upper one in a socket in the span-beam or cross-bar of the supporting frame. Under the barrel is a long driving beam to which a horse is harnessed, and, as will be readily understood, the kibble is drawn up or lowered down as the horse walks round. It is most economical to have two kibbles, for then they balance each other.

Where steam and water-power are not available, a large number of horses or mules are sometimes harnessed to whims, and ore raised from depths of 200 fathoms. These, however, are exceptional cases; and, especially since the introduction of portable engines, the use of steam-power even for comparatively small depths, such as 100 yards, is daily increasing. In hilly districts water-power is generally at hand, and huge reservoirs are frequently constructed for storing the rainfall, and so affording an adequate and constant supply. It may be utilized by water-wheels, turbines, and water-pressure engines.

There are three systems of winding by steam or water-power which are in regular use:—(1) by buckets (*kibbles*), baskets, or bags swinging loose in the shafts; (2) by boxes working between guides (*skips*, Cornwall); (3) by cages carrying one or more waggons.

Buckets. The buckets are made of wood, sheet-iron, or sheet-steel. Their shape varies; it may be round or elliptical, straight in the side or bulging in the middle. Fig. 84 represents a kibble made of sheet-iron. When the shaft is inclined, the side upon which the kibble slides is carefully lined with boards (*bed-planks*) resting upon cross sleepers. Planks of hard wood like beech last longer and require fewer repairs than deal boards. In the Harz, poles fixed lengthwise take the place of boards, which are customary in Great Britain. Even where shafts are perpendicular a lining of planks is often put in round the winding compartment, unless the space is considerable, and the kibble then glides up smoothly, and there is less risk of accidents. A more modern system is to use wire-rope guides for the kibble, which is thus kept from swinging about. Another advantage of this plan is that a light cage can easily be substituted for the kibble and used for the ascent and descent of the men. Mr Galloway has patented a method of sinking shafts with wire-rope guides, the upper ends of which are coiled upon drums at the surface. By adopting this expedient the guides can be lengthened as the shaft is deepened.

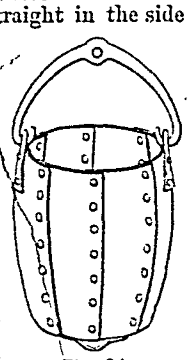

Fig. 84.

A word must be said about the actual loading and emptying of the kibble. Sometimes, as already mentioned, the kibble is filled at the working place or from a shoot (*pass*, Cornwall) carried down into the level, and then conveyed on a trolley to the shaft, where it is hooked on to the rope and drawn up. More frequently the filler standing in the *plat* loads the kibble with a shovel; and in order to save time two kibbles are often provided, one being filled while the other is making the journey to and from the surface. In this case it is necessary to have some kind of *clevis*, which will enable the kibble to be readily detached from the winding-rope, and quickly and securely fastened on again. On its arriving at the surface the *lander* seizes an eye or ring at the bottom of the kibble by a pair of tongs suspended by a chain, and the rope is now lowered. The kibble is thus turned over and the contents fall into a tram-waggon.

The inconveniences of this method of winding are considerable, especially in inclined shafts where the direction and amount of the inclination are not constant. There is great wear and tear of the bed-plank and casing-boards; and, unless constant attention is paid to repairs, places are worn out where the kibble catches, causing the rope to break. The fall of a kibble and its contents not only does much damage to the shaft, but also is a source of danger to the men. The introduction of boxes (*skips*) working between guides or conductors was therefore a decided step in advance, for the system allows the winding to be carried on with less friction and with greater rapidity and safety. The guides are often made of pieces of timber (like *r*, fig. 53) bolted to the end-pieces and dividings. It is only in perpendicular shafts that guides made of wire-rope or iron rods can be applied. The skip is a box of rectangular section made of sheet-iron or sheet-steel, with a sloping bottom, and provided with a hinged door closed by a bolt for discharging its contents. Fig. 85 [1] shows how the skip runs upon Skips.

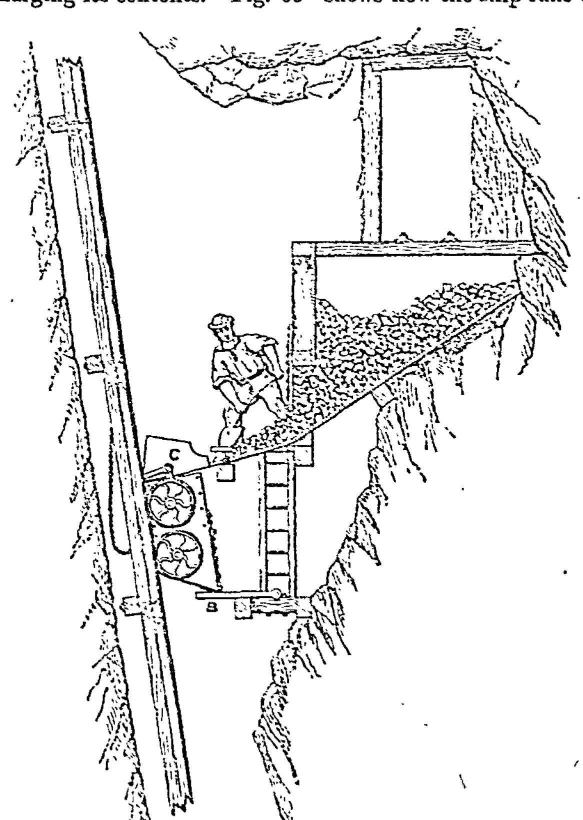

Fig. 85.

the guides by means of four cast-iron or (better) cast-steel wheels. In an inclined shaft the guides sometimes have iron rails laid on them so as to diminish the wear. Some of the skips in Cornwall are made to hold as much as a ton and a half of tin-bearing rock. The skip is filled with a shovel by a man standing in the plat, but a better plan is to arrange shoots leading from large hoppers, so that the ore can be made to run in without any shovelling. The skip is sometimes tilted completely over instead of being emptied by a hinged door; this arrangement is in use in some of the German mines, where the skip is made of wood, and is guided on each side by two pins or rollers running between two conductors. When the skip has reached the surface two catches are made to support the lower rollers, whilst the upper ones pass through openings in the front guides, and the skip, turning upon the lower ones, is tipped over and so emptied.

The most satisfactory system of winding is by cages; there is Cage. less handling of the mineral, and the hoisting proceeds at far greater speed. This system, which is almost universal in collieries, is employed also for working deposits of other minerals, and, though

[1] Moissenet, *Annales des Mines*, ser. 6, vol. ii., 1862, plate vii.

in vein-mining the skip and kibble still prevail in England, the managers are beginning to recognize the advantages of the cage and equip their mines with more modern appliances than have hitherto been customary. The cages used in the mines on the Comstock lode are very light and simple in construction, as will be seen from fig. 86. The cage in fact is a mere timber platform, 5 feet by 4,

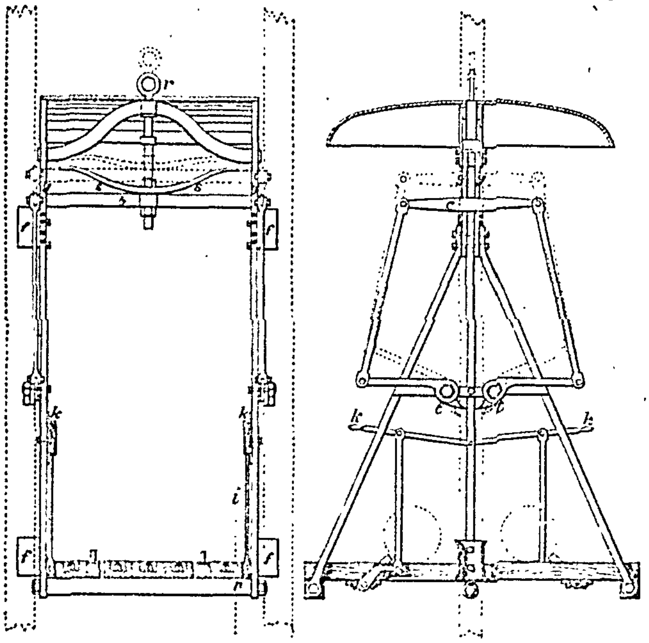

FIG. 86.—Cage used in Comstock Lode.

resting on iron bars p, and supported by iron rods on each side. It is provided with a sheet-iron bonnet to protect the men if they are inside, and also with safety catches t, t, which come into play if the rope breaks. The hand levers k, k at the ends of the cage raise up blocks which keep the car in its place during the ascent or descent; g, g are guides for the end of the crossbar b; c, bar working teeth t, t by levers; f, "ear" or "shoe" embracing the guide-rod in shaft; r, lifting bar; s, strong spring.

The most important details concerning the use of cages, ropes, and other hoisting appliances such as pulleys, pulley-frames, detaching hooks, and winding engines, have already been set forth in the article COAL, vol. vi. p. 74; and it is therefore needless to repeat these particulars, especially as the art of winding mineral cheaply, speedily, and safely has been carried to a far greater pitch of perfection in collieries than in the majority of metal mines. It is often convenient to fix winding engines underground for the purpose of sinking shafts and winzes, and drive them by compressed air brought down in pipes from the surface.

Koepe system. The Koepe system of winding, which appears to be viewed with favour on the Continent, consists in having what is practically an endless rope with one large sheave over the shaft, in the place of the two drums. There are two cages, and the rope below them acts as a counterbalance, so that the load is uniform throughout.

Blanchet's method. The most novel hoisting apparatus is that of M. Blanchet (COAL, vol. vi. p. 76), which has now been regularly at work in the Hottinguer shaft at Épinac in France for the last six years. M. Blanchet's method consists in fixing in the shaft a large pipe in which is arranged a piston; from this is suspended a cage carrying waggons. By exhausting the air above the piston the load is gradually forced up by the atmospheric pressure below it. The Hottinguer shaft is 660 yards deep, and the pipe is 5 feet 3 inches in diameter, made up of a succession of cylinders of sheet-iron about $\frac{5}{16}$ inch thick and 4 feet 4 inches high, joined by flanges and bolts. The 485 rings composing the long pipe weigh altogether 418 statute tons. The cage has nine decks, and arrangements are made for unloading three at a time; each waggon holds half a ton, so that the total useful load is $4\frac{1}{2}$ tons. The speed of hoisting is 20 feet per second. If two hoisting pipes are connected the dead weights may be made to balance each other, and the power required is simply that which is necessary to overcome the weight of the useful load. All the men prefer the pneumatic hoist to the ordinary cage for descending and ascending the mine, and are regularly lowered and raised by it. The advantages claimed by M. Blanchet for this system are—(1) the possibility of hoisting from depths at which rope-winding would no longer be practicable; (2) getting rid of the costly ropes and dangers connected with rope-winding; (3) better utilization of the engine power; (4) improvement of the ventilation and diminution of the amount of fire-damp.

10. *Drainage.*—The mineral having been raised to the surface, the task of the miner might appear to be at an end; but this is not the case, for it is further necessary that he should keep his mine free from water and foul air. These two indispensable operations of draining and ventilating frequently require special appliances which add considerably to the general cost of mining.

In all cases where it is possible, endeavours should be made to keep the water out of a mine, so as to save the expense of pumping it; and the method of putting in a watertight lining (*tubbing*) in a shaft has been already described (COAL, vol. vi. p. 62). When large streams of water happen to be intersected by underground workings, and threaten to overpower the available pumping machinery, or when it is advisable to save the expense of draining abandoned workings, the entry of this water into the mine may often be prevented by stoppings, called *dams*, constructed of timber or brickwork. Drainage.

In spite of all precautions, the miner generally has to contend with water which percolates into the workings. Four methods of getting rid of this water are available, viz., adits, siphons, winding machinery, and pumps.

An adit, day-level, or sough is a nearly horizontal tunnel with one end opening at the surface, allowing the water to drain away naturally. In hilly countries mines are often worked entirely by adits, and even when a mine is deepened below the drainage level the utility of the adit is still threefold:—it lessens the quantity of water which tends to percolate into the lower workings; it lessens the depths to which the water has to be pumped; and, by furnishing a certain amount of fall, it enables water to be applied as power. On account of these important advantages some very long and costly adits have been driven for the purpose of aiding the miners in certain metalliferous districts. Adits.

Thus in the Harz the Ernest Augustus adit ("Ernst August Stolln") has been driven a distance of nearly $6\frac{1}{2}$ miles into the Klausthal district. The total length of the adit, including the branches, is no less than 14 miles. It intersects many of the lodes at a depth of upwards of 400 yards from the surface. The total cost of this adit is estimated at £85,500.

Another long adit is the celebrated "Rothschönberger Stolln," which unwaters some of the most important mines at Freiberg in Saxony. The length of the main or trunk adit is more than $8\frac{1}{2}$ miles; the gradient of the greater part of it is only 1·18 inch in 100 yards. The branches of this adit among the mines are more than 16 miles in length, so that the total length of the main adit with its branches amounts to nearly 25 miles. Many of the mines are now drained naturally to a depth of 250 to 300 yards. The cost of the main tunnel was £359,334, or nearly £24 per yard, but this includes the cost of eight shafts, heavy expenses for pumping from these shafts, the walling of the adit for $\frac{3}{4}$ mile, and all general expenses. The length of time occupied in driving this adit was thirty-three years. The "Kaiser Josef II. Erbstolln" in Hungary is another remarkable mining tunnel, which was commenced in 1782, and completed in 1878 at a total cost of 4,599,000 florins. It is $10\frac{1}{4}$ miles in length, extending from the valley of the river Gran to the town of Schemnitz, where it intersects the lodes at depths varying from 300 to 600 yards according to the contour of the surface.

In Cornwall the Great County adit was driven for the purpose of relieving the Gwennap mines of their water, and it was pushed on nearly to Redruth. This adit differs from the great works undertaken in Germany by the fact that it commences in the mining district, and, though the length of all the drivages amounts to more than 30 miles, the water from the most distant mine does not run more than about 6 miles before reaching daylight. The average depth is only 70 or 80 yards from the surface. In fact this great adit, though a work of great utility when the Gwennap district was in a flourishing condition, is merely a network of comparatively shallow drivages, often along the lodes themselves, among the mines, and therefore for boldness of execution cannot for one moment be compared to the great Schemnitz, Freiberg, and Klausthal drainage tunnels which have just been mentioned. The Blackett Level in Northumberland is an adit which has been driven a distance of about $4\frac{3}{4}$ miles, and it will have to be extended about 2 miles further before reaching Allenheads. Its depth from the surface at this place will be about 200 yards.

The main part of the Halkyn tunnel in Flintshire is 2 miles 1256 yards in length, and the branch driven out to Rhosesmor mine intersected the vein at a distance of 809 yards, making a total of about $3\frac{1}{4}$ miles. The greatest depth from the surface is 230 yards, and the average depth in Halkyn Mountain about

215 yards. The length and depth of this adit are not remarkable; but the great quantity of water discharged is a point of considerable interest and importance. It is estimated that this adit is now discharging 15 million gallons or 66,000 tons of water in twenty-four hours, although the outflow is purely natural, for no mines are pumping water into it. It is now easy to understand that the Rhosesmor mine, though provided with powerful pumping machinery, was unable to cope with the springs it encountered.

In the United States the famous Sutro tunnel is an adit of which the main branch, 4 miles in length, reaches the great Comstock lode in Nevada at a depth of 1700 feet. The total cost of this tunnel, which was completed in nine years, is estimated to have been $7,000,000. The quantity of water running out daily in 1879 was 12,000 tons, at a temperature of 123° Fahr. at the mouth of the tunnel. All this water must otherwise have been pumped to the surface at a cost estimated at $3000 a day. The obstacles to progress were very great: not only was the heat extreme, but swelling ground was encountered which snapped the strongest timber. Thanks, however, to the untiring energy of Mr Adolph Sutro, the difficulties were at last successfully overcome, and this great work will long remain as a monument to his foresight, skill, and patient pertinacity.

The Atlantic-Pacific tunnel,[1] which was commenced in 1880, will pierce the heart of the Rocky Mountains under Grey's Peak, Colorado. It is being driven from both sides of the watershed, and will have a total length of 4⅝ miles from end to end.

Siphons. Siphons have been used for unwatering workings in special cases; but of course they will not act unless the barrier over which the water is raised is very decidedly less than 33 feet.

Winding machinery. When workings cannot be drained by tunnels or siphons it is necessary to raise the water mechanically, either to the surface or at all events to an adit through which it can flow away naturally. If the amount of water is not too considerable, it is often convenient to use the winding machinery and draw up the water in special buckets (*water-barrels*) or tanks. The bucket may be tilted over on reaching the surface, or it may be emptied by a valve at the bottom. This means of raising water is often adopted while sinking shafts, when it may be desirable to wait till the whole or a portion of the shaft is completed before putting in the final pumping machinery.

Pumps. The varieties of pumps used in mines are numerous. In small sinkings hand-pumps, either direct-acting or rotary, may be applied; steam-jet pumps on the principle of the Giffard injectors are also used; and pulsometers, though requiring a large expenditure of steam, have the advantages of being quickly fixed, of occupying little space, and of working with sandy or muddy water. They are capable, therefore, of rendering great services in special cases. When we come to the definitive machinery erected in large mines of considerable depth, we find that the prevailing types of pumps are few. They may be classified as follows:—(A) lifting and force pumps worked by rods in the shaft actuated by wind, water, or steam power; (B) force-pumps at the bottom of the shaft worked by steam, compressed air, or hydraulic pressure.

A. In describing the first method we have to consider the motive power, the rods, and the actual pumps themselves.

Windmills have the disadvantage, which is often fatal, that the power is not constant. By erecting an auxiliary steam-engine, which can be set to work if wind fails, this evil is overcome; and at the Mona mines in Anglesea a windmill pumps up water from a depth of 80 fathoms at the rate of upwards of 90 gallons per minute. As the site of the mine is breezy, there is wind enough to work the mill about one-half of the time.

Water-power was for a long period the principal agent employed in draining mines, and it is still of the greatest utility in many districts, reservoirs being constructed to collect and store the rainfall. Some idea of the scale upon which these works are conducted will be gathered from the following figures relating to the Harz mines. In 1868 there were "sixty-seven reservoirs covering an area of 604 acres, and having a storage capacity of 336,000,000 cubic feet."[2] The total length of the various leats, races, and other water-courses, including the six principal adits, is about 170 statute miles. The net power extracted is reckoned at 1870 horse-power, but less than one-fourth of this is used for pumping.

Water-power is applied to pumping machinery by water-wheels, turbines, and rotary or non-rotary water-pressure engines. Excepting the case of the latter, the rotary motion has to be converted into a reciprocating motion by a crank; and furthermore with turbines the speed must be reduced very considerably by intermediate gearing.

Overshot wheels are the commonest prime movers when pumps are worked by water-power; water-wheels are frequently constructed 40 or 50 feet in diameter, and at the Great Laxey mine, in the Isle of Man, one of the wheels is no less than 72 feet 6 inches in diameter and 6 feet in the breast. The power is conveyed from the water-wheel by a connecting rod to a bell-crank (*bob*) placed over the shaft; and when, owing to the contour of the ground, the wheel has to be placed at a distance, it is connected to the bob by the so-called *flat rods*, made of wood, bars of iron, or wire-rope, travelling backwards and forwards, and supported by pulleys or oscillating upright beams.

Water-pressure engines have the advantage of being able at once to utilize any amount of fall, and those which are direct-acting can be applied immediately to the main rod of the pumps.

Steam, however, is the power used *par excellence* in draining mines; indeed the first applications of steam-power were made for this purpose, and Watt's great inventions owed their birth to the necessities of mines which could no longer be drained by the water-power at their command.

Cornish engine. The principal type of engine is that known as the Cornish engine, which is a single-acting condensing beam engine working expansively. Its mode of action may be briefly described as follows. The steam is let in at the top of the cylinder and presses down the piston, which is connected with one end of a large beam, whilst the main rod of the pumps is attached to the other. When the piston has completed its course the equilibrium valve is opened by a cataract, and, the pressure on both sides of the piston being now equal, the weight of the pump rods, or rather the excess of their weight over that of the counterbalances, causes them to drop and force up the water from the mine by means of the plungers, which will be described immediately. Double-acting rotary engines working the pumps by cranks may also be met with.

The rod in the shaft, known as the *main rod* or *spear rod*, is usually made of strong balks of timber butted together and connected by *strapping plates* fastened by bolts. It serves to work either lifting-pumps or force-pumps, or both.

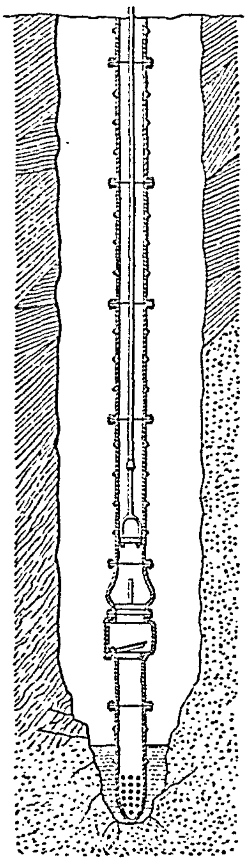

Fig. 87.

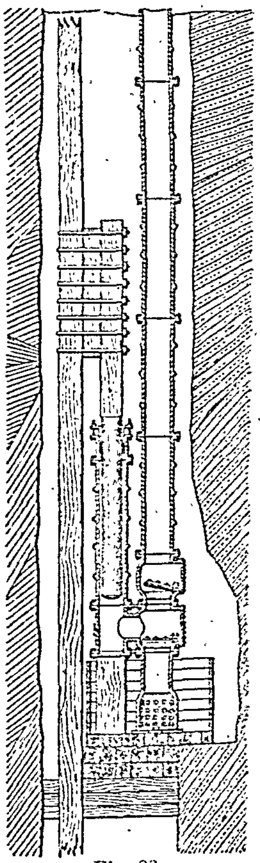

Fig. 88.

The lifting-pump, or drawing lift (fig. 87),[3] consists of the wind-bore, the clack-piece, the clack-seat piece, the working barrel

[2] "Notes on the new Deep Adit in the Upper Harz Mines," by H. Bauerman, *Report of the Miners' Association of Cornwall and Devonshire*, 1868, p. 21.

[3] Michell and Letcher on "Cornish Mine Drainage," *Forty-Third Annual Report of the Royal Cornwall Polytechnic Society*, p. 211.

surmounted by pumps; and the bucket with its rod. The whole works like any ordinary pump, and needs no special explanation.

The force-pump used in mines, known as the plunger-pump, consists of a solid piston (*plunger*) (fig. 88)[1] working through a *stuffing-box* in a pump standing on the H-piece. This has a valve which communicates with the *windbore* resting in the cistern. Above the H-piece comes the *door-piece* with another valve, and then a series of pipes, generally of cast iron, but occasionally of wrought iron, constituting the column. The upward motion of the plunger, which is attached to the main rod, causes an inflow of water, which is forced into the column when the plunger descends. It is usual to fix a drawing lift at the bottom of the shaft, which raises the water into a first cistern, and thence a plunger forces it into a second cistern some 60 yards higher up; and it is continually forced up from cistern to cistern until it reaches the adit or the surface.

There are numerous important matters which require special attention, such as the valves, catches, balance-bobs, guiding arrangements for the rod in inclined shafts, the V-bobs, fend-off bobs, and running loops, which have to be used when there are bends in the shaft; but space will not permit of more than mere mention of these details.

Such then is the standard arrangement worked by steam or water power for pumping from mines. The great advantage of the system consists in the employment of the plunger, because it is simply necessary for the machine to raise a weight slightly greater than that of the water, which is forced up afterwards by the down-stroke of the rods. Leaks are readily discovered, and the stuffing-box can be easily screwed up as the packing wears; this is one great reason of the superiority of the plunger compared with a piston working in a barrel.

The modifications of this system relate more to the engines employed than to the actual pumps themselves.

The cylinder of the Cornish engine is sometimes reversed and stands over the shaft, the main rod being attached directly to the piston. This type of engine, known as the Bull engine in Cornwall, dispenses with the ponderous beam, but it has the great disadvantage of obstructing the mouth of the shaft. The use of two cylinders combined, as invented by Woolf, causes less strain upon the main rod and pumps (*pit-work*) and machinery generally, as the initial velocity of the piston is smaller and the engine starts with less jerk. The cylinders are placed side by side or one above the other.

Kley's engines.

Kley, of Bonn, has constructed engines on the Woolf system with steam acting on both sides of the pistons. He makes the excess of the weight of the rod over that of the counterbalances sufficient to raise only half the weight of the water and to overcome the friction; and then in the descending stroke the steam acts on the top of the piston and so makes up for the insufficiency in force of the rods. As the steam acts on both sides of the piston the same amount is consumed, it is true, but a smaller cylinder will do the work, and the original cost of the engine is lessened. The same engineer of late years has put up several pumping engines in Belgium, Germany, and France of 30 to 560 horse-power, with a fly-wheel which serves simply to regulate the stroke of the piston, so that the crank always stops before or after the dead point till the cataract starts another stroke. The engines are double-acting, with two cylinders and beam. The advantage of working with the fly-wheel is that the main rod and pumps are set in motion without the injurious jerk unavoidable with a Cornish engine worked at a high rate of expansion.

Guinotte's engine.

M. Guinotte, the well-known Belgian engineer, also adopts a fly-wheel, and the engines he has erected at Mariemont and elsewhere are single-acting rotary engines with one cylinder. The peculiarity of the fly-wheel is that he can weight it in any way he pleases; and he so overcomes the difficulty, which occurs in other rotary machines, of its being impossible to work them below a certain speed. His object has been to make the speed slow at the beginning and end of a stroke, so as to avoid the injurious shocks to the valves and machinery generally from sudden starts and stoppages. In order to make the main rod act by traction only and not compression, which may be advisable with iron rods, the plungers are sometimes reversed; whilst Kraft of Seraing has introduced the Rittinger pump, which consists of a hollow moving plunger with a valve inside, and a plunger case above it working over a hollow fixed plunger. By this arrangement both the up and the down stroke of the engine cause water to be forced up; and this pump is used with a double-acting rotary engine.

B. We must now speak of the second class of pumps, viz., force-pumps worked by steam, water-power, or compressed air at the bottom of the shaft.

The steam pumps are of very various descriptions,[2] but they mostly consist of one or two plungers, or rams, set in motion by a rotary or a non-rotary engine, which may or may not work with expansion and condensation. The plunger or ram is generally fixed directly on to the piston, and works in the same line, consequently the power is transmitted to the plunger with the least possible loss. The water is forced up the shaft in one long column. Engines and pumps of this kind are easily kept in order; all the parts are readily accessible. The miner is able to dispense with the heavy beam, the massive engine-house, the long main rod and its connexions and bobs, the various cisterns and plungers, and instead he has a compact and easily supervised machine and a simple line of pipes taking up but little space in the shaft; the pump can therefore be erected and set to work very quickly, and this is a matter of the utmost importance in emergencies. It is true that these direct-acting steam-pumps, even when worked by a compound engine, cause a greater consumption of coal than the Cornish engine; but, as a set off, there is the economy in first cost, erection, and repairs which has led to their adoption more especially in collieries. The steam is generated by boilers underground, or is conveyed from the surface in well-jacketed pipes.

If natural water-power is available water-pressure engines working the plunger directly are often employed, and indeed such water-power may be created artificially for use in workings where steam-power is objectionable on account of the heat. There are other reasons too for employing water for transmitting power; where the length of the rods is very great, and they have to be worked quickly, there is a great liability to breakages; in order to overcome these difficulties at the mines on the Comstock lode, Mr Joseph Moore[3] uses a steam-engine at the surface to work an hydraulic accumulator, and then by pipes conveys the water under pressure to hydraulic engines working plungers. These are fixed at 2400 feet from the surface, and force the water in one column, 813 feet high, to the level of the Sutro tunnel. The exhaust water is returned to the surface in pipes and used over again. The pumps are now raising 1600 to 1700 gallons per minute.

Where compressed air is being supplied to a mine for drilling and winding purposes, it is often convenient to employ it, by means of direct-acting pumps, such as are generally used with steam, for the drainage of small temporary sinkings; and occasionally large pumps raising considerable quantities of water are worked in this way.

11. *Ventilation and Lighting.*—The composition of the air of the atmosphere is about one-fifth by volume of oxygen and four-fifths of nitrogen, with a little carbonic acid gas; more exactly, the standard amount of oxygen may be taken at 20·9 per cent., and that of the carbonic acid gas at 0·03 per cent. The atmosphere of mines is subject to various deteriorating influences: not only do noxious gases escape from the rocks into the underground excavations, but also the very agents employed in the execution of the work itself pollute the air considerably.

Deleterious gases.

The dangerous emanations of fire-damp in collieries have been already described (COAL, vol. vi. p. 72); and with reference to this gas it is simply necessary to say that its presence is not entirely confined to coal mines. Large quantities have been observed in Silver Islet mine,[4] Lake Superior, where several explosions have occurred, whilst small quantities are met with in the stratified ironstone of Cleveland, and also in the Cheshire salt mines; jets of the gas may be seen constantly burning in the salt mine at Bex in Switzerland; a little has been noticed also in lead mines in Wales and Derbyshire. In the Sicilian mines the amount given off by the black carbonaceous shales inter-stratified with the sulphur beds is sufficient to cause dangerous explosions. It has been pointed out (vol. vi. p. 72) that carbonic acid gas exudes from coal;[5] it escapes also from some mineral veins. At the lead mines of Pontgibaud in central France it is so abundant that special fans have to be provided for getting rid of it; very distinct issues of this gas may be observed at the Foxdale mines in the Isle of Man, and in the Alston Moor district it is not

uncommon. This gas is likewise given off in the Sicilian sulphur mines, where also the highly poisonous sulphuretted hydrogen is of frequent occurrence, the water in the workings being often saturated with it. Small quantities of mercurial vapour occur in quicksilver mines.

Products of respiration, blasting, &c.

Such then are the principal gases which naturally pollute the atmosphere of mines, and have to be swept out by ventilation. In addition to these we have the products of the respiration of the men and animals in the pit, and those due to the combustion of candles or lamps, and the explosion of gunpowder, dynamite, &c.

Dr Angus Smith[1] reckons that two men working eight hours, and using ½ lb of candles and 12 oz. of gunpowder, produce 25·392 cubic feet of carbonic acid (anhydride) at 70° F.,—viz., 10·32 by breathing, 12·276 by candles, and 2·796 by gunpowder.

The products of the explosion of gunpowder have been carefully studied by Captain Noble and Sir Frederick Abel, and the following figures, showing proportions by weight, are copied from the valuable paper[2] containing the results of some of their researches:—

	Curtis & Harvey's No. 6 Gunpowder.	Mining Powder.
Total solid products	57·74	47·04
Total gaseous products	41·09	51·35
Water	1·17	1·61
	100·00	100·00

The solid residue of the mining powder consisted mainly of potassium carbonate, potassium monosulphide, and sulphur. The percentage composition by volume of the gas produced was:—

	Curtis & Harvey, No. 6.	Mining Powder.
Carbonic anhydride	50·22	32·15
Carbonic oxide	7·52	33·75
Nitrogen	34·46	19·03
Sulphuretted hydrogen	2·03	7·10
Marsh gas	2·46	2·73
Hydrogen	3·26	5·24
	100·00	100·00

The volume (calculated for a temperature of 0° C. and barometer 760 mm. of mercury) of permanent gases generated by the explosion of 1 gramme of dry powder is—

Curtis & Harvey, No. 6	241·0	cubic centimetres.
Mining	360·3	,, ,,

MM. Sarrau and Vieille have communicated to the Academy of Sciences[3] the results of their researches concerning the decomposition of certain explosives, and more particularly gun-cotton and nitrated gun-cotton. The following table shows, in litres, the volume (at 0° C. and 760 mm. of mercury) of each of the gases per kilogramme of the substance exploded in a closed vessel:—

Kind of Explosive.	CO.	CO_2.	H.	N.	O.	C_2H_4.	HS.	Total.
Pure gun-cotton	234	234	166	107	...	...	...	741
Gun-cotton and nitrate of potash (50 per cent. of each)	...	171	...	109	45	...	...	325
Gun-cotton (40 per cent.) and nitrate of ammonia (60 per cent.)	...	184	...	211	6	...	...	401
Nitro-glycerin	...	295	...	147	25	...	...	467
Ordinary blasting powder	64	150	4	65	...	4	17	304

If, however, the explosive is decomposed at a pressure approaching that of the atmosphere, the volumes (again at 0° C. and 760 mm. of mercury) are very different, as shown below:—

Kind of Explosive.	NO_2	CO.	CO_2.	H.	N.	C_2H_4	Total.
Pure gun-cotton	139	237	104	45	33	7	565
Gun-cotton and nitrate of potash (50 per cent. of each)	71	58	57	3	7	...	196
Gun-cotton (40 per cent.) and nitrate of ammonia (60 per cent.)	122	65	103	12	112	...	414
Nitro-glycerin	218	162	58	7	6	1	452

When explosives are decomposed in this way they liberate nitric oxide and carbonic oxide, and the analyses of MM. Sarrau and Vieille confirm the practical experience of miners, who complain greatly of noxious fumes when, owing perhaps to a bad detonator, a charge of dynamite or tonite fails to explode properly.

The air of mines is finally deteriorated by organic matter contained in the exhalations of the men and animals employed and in the products of decaying timber, by dust, and by the solid particles constituting the smoke of explosives. It must be recollected also that the injury to the air is not confined to the addition of the gases and substances just mentioned; but the proportion of oxygen is diminished by the combustion of candles, by respiration, the decay of timber, and decomposition of some minerals such as iron pyrites. Dr Angus Smith[4] sums up the results of his analyses of the air of British metal-mines as follows:—

	Percentage by volume.
Oxygen, average of 339 specimens	20·26
,, of ends	20·18
,, other parts	20·32
,, in currents	20·65
,, in large cavities	20·77
,, just under shafts	20·42
,, in sumps	20·14
Carbonic acid	0·785

He considers air with 20·9 per cent. oxygen as normal, and air with proportions between that and 20·6 as impure; and where the percentage of oxygen descends below 20·6 he calls the air exceedingly bad. According to these standards, only 10·67 per cent. of the samples showed the air to be normal or nearly so; 24·69 per cent. were decidedly impure; whilst 64·63 per cent. or nearly two-thirds of the samples were exceedingly bad. The amount of oxygen in one specimen was as low as 18·52 per cent., whilst the carbonic acid often exceeded 1 per cent. and in several instances 2 per cent. It is evident that twenty years ago the ventilation of British metal mines was anything but satisfactory, and even now there is room for improvement.

Having explained the reasons why the air of mines must be constantly renewed, we must now point out how this desirable end is effected.

Systems of ventilation.

Two systems are employed,—natural ventilation and artificial ventilation; but, as both systems have been described (COAL, vol. vi. p. 70), little remains to be said here, especially as the ventilating machines in metalliferous mines generally cannot for one moment be compared with the powerful appliances employed in collieries. In vein-mining there are generally many more shafts than in collieries, and natural currents are set up which are often considered sufficient for ventilating the mines; nevertheless, the advanced workings, such as the ends, rises, and winzes,—in fact all workings in the form of a *cul-de-sac*,—are likely to require special means of ventilation as soon as they proceed a little distance from the main air-current.

The means of ventilating a drift or heading are various. If a natural or artificial draught exists at the mouth of the drift, it may be diverted by an upright partition (*brattice*), or an air-way may be constructed along the roof or floor by a horizontal partition of planks (*air-sollar*) (fig. 89). In this way a sufficient supply is secured at the end or fore-breast.

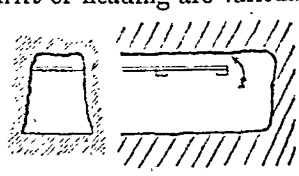

Fig. 89.

The water-blast is another simple appliance; it is precisely the same as the well-known tromp, and it blows a current of air through square pipes made of boards, or better through cylindrical pipes of sheet zinc. The fall of water may be applied by Williams's water-jet, shown in fig. 90. The jet of water acts like an injector, and creates a powerful current.

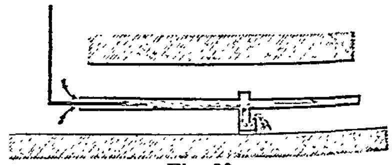

Fig. 90.

Small fans driven by boys, or better by small water-wheels or other machinery, are frequently applied, and the

[4] *Op. cit.*, p. 222.

Harz blower (*duck machine*, Cornwall) (fig. 91) is not uncommon. This is merely an air-pump of very simple construction which is worked by the main rod of the pumps, and can be arranged so as to exhaust the foul air or force in fresh air.

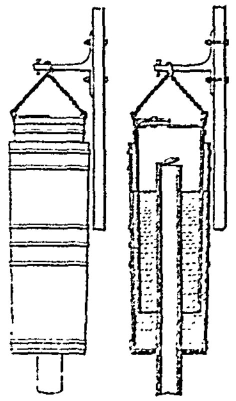

Fig. 91.

In working in blasting ground, boring-machines driven by compressed air are becoming more and more largely used every day, and the exhaust air escaping from the machines is invaluable for ventilation. At the same time, on account of volley firing, the quantities of deleterious gases generated in a short space of time are very considerable; and, in order to get rid of them speedily, the compressed air may be utilized for working a Körting aspirator or the somewhat similar ventilator of Mr Teague, a jet of compressed air turned into a ventilating pipe, which creates an exhaust (fig. 92[1]). Naturally this ventilator is merely brought into play at the time of blasting, and while the boring machinery is out of use. When compressed air is being supplied on a large scale to a mine for boring and winding machinery, it is often convenient to convey it by a small gas-pipe to working places in which the ventilation is inadequate. Of course, in one sense, it is very uneconomical to compress air to a pressure of 60 or 70 ℔ to the square inch for ventilating purposes only; but, where compressing machinery is always at work on the mine, it may be better to be a little wasteful of cheap power at the surface than to go to the greater expense of having a man or boy to work a fan underground.

Aspirators.

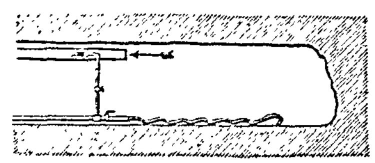

Fig. 92.

Lighting.

Mines are lighted by lamps, torches, candles, and electricity. The subject of safety lamps for fiery mines has already been discussed (see COAL, vol. vi. p. 72), and consequently the question of illuminating mines may be treated in a very summary manner.

Lamps vary very much in shape and size. The Sicilian miner has a mere shallow cup of unglazed pottery; the Saxon a small tin or brass lamp in a wooden box lined with tinplate and open in front. In the Harz the miner prefers a heavy flat iron lamp with a hook by which it is stuck into the timber or any crack in the rocks; in France, northern Italy, and parts of Spain, the iron lamp is lenticular in shape and also suspended by a hook. In Scotland, and parts of Germany and the United States, a small tin lamp of the shape shown in fig. 93 is very common; the hook enables it to be carried on the hat while climbing ladders, and to be fixed up underground. Olive oil and rape oil are burnt in these lamps; petroleum lamps are employed occasionally.

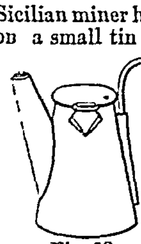

Fig. 93.

The miners of England and Wales still cling to the tallow candle; and when surrounded by a lump of clay it can easily and quickly be fixed in the working place or carried upon the hat when climbing. Gas brought down from the surface answers for illuminating large excavations, such as on-setting places and engine-rooms.

Up to the present time the electric light has been but little used underground on account of its want of portability, and the smallness of the spaces requiring illumination. Very often a few men only are employed in each working place, and consequently the expense incurred in fixing and shifting the lamps and maintaining them alight would be out of proportion to the value of the work executed. However, an incandescent electric lamp has been invented weighing only 10 ℔, which gives the light of three candles for six hours, and it may be reasonably expected that improvements will be made which will render the electric light more available for underground purposes than it is at present. When the area requiring illumination is large, an arc-lamp may be used with advantage.

Among the first successful applications of electric lighting to underground excavations may be mentioned that of M. Blavier at the Angers slate quarries.[2] In the year 1879 he fixed two Serrin lamps in one of the large underground chambers with an area of 2400 square yards, and he found that they gave light enough for all the men at work. The total cost, reckoning everything, viz., coal, carbons, repairs, labour, depreciation of plant, and interest on capital, is 50 francs per day; the gas formerly in use cost 54 francs a day and gave much less light. It is evident, however, that the arc lights can only be applied with advantage in special cases where a large number of men are concentrated in one working area which can be illuminated from one or two points.

The large chambers in the salt mine of Maros-Ujvár in Hungary have been regularly lighted up by electricity since 1880. The cost is somewhat greater than that of the tallow, oil, or petroleum formerly in use; but, on the other hand, the illumination is better, the men can do more work and are more easily supervised, whilst the air of the mine is not deteriorated by the products of combustion of the lamps.[3]

Means of access.

12. *Means of Descending into and Ascending from Mines.*—Where mines are worked by adit-levels the men naturally walk in along the ordinary roadways; such mines, however, are exceptional, and the men generally have to climb down and up by ladders, or are raised and lowered by machinery. The means of access to and from workings may be classified as follows:—(1) steps and slides; (2) ladders; (3) cages; (4) man-engines.

Steps.

If a lode or seam is inclined at an angle or 40° or 50° from the horizon, steps may be cut in the floors of the deposit if it is firm enough, or wooden stairs may be put in with a hand-rail. Even with higher dips steps may be arranged by directing them in a line intermediate between the dip and the strike. In speaking of conveyance underground, reference has already been made to the practice of carrying sulphur ore in Sicily and slate in Germany up to the surface by steps; and steps may be found in other foreign mines and occasionally in Great Britain. They are much less fatiguing than ladders placed so flat that part of the weight of the body rests upon the arms. In some of the Austrian salt mines the men descend by wooden slides inclined at angles varying from 30° to 50°, flattening at the bottom to destroy the velocity gradually; the ascent is effected by steps.

Slides.

Ladders.

Ladders are very largely used in metal mines all over the world, but they vary a good deal in different countries. The ladder consists of two sides and a series of rungs (*staves*, Cornwall). The sides are usually made of wood, and the rungs of wood or iron. The distance between the rungs is important; 10 inches from centre to centre is sufficient, for climbing upon ladders with the rungs 12 inches apart is decidedly more fatiguing. On the Continent wooden rungs are commoner than iron ones, and oak is preferred. Sometimes the wooden staves, instead of being round, are flat, so as to stand more wear, and iron sides may be seen in places where dry rot is very bad. Platforms should be fixed at short intervals, not exceeding 3 or 4 fathoms in perpendicular shafts, so as to prevent falls from having fatal consequences.

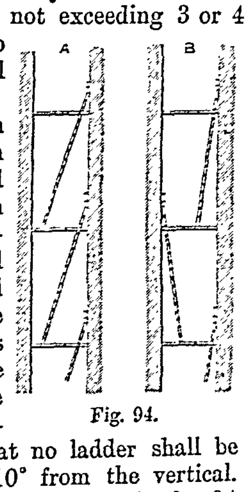

Fig. 94.

In many cases sufficient attention is not paid to the angle of inclination of the ladders. A ladder is climbed with the least fatigue when the person uses his arms simply to steady himself, and is not compelled to pull himself up by them, as on a vertical ladder, or to support much of the weight of his body by them, as happens with a very flat one. The best angle is about 20° from the vertical, and in Belgium the authorities have very wisely decreed that no ladder shall be inclined at an angle of less that 10° from the vertical. Furthermore, of the two arrangements shown in fig. 94

[1] *Trans. Roy. Geol. Soc. Cornwall*, vol. x. p. 142.

[2] M. Blavier, "L'Éclairage électrique aux Ardoisières d'Angers," *Annales des Mines*, ser. 7, vol. xvii., 1880, p. 5.

[3] *Oesterreichische Zeitschrift für Berg- und Hüttenwesen*, 1882, No. 25, p. 296.

A is better than B, because it not only affords a greater inclination for the ladders, but also renders it less likely that a man will drop through the opening (*manhole*) in the platform (*sollar*) if he loses his hold and falls. These may seem trifling matters; but, leaving aside the question of safety, the economy derived from fixing the ladders at the best inclination is by no means small. To make this apparent we must recollect the depths to and from which men have to climb, viz., 300, 400, and even 500 yards. It is important, therefore, to save every unnecessary expenditure of energy, which, though trifling for one ladder, becomes considerable when repeated a great number of times. When a mine has reached a depth of 200 yards, and *a fortiori* when it exceeds it, mechanical appliances should be introduced for raising and lowering the men, because time and strength are wasted by climbing. Medical men also are agreed that excessive ladder-climbing is injurious to the health of the miner. Therefore, both upon hygienic and financial grounds, one of the first thoughts in working a mine should be the conveyance of the men up and down the shafts by machinery with the least possible fatigue.

Cages. In collieries and other mines worked by perpendicular shafts, it has long been customary to raise and lower the men by the ordinary winding machinery already described. In the United Kingdom it is necessary that guides should be used if the shaft exceeds 50 yards in depth; safety-catches and disengaging hooks (COAL, vol. vi. p. 75) are frequently applied for the purpose of preventing accidents. The simplicity of this method of ingress and egress naturally renders it popular, and statistics prove that, where proper precautions are used, it is exceedingly safe.

Man-engines. The first man-engine was put up in the Harz in 1833, and nine years later a similar machine was fixed in Tresavean mine in Cornwall. Since that time this very useful means of conveying workmen up and down shafts has been resorted to in other mining districts, and especially in Belgium and Westphalia.

Two kinds of man-engine are in use, the double-rod machine and the single-rod machine. The double-rod or original man-engine consists of two reciprocating rods like the main rods of pumps, carrying small platforms upon which the men stand. The stroke is from 4 to 16 feet, and the little platforms are so arranged that they are always opposite each other at the beginning and end of each stroke.

Figs. 95 and 96 represent the rods in the two final positions. A man who wishes to descend steps upon platform *b* (fig. 95); the rod B goes down, and A goes up, so that *b* (fig. 96) is brought opposite *c*. The man steps across from *b* to *c*, and then the rod A makes a down-stroke, B an up-stroke. Platform *c* is now opposite *d* (fig. 95), and the man again steps across; and thus, by constantly stepping from the rod as it completes its down-stroke, the man is gradually conveyed to the bottom of the shaft. By reversing the process, or, in other words, by stepping off on to the opposite platform as soon as the rod has completed its up-stroke, the man is raised to the surface, without any fatigue beyond that of the very slight effort of stepping sideways. If each rod makes four up and down strokes of 10 feet each per minute, the rate of ascent or descent will be 80 feet per minute.

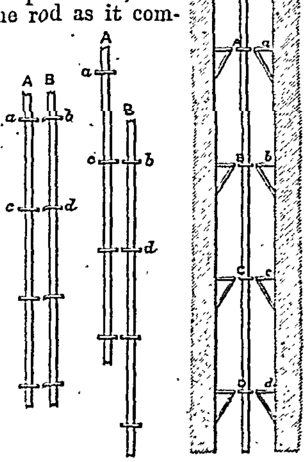

Fig. 95. Fig. 96. Fig. 97.

The single-rod man-engine has one rod carrying steps, whilst fixed platforms are arranged in the shaft so as to correspond exactly with them (fig. 97). If a man wants to go down, he steps on to A when the up-stroke is completed; the rod goes down and A is brought down opposite to the fixed platform *b*, on to which he steps off. He then waits on *b* until the rod has finished its up-stroke. B is brought opposite *b*; he steps on to B, the rod goes down and he is brought opposite *c*, where he steps off again and waits. By reversing the operation he is gradually lifted to the top of the shaft. The single-rod engine may be used by men going up while others are going down, provided that there is sufficient room upon the fixed platforms (*sollars*). The best plan is to have sollars right and left, as shown in the figure, and then the ascending men step off to the left, for instance, while the descending men take the right-hand sollars. The ascending man steps on to the man-engine as soon as the descending man steps off, and so the rod may be always carrying men up or down. The usual stroke in Cornwall is 12 feet, and there are from three to five or six strokes a minute. With five strokes the men descend 10 fathoms a minute, or in other words a descent or ascent of 300 fathoms occupies half an hour. The reciprocating motion is best obtained from a crank, because in this case the speed is diminished gradually at the dead points, and the danger of an accident in stepping off and on is thereby diminished; man-engines, however, are sometimes driven by direct-acting engines.

Man-engine rods are constructed of wood or iron; and at Andreasberg in the Harz each rod is replaced by two wire ropes. Like a pump rod the man-engine rod requires proper balance bobs and catches, and for the safety of the men a handle is provided at a convenient height above each step.

The man-engine has one great advantage over the cage, which consists in the fact that it can be safely applied in inclined and even crooked shafts; and it is for this reason that man-engines have been adopted in many metal mines unprovided with vertical shafts.

Careful comparisons as regards safety of travelling have been made in Prussia between ladders, man-engines, and cages. The average accidental death-rate is shown by the accompanying table, which gives averages for a period of ten years, 1871 to 1880:—

	Ladders.	Man-engines.	Cages.
Average annual number of men travelling.	73,942	7,191	64,071
Total number of persons killed..............	75	41	74
Average annual death-rate per 1000........	0·101	0·570	0·115

The table shows that the cage is nearly as safe as ladders. In reality, if the actual distance travelled were taken into account, the cage would appear to be safer, because we may fairly assume that the mines in which men are hoisted by cages are on the whole very much deeper than those in which men ascend and descend by ladders. The man-engine appears to be decidedly more dangerous than either the cage or ladders. Here again a distinction requires to be made between the single-rod and the double-rod machines, and the Prussian statistics include many of the latter. It will be readily understood that a fall in a naked shaft with few fixed platforms is much more likely to be fatal than a fall in the shaft of a single-rod man-engine which is closed with the exception of the manhole at intervals of 12 feet. The Belgian *warocquères* are rendered safer than the Harz or Saxon man-engines by having a railing round the back of each platform on the rod. Some of the double-rod machines are made with large platforms so that two persons can stand on them, one going up and the other going down, or both travelling in the same direction. The use of double-rod man-engines has been entirely abandoned in the United Kingdom. The death-rate from accidents on man-engines in Cornwall and Devon during the nine years 1873 to 1881 was 0·17 per 1000 persons using them, whilst the annual death-rate per 1000 persons using ladders was slightly higher, viz., 0·19. If the actual distance travelled were taken into account, the scale would turn more decidedly in favour of the man-engine.

The cost of raising and lowering men by the man-engine is not great. At Dolcoath, a tin mine in Cornwall approaching 400 fathoms in depth (see figs. 62, 63), it is reckoned that 1½d. per man per day covers all expenses, including interest upon the capital expended and depreciation of plant.

13. *Dressing or Mechanical Preparation of Ores.*—In a large number of cases the mineral, as it is raised from the mine, is not ready for sale. It usually requires to be subjected to mechanical processes whereby the good ore is entirely or partly freed from valueless veinstone. These processes, which in a few special instances are aided by calcination in furnaces, are known as the dressing or mechanical preparation of the ores. As a rule the valuable ore is specifically heavier than the veinstone, and most of the separating processes are based upon the fact that the heavy particles of ore will fall in water more quickly than the light particles of veinstone. Dressing of ores.

The processes of mechanical preparation may be classified as follows:—(1) washing and hand-sorting; (2) disintegration, or reduction in size; (3) classification by size or by equivalence; (4) concentration.

(1) Sometimes the ore coming from the mine requires simply to be freed from adhering particles of clay in order Washing.

to be rendered fit for sale, at other times the washing is necessary as a preliminary process previous to sorting by hand. The operation is performed either by raking the ore backwards and forwards upon a grating under a stream of water, or in a box containing water, or, thirdly, by means of an inclined revolving iron drum worked by hand or any other motive power. The machines used for this purpose, known as washing trommels, are revolving cylinders or truncated cones of sheet-iron provided with teeth inside. The ore is fed in at one end, is subjected to the action of a stream of water, and is discharged at the other end.

The *stuff*, *i.e.*, the mixed ore, veinstone, and country rock, having been cleansed, it is now possible to make a separation by hand. Women and children are generally employed for this work, as their labour is cheaper and their sight sharper than that of men. The stuff is spread out on a table, and various classes are picked out according to the nature of the products furnished by the mine. Thus in a lead mine we may have—(*a*) clean galena, (*b*) mixed ore, *i.e.*, pieces consisting partly of galena and partly of barren veinstone, (*c*) barren veinstone and country rock. This is a most simple case; very frequently we have to deal with a vein producing ores of two metals, especially in the case of lead and zinc, and then the classification into various qualities becomes more complicated.

Disintegration. (2) Reduction in size is necessary for two reasons. Even when an ore is sufficiently clean for the smelter, the large lumps are often crushed by the miner for the sake of obtaining a fair sample of the whole, or supplying a product which is at once fit for the furnace. The chief reason, however, for disintegration lies in the fact that the particles of ore are generally found enclosed in or adhering to particles of barren veinstone.

The disintegration is effected by hand or by machinery. Large blocks of ore and veinstone are broken by men with large sledge hammers, and the reduction in size is continued very often by women with smaller hammers. Sometimes the blow of the hammer is directed so as to separate the good from the poorer parts, and hand-picking accompanies this process, called *cobbing*. Ore may be crushed fine by a flat-headed hammer (*bucking iron*) on an iron plate.

The machines used for reducing ores to smaller sizes are very numerous; here it is impossible to do more than briefly call attention to those most commonly used. These are stone-breakers, stamps, rolls, mills, and centrifugal pulverizers.

Stone-breaker. The stone-breaker, or rock-breaker, is a machine with two jaws, one of which is made to approach the other, and

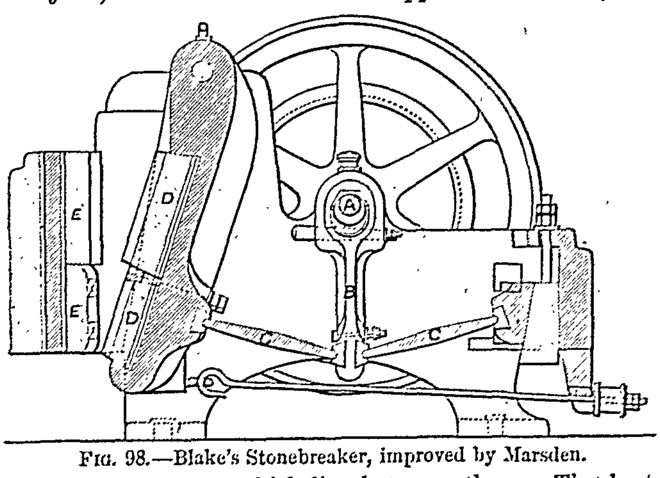

Fig. 98.—Blake's Stonebreaker, improved by Marsden.

so crack any stone which lies between them. The best-known stone-breaker is the machine invented by Blake, which has rendered inestimable services to the miner for the last twenty years, and the introduction of which constituted a most important step in advance in the art of ore-dressing. Its mode of action is very simple. When the shaft A (fig. 98) revolves, an excentric raises the "pitman" B, and this, by means of the toggle-plates C, C, causes the movable jaw D to approach the fixed jaw E by about $\frac{3}{8}$ inch at the bottom. When the pitman descends the jaw is drawn back by an india-rubber spring. The jaws are usually fluted, the ridges of one jaw being opposite the grooves of the other, and they are so constructed that the wearing parts are quickly and easily replaced.

Mr Marsden of Leeds has lately introduced a pulverizer, constructed on the principle of the stone-breaker, which will reduce large stones to the finest powder in one operation. The moving jaw has an up-and-down as well as the old backwards-and-forwards motion, and the stones are first cracked and then ground by the double action.

Stamps are pestles and mortars worked by machinery. Stamps. The construction of the modern California stamp mill with revolving heads is explained in Gold, vol. x. p. 747, and the description need not be repeated. In Cornwall the older form with rectangular heads still prevails.

It is impossible to give any correct average figures representing the work done by a stamping mill, because this varies with the hardness of the stuff treated and the fineness to which it must be reduced. However, it is usual in Cornwall to reckon 1 ton of tinstuff and in California 1 to $1\frac{1}{4}$ ton of gold quartz stamped per horse-power in twenty-four hours.

Stamps are principally used in dressing the ores of gold, silver, and tin, but are occasionally employed for those of copper and lead. The stamps described at vol. x. p. 747 act simply by gravity. Another form, which has met with favour in the Lake Superior district, is the direct-acting or Ball stamp, which works like a steam hammer, the blow of the head being assisted by the pressure of steam. At the Calumet and Hecla Mill, Lake Superior, each Ball stamp is capable of crushing 130 tons in twenty four hours. In a third kind of stamps, the heads are lifted by a crank and the power of the up-stroke compresses a cushion of air (pneumatic stamps) or a spring, storing up power which makes the down-stroke strike a heavier blow.

Revolving rolls were introduced in the west of England Rolls. in the early part of the present century to replace *bucking* by hand. The machine, now often known as the Cornish crusher, consists of two cast-iron or steel cylinders which revolve towards each other, whilst at the same time they are kept pressed together by levers or springs. The cylinders or rolls are generally from 18 inches to 2 feet or 2 feet 8 inches in diameter and 12 to 22 inches wide.

Stone mills constructed like flour mills are employed in Mills. some countries for reducing ores to powder; and the *arrastra*, which consists of heavy stones dragged round upon a stone bed, has rendered good service in grinding and amalgamating gold and silver ores, in spite of its being slow and cumbersome. Edge-runners (Chilian mills) also deserve mention.

Iron mills, known as *pans*, with grinding surfaces made of chilled cast-iron and arranged so that they can be quickly and easily replaced when worn out, are greatly in vogue in the United States for the treatment of ores of gold and silver; the ore delivered to them is already finely divided, and they are intended, not only still further to reduce the size of the particles, but also and more especially to effect the amalgamation of the precious metals with quicksilver. The pulverizers used in Cornwall for grinding grains of tin ore with a little waste still adhering to them are also iron mills.

The centrifugal pulverizers are machines by which the

Centrifugal pulverizers. pieces of ore are thrown with great velocity against bars or arms, or against each other, and so reduced to powder; in other machines iron balls or iron rollers are whirled by centrifugal force against an iron casing and grind any mineral contained inside it. These pulverizers are much less used than stone-breakers, stamps, and rolls for the disintegration of metallic ores.

Classification of ores. (3) Classification of a crushed ore into sizes is absolutely necessary in some cases and advisable in others, because the subsequent concentration is dependent upon the fall of the particles in water, as will be presently explained. Classification by size is effected by sieves. Hand sieves and flat sieves placed one above the other have been superseded at most dressing establishments by cylindrical or conical revolving screens known as trommels. These screens are made of wire web or of perforated sheets of metal, and they are often arranged so as to discharge one into the other, so that the ore from a crusher can quickly be separated into classes of various sizes.

With sizes of less than 1 millimetre ($\frac{1}{25}$ inch) trommels are no longer employed, and recourse is had to the so-called separators or classifiers. These are boxes in the shape of inverted cones or pyramids into which the finely crushed ore is brought by means of a current of water; a jet of clean water is often made to rise up in the bottom; the larger and the specifically heavier particles fall and are discharged with a stream of water at or near the bottom, whilst the smaller and specifically lighter particles flow away at the top. The separators do not effect a true classification by size; they merely cause a division by *equivalence*, a term which will be explained immediately.

Concentration. (4) We now have to deal with the enriching of the ore, or the concentration of the valuable particles into as small a bulk as is economically advantageous. The concentration is generally brought about by the fall of the particles in water. Occasionally the fall in air is utilized; mercury is employed as a collecting agent in the case of gold and silver, and in a few instances magnetism can be applied.

The concentration in water depends upon the difference in specific gravity of the valuable ore and the waste veinstone or rock. A piece of galena with a specific gravity of 7·5 sinks to the bottom more quickly than a similar piece of quartz, the density of which is only 2·6. Nevertheless a large piece of quartz may fall to the bottom as quickly as a small piece of galena. Particles which have equal velocities of fall, though differing in size and specific gravity, are said to be *equal-falling*, or *equivalent*. P. von Rittinger shows that a sphere of quartz of $\frac{1}{4}$ inch in diameter would sink in water exactly as quickly as a sphere of galena of $\frac{1}{16}$ inch in diameter, and these two particles are therefore equal-falling. Consequently, before we can separate properly by water it is necessary to classify the particles by size, so that equivalence shall not prevent a separation or lessen its sharpness. It is nevertheless true that in the early part of the fall of equivalent grains the influence of the specific gravity preponderates, and the denser particles take the lead; therefore, by a frequent repetition of very small falls, particles which have not been closely sized may still be separated.

Jiggers. The principal machine for concentrating particles of sizes ranging between 1 inch and $\frac{1}{50}$ inch is the jig or jigger. The hand jigger is merely a round sieve which is charged with the crushed ore and then moved up and down in a tub full of water. The particles gradually arrange themselves in layers, the heaviest on the bottom and the lightest at the top. On lifting out the sieve the light waste can be skimmed off with a scraper, leaving the concentrated product below ready for the smelter or for further treatment. Similar sieves worked by machinery were for a long time employed in dressing establishments, but the introduction of the improved continuous jiggers has led to their abandonment in all works of any importance. The continuous jigger is one of the most useful dressing machines of the present day. It consists of a box or hutch divided by a partial partition into two compartments; in one is fixed a flat sieve *s* (fig. 99), which carries the ore, and in the other a piston *p* is made to work up and down by means of an excentric. The hutch being full of water, the movement of the piston causes the water to rise up and fall down through the ore, lifting it and letting it fall repeatedly. The effect of these frequent lifts and falls is to cause a separation of the previously sized ore into layers of rich mineral at the bottom, light waste at the top, and particles of ore mixed with waste in the middle.

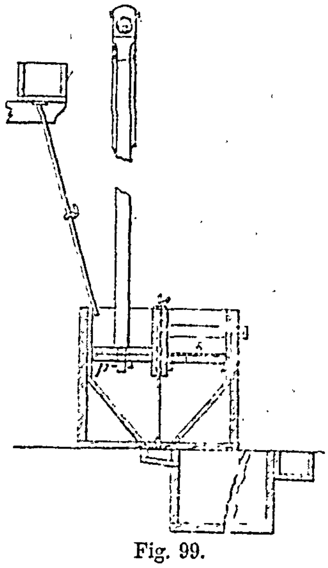

Fig. 99.

The great value of these jiggers is the continuous discharge of the products without stoppages for their removal. Several methods are in vogue, viz., the end discharge, the central discharge, and the discharge through the meshes of the sieve. With the first, the enriched product lying at the bottom of the sieve passes out through openings at the end of the jigger, and the amount escaping is governed by an adjustable cap or shutter, by which the size of the openings can be increased or diminished at pleasure; the middle product can be discharged by openings placed a little higher up, whilst the waste is washed over the top of the end of the jigger at each pulsation. Very often a first sieve simply separates a concentrated product and discharges the poorer product into a second sieve, where a similar separation is effected. With the central discharge, a pipe is brought up through the bottom of the sieve, and the size of the opening for the escape of the concentrated ore is regulated by a cylindrical cap which can be raised or lowered by a screw. The discharge through the sieve is especially adapted for the finer products from the crusher, though it is also used in some cases for grains up to $\frac{1}{4}$ inch in diameter. The mesh of the sieve is chosen so that the particles under treatment will just pass through, but above the sieve a layer of clean ore is placed which prevents anything but the heavier particles from being discharged. The pulsations of the water, as before, cause a separation into layers, and the heavy rich particles find their way through the bed and drop into the hutch, whence they can be drawn off through a hole at pleasure. The poorer part passes over a simple sill at the end of the sieve, or to a second sieve if necessary. Three or four sieves are occasionally arranged in a row in one machine.

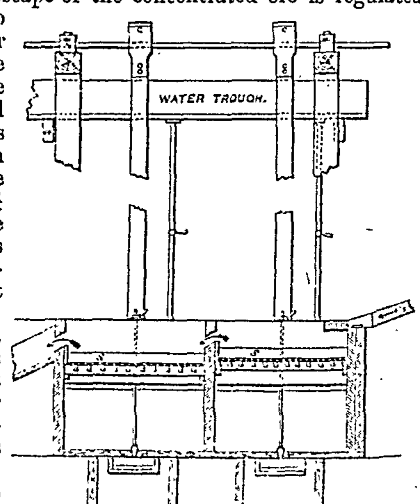

Fig. 100.

Fig. 100 is a section through the two sieves of a Harz sand jig. The pistons act in the manner explained by fig. 99.

The smaller sizes are concentrated by a variety of machines. The action of many of them is based upon the behaviour of particles carried down an inclined plane by a thin stream of water. If the gradient of the plane and the strength of the thin current are properly arranged, the denser particles will be deposited and the specifically lighter ones washed away, although they may be *equal-falling* if allowed to settle in deep water.

The principal machines for concentrating fine sands and slimes are the frame, rotating frame, percussion frame, side-blow percussion frame, revolving belt and Frue vanner, the hand buddle, the round buddle, and the keeve.

Frames. The frame is simply an inclined wooden table upon which a thin deposit is formed by the sheet of ore-and-waste-bearing water which is made to flow over it gently. The stream is then stopped and the deposit washed off by hand or automatically, and collected in pits for subsequent retreatment by similar appliances if necessary.

The rotating frame is a round table with a very flat convex conical surface; the ore for suspension flows on at one part of the centre and forms a thin deposit which is richest at the top and poorest at the bottom, and this deposit is washed off so as to form two classes by means of jets of water, under which the table passes as it turns round. Concave rotating tables, fed at the circumference, are also employed.

The percussion frame, the *Stossheerd* of the Germans, is a table suspended by four chains which receives a succession of blows from a cam in the direction of the stream flowing over it; after each blow it bumps against a piece of timber before receiving the next blow. These bumps cause the ore to settle, and after a thick deposit is formed it is dug off with the shovel, the upper end being richer than the middle or the tail.

Rittinger's side-blow percussion frame is a suspended rectangular table ABCD (fig. 101), receiving blows and bumps on the side and not on the end. A stream of orey water S is fed on at the corner A; clean water W is supplied by the other head-boards H, H, H; and the table is pushed out by cams in the direction of the arrow, and is driven back by a spring so that the cross-piece E strikes against a bumping-block K. The light particles travel down the table much faster than the heavy ones, and take a comparatively straight course; whereas the heavy and richer particles remain on the table, subject to the influence of the side-blows, for a much longer time, and travelling along a curved path reach the bottom at F. The middle class is discharged at G and the poor waste at K. The exact degree of richness of the products can be regulated by altering the pointers, strips of wood which can be turned so as to divide the stream of ore and waste where thought most desirable. The great advantage of this machine over the old percussion frame is its continuous action.

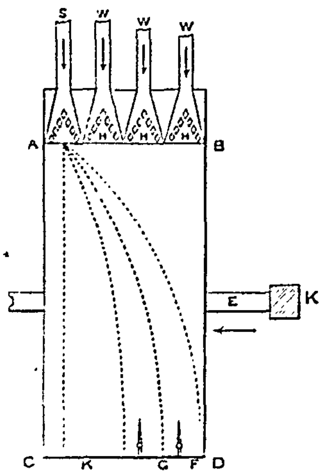

Fig. 101.

Frue vanner. The Frue vanner (fig. 102) may be looked upon as an improved form of Brunton's simple revolving belt. It is an endless band of india-rubber cloth, flanged on each side, which revolves slowly in the direction of the arrows, whilst at the same time it is shaken sideways by a crank motion. The orey water is fed on at A, clean water at B. The natural path of the particles is down the inclined belt, but the specifically heavier ones settle upon it and are carried upwards. Those that can resist the action of the stream of clean water at B go over the end and are washed off as the belt passes through the tank. The poor stuff falls into the waste launder. The degree of concentration can be regulated by the slope and speed of the belt and the strength of the streams of ore and water. The Frue vanner has the disadvantage that it makes only two classes, rich and poor, without any intermediate product.

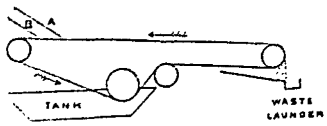

Fig. 102.

Buddles. The hand buddle is a rectangular wooden box with a sloping bottom. A stream of fine ore and waste suspended in water is fed in at the upper end and gradually forms a deposit on the bed of the buddle. A boy with a broom keeps the top of the sediment smooth, so as to ensure regularity of action. After a thick deposit has accumulated, it is dug out in sections which decrease in richness from the upper end (*head*) to the lower end (*tail*).

Round buddles, like rotating frames, are of two kinds, convex and concave. The convex round buddle (figs. 103[1] and 104) is a circular pit with a truncated cone, or head, of varying size in the centre, and a bottom sloping towards the circumference. The orey stream A falling over this head runs down gently, depositing the heaviest particles near the top, the lighter ones further down, whilst the lightest of all flow away at C. The surface of the sediment is kept even by revolving brushes D. This machine may be compared to a number of hand buddles arranged radially round a centre. The deposit that is formed is dug out in rings of varying richness.

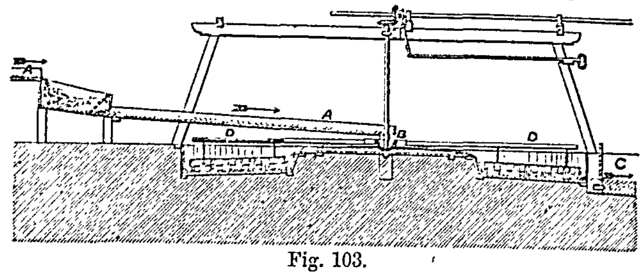

Fig. 103.

Scale.

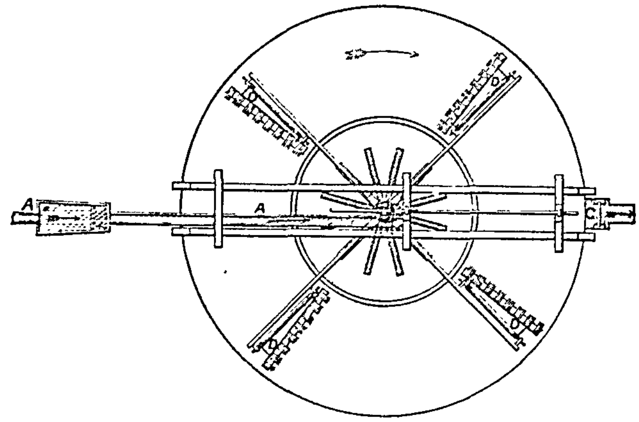

Fig. 104.

The concave buddle is a circular pit with the bottom sloping towards the centre. The stream of ore is fed all round the circumference, and runs inwards to the middle, where the lightest particles escape. The rich head is of course near the circumference.

Keeve. The keeve is a large tub in which the fine stuff is stirred with water and then is allowed to settle from a state of suspension while blows are being struck on the side of the tub. The deposit is afterwards scraped out in layers which increase in richness as they approach the bottom.

Dressing different ores. The series of processes employed in dressing an ore varies, not only according to the nature of the particular mineral to be concentrated, but also according to the size of its particles and the nature of the other minerals with which it is associated.

Gold. With gold the reduction in size is usually effected by stone-breakers and stamps, and much of the metal is then caught by mercury; what escapes is concentrated with its accompanying pyrites by inclined tables covered with blankets, or by buddles, and the concentrate is treated by amalgamation or chlorination. See GOLD, vol. x. p. 746.

Silver. In the case of silver the ore is frequently pulverized by stamps, and the resulting *pulp* amalgamated in pans or barrels. The ore may also be concentrated by any of the various machines described, and delivered to the smelter. Many of the ores of silver are sent to the smelting works without any concentration by water, as this would cause a serious loss.

Lead. Lead ore is generally crushed by rolls, often after a preliminary reduction in size by the stone-breaker. The crushed ore is classified by revolving screens down to the size of 1 mm., and the resulting grains concentrated by jigging; *dredge*, or grains of ore and matrix, must be recrushed, sized, and jigged. The finer sizes are classified by pyramidal boxes and concentrated by frames, rotating tables, and buddles.

Zinc. Zinc ore is dressed in the same way as lead ore; and, as galena and zinc-blende are frequently intimately associated together, it is necessary to separate them by the use of the jig, buddle, and frame.

[1] Henry T. Ferguson, "On the Mechanical Appliances Used for Dressing Tin and Copper Ores in Cornwall," *Proc. Inst. Mech. Eng.*, 1873 pl 41.

Tin. Tin-bearing rock is crushed by the stone-breaker and then stamped fine. The resulting sand and slime may be concentrated by the repeated use of the round buddle, with the keeve for a final cleaning; but often the sand only is enriched by the buddle, whilst the very finest particles, constituting an almost impalpable mud (*slime*) when mixed with water, are treated by frames. When much pyrites is present it is necessary to make a preliminary concentration and roast the enriched product (*witts*) in a furnace. The calcination converts the heavy iron and arsenical pyrites into a light oxide which can be got rid of with the rest of the waste by buddling and framing. The final product from the keeve is clean enough to approach pure cassiterite in the percentage of metal. Alluvial tin ore is concentrated in *sluice-boxes*, and sometimes by jiggers, after a preliminary treatment in a *puddling-machine* (GOLD, vol. x. p. 745) if there are balls of clay which have to be broken up. When the alluvial ore occurs as a hard conglomerate (*cement*), it has to be stamped.

Copper. Copper ores are treated by crushing by rolls and sometimes stamps, sizing by trommels, and then jigging and buddling; but, as some of the ores are very friable and easily carried away by water, hand-picking is employed to a greater extent than with lead and tin ore, and the enrichment by water is not carried so far on account of the inevitable loss that would ensue. The amount of concentration depends upon the distance from the smelting works, and the mine-owner has to calculate whether it is best to get a low price for a large quantity of ore, after paying the carriage, or a higher price for a smaller lot (*parcel*) when due allowance has been made for the cost of dressing and loss sustained in that process. Thus, for instance, in Cornwall, the ore containing copper pyrites is dressed so as to contain only from 5 to 8 or 9 per cent. of metal, because it can easily be conveyed to Swansea by sea, and because further reduction in bulk would cause greater loss in value than the saving of freight.

Loss in dressing. The loss in dressing is very considerable. P. von Rittinger estimates it at from 30 to 50 per cent., and stubborn facts bear out his conclusions. Heaps of refuse from dressing floors are frequently worked over again with profit; and in the year 1881 no less than 909 tons of "black tin" (*i.e.*, concentrated tin ore fit for the smelter), worth £35,283, were extracted from the muddy water allowed to flow away from the dressing floors of some of the principal Cornish tin mines.

The fall in air has been employed instead of the fall in water for concentrating purposes, and several ingenious air-jigs have been constructed and worked upon this principle.

Separation by magnetism. In exceptional cases magnetic attraction may be utilized. Magnetic iron can be separated in this way, and the magnetic process is applied for treating mixed blende and chalybite, the specific gravities of which are too close to render concentration by water practicable. The mixed ore is calcined, and the chalybite is thus converted into magnetic iron, which can be extracted by a magnetic separator, leaving saleable blende.

Recent improvements. Before concluding this part of the subject we will briefly enumerate the principal improvements that have been made in metal-mining during the last quarter of a century. They are as follows:—diamond-drill for prospecting; machine drills for driving, sinking, and stoping; use of compressed air for winding underground; stronger explosives, especially the nitro-glycerin compounds dynamite and blasting gelatin; increased use of steel for various purposes; Blake's stone-breaker and continuous jiggers; extended application of hydraulic mining; larger employment of electricity both for blasting purposes and for signalling by telegraph and telephone. It may be reasonably hoped that ere long electricity will render increased services to the miner for lighting the workings and for the transmission of power.

Recent British legislation. 14. *Recent Legislation affecting Mines in the United Kingdom.*[1]—In England the person owning the surface of a freehold is *prima facie* entitled to all the minerals underneath, excepting in the case of mines of gold and silver, which belong to the crown. The crown, however, does not claim gold and silver extracted from the ores of the baser metals. The ownership of the minerals can be, and often is, severed from that of the surface, the latter being sold whilst the mineral rights are reserved by the original owner. Local customs, now regulated by Acts of Parliament, are still in force in Derbyshire (High Peak Mining Customs and Mineral Courts Act, 1851, 14 & 15 Vict. c. 94, and the Derbyshire Mining Customs and Mineral Courts Act, 1852, 15 & 16 Vict. c. 43) and in the Forest of Dean (1 & 2 Vict. c. 43, and 24 & 25 Vict. c. 40). The Stannaries Act (32 & 33 Vict. c. 19) regulates the commercial dealings of mining companies in Cornwall and Devon, and provides for their liquidation.

The working of mines in the United Kingdom is controlled by five Acts of Parliament, viz., "The Coal Mines Regulation Act, 1872" (35 & 36 Vict. c. 76), "The Metalliferous Mines Regulation Acts, 1872 and 1877" (35 & 36 Vict. c. 77, and 38 & 39 Vict c. 39), "The Stratified Ironstone Mines (Gunpowder) Act, 1881" (44 & 45 Vict. c. 26), and "The Slate Mines (Gunpowder) Act, 1882" (45 Vict. c. 3). The last three Acts simply refer to the annual returns, and exemptions from certain restrictions concerning the use of gunpowder.

The Coal Mines Regulation Act applies to mines of coal, stratified ironstone, shale, and fire-clay. The Metalliferous Mines Regulation Act applies to all mines not included under the Coal Mines Act, and therefore controls not only workings for lead, tin, copper, and iron, commonly known as mines, but also the salt-mines, and underground quarries worked for stone, slate, or other earthy minerals. The principal provisions of the Coal Mines Regulation Act have been set forth at vol. vi. p. 78; those of the Metalliferous Mines Regulation Act are similar, but less strict owing to the almost complete absence of fire-damp. One important difference is that the manager of a mine under the Metalliferous Act need not hold any certificate of competency or service.

Other Acts of Parliament are the "Explosives Act, 1875" (38 Vict. c. 17), regulating the manner in which explosives are stored; the "Elementary Education Acts, 1876 and 1880" (38 & 39 Vict. c. 79, and 43 & 44 Vict. c. 23), regulating the employment of children; the "Factory and Workshop Act, 1878" (41 Vict. c. 16), which applies to the dressing floors of mines under the Metalliferous Mines Regulation Act.

The statute of Elizabeth (43 Eliz. c. 2) which was passed for raising money for the relief of the poor mentions coal mines, but omits other mines; these have been made subject to poor-rates by "The Rating Act, 1874" (37 & 38 Vict. c. 54). The "Employers' Liability Act, 1880" (43 & 44 Vict. c. 42), extends and regulates the liability of employers to make compensation for personal injuries suffered by workmen in their service. Finally, if, as sometimes happens, works are put up at a mine for roasting copper ores with common salt in order to extract the metal by the wet way, the provisions of the "Alkali, &c., Works Regulation Act, 1881" (44 & 45 Vict. c. 37), must be attended to.

It is thus very evident that the laws affecting mines have received most important additions during the last few years.

Accidents. 15. *Accidents in Mines.*—Mining is one of the occupations that may decidedly be called hazardous. This fact has been thoroughly impressed upon the public mind by explosions of fire-damp in collieries; but, though accidents of this kind are appalling, owing to the number of victims who perish at one time, fire-damp is by no means the worst enemy with which the miner has to contend. Falls of roof and sides both in collieries and metal mines are far more fatal in their results. With the risks attending the collier's calling we need not deal, as statistics upon

[1] For information concerning the laws relating to mines in the United Kingdom, see W. Bainbridge, *A Treatise on the Law of Mines and Minerals*, 1878, and Arundel Rogers, *The Law relating to Mines, Minerals, and Quarries in Great Britain and Ireland, with a Summary of the Laws of Foreign States*, 1876.

this subject have been already given (see COAL, vol. vi. p. 79); but the figures below relating to metalliferous mines prove that the occupation of the metal miner is very little less dangerous.

Mines classed under the Metalliferous Mines Regulation Act in Great Britain and Ireland.

1882	33,814	21,692	55,506	30	27	17	74	18	92	2·18	0 83	1·65
Total and averages for the nine years	295,184	196,016	491,200	286	211	202	699	106	805	2·37	0·54	1·63

This table[1] shows that the average accidental mortality of the persons employed *underground* in metalliferous mines is 2·37 per 1000. During the ten years 1873–1882 the corresponding mortality at mines under the Coal Mines Act was 2·57, showing a difference of only 0·20 per 1000 in favour of the metal miner; and when we take the well-known metalliferous district of Cornwall and Devon we find a death-rate for the ten years mentioned of 2·63 per 1000, which therefore exceeds that of coal mines.

Reference to the table shows that more than one-third of the deaths were caused by falls of ground. The actual percentages of the deaths are as follows:—falls of ground 35·5, in shafts 26·2, miscellaneous 25·1, on surface 13·1. The accidents in shafts are due to falls from ladders, cages, and man-engines, ropes and chains breaking, overwinding, and other causes, whilst the miscellaneous accidents include numerous fatalities in connexion with blasting operations. The surface accidents are mostly caused by persons becoming entangled in machinery, and there have been several fatal boiler explosions.

In spite, however, of all the dangers to which miners are exposed, they are less likely to be the victims of accident than railway servants, among whom the rate of fatal accidents varies from 2·5 per 1000 on passenger traffic lines to 3·5 per 1000 on lines possessing a heavy goods traffic.[2]

Statistics concerning accidents in mines are published by many foreign countries; the most minute are those prepared by the Government mining engineers in Prussia. The average annual death-rates per 1000 persons employed below ground and above ground from accidents in mines in Prussia during the fifteen years 1867 to 1881 have been:—coal mines 2·952, lignite mines 2·474, metal mines 1·446, other mines 1·693, all the mines together 2·476. In making any comparison between these figures and those we have given for Great Britain, it is necessary to recollect that the mines under the Coal Mines Act include some workings which in Prussia would be classed as metalliferous, and that British mines under the Metalliferous Act include underground stone-quarries.

Before concluding the subject of accidents, it is necessary to point out that successful efforts have been made of late years to mitigate their results. In the first place, persons equipped with the Fleuss breathing apparatus can now enter mines after explosions, in spite of the noxious and irrespirable gases, and save lives which would otherwise be sacrificed.[3] Secondly, by means of the instruction afforded by classes established by the St John Ambulance Association, miners are learning how best to render first aid to the injured before the arrival of a medical man, and there is no doubt that many valuable lives have been lost in times past for want of this knowledge. Thirdly, a vast amount of good has been done by the establishment of Miners' Permanent Relief Societies in different districts, which afford aid to persons disabled by accidents and to the dependent relatives of those who have unfortunately lost their lives by any mining fatality.

16. *Useful Minerals produced in Various Parts of the Globe.*

Great Britain and Ireland.—The mineral produce of the United Kingdom for the year 1881 is summed by Mr Robert Hunt[4] as follows:—

[1] From *Reports of H.M. Inspectors of Mines for the year* 1882, p. xxxvi.

[2] *The Rate of Fatal and Non-Fatal Accidents in and about Mines and on Railways, with the Cost of Insurance against such Accidents*, by Francis G. P. Neison, London, 1880.

[3] *Reports of H. M. Inspectors of Mines for the year* 1881, Mr Bell's Report, p. 463.

[4] *Mineral Statistics of the United Kingdom* for 1881, p. ix.

Minerals.	Quantities.		Values.		
	Tons	cwts.	£	s.	d.
Coal	154,184,300	0	65,528,327	10	0

Clays	2,401,421	0	1,200,210	0	0
Salt	2,298,220	0	1,149,110	0	0
Barytes	21,313	11	23,894	3	10
Sundry minerals, including coprolites, gypsum, calcspar, shales, &c.	...		349,500	0	0

The total value of minerals produced in 1881 was £76,201,695, 2s., exclusive of slate, building-stone, limestone, and other stones worked by mines and quarries.

The quantity of coal raised in 1882 was 156,499,977 tons.

The metals obtained from the ores produced in the United Kingdom in 1881 were—

Metals.		Quantities.	Values.
			£
Gold	ounces	4½	18
Silver, from ore	"	1,650	360
Silver, from lead	"	308,398	67,140
Pig iron	tons	8,144,449	20,361,122
Tin	"	8,615	839,680
Copper	"	3,875	263,500
Lead	"	48,567	728,805
Zinc	"	14,947	252,608
Other metals, estimated		...	1,275
Total value of metals produced in 1881		...	£22,514,508

The total value of minerals and metals obtained from the mines and other mineral workings of the United Kingdom in 1881 was—

	£
Coal	65,528,327
Metals, as above	22,514,508
Minerals, not reduced—salt, clays, &c.	2,817,652
	£90,860,487

From these tables it is evident that coal and iron are by far the most important mineral productions of the United Kingdom, as 94 per cent. of the total value is due to these two substances.

France.—The mineral productions of France[5] for the year 1880 are set forth in the following table:—

	Quantities.	Values.
	Metric Tons.	Francs.
Mineral fuel	19,362,000	246,687,000
Peat	248,000	2,755,000
Asphalt rock and bituminous shale	144,000	1,023,000
Iron ore	2,874,000	14,909,000
Iron pyrites and sulphur	133,000	2,114,000
Metallic ores	53,000	4,690,000
Rock-salt	333,000	11,814,000
Bay-salt	367,000	6,719,000
General totals	23,514,000	290,711,000

[5] *Statistique de l'Industrie Minérale et des Appareils à Vapeur en France et en Algérie*, Année 1880, Paris, 1882, p. 45.

The quantities of metal produced in France from native and foreign ores in 1880[1] were—

Pig iron	1,725,000 metric tons.	Nickel	30 metric tons.
Lead	6,500 ,, ,,	Gold	31 kilogrammes
Copper	3,400 ,, ,,	Silver	40,400 ,,
Zinc	16,200 ,, ,,	Aluminium	1,150 ,,

Germany.—The mining industry of the German empire is of high importance. The output of the mines in 1881 is shown by the following table,—taken from the *Stat. Jahrb. für das Deutsche Reich*, Berlin, 1883, p. 27. The production of common salt, potassium chloride, and other salts from brine is also considerable. The total quantity for the German empire in 1881 was 693,000 metric tons, worth 33,567,000 marks, including 113,200 tons of potassium chloride valued at 14,090,000 marks.

Austria-Hungary.—Among the famous mines of the Austria-Hungarian empire may be mentioned those of Hungary and Transylvania for gold and silver; Styria produces much of the iron; quicksilver is yielded by the mines of Idria in Carniola, lead and silver by those of Przibram in Bohemia; salt is obtained in the Austrian Alps and in Galicia, which also produces petroleum and ozokerite.

The production of minerals and metals in Austria[5] during the year 1881 was as follows:—

Gold ore	784 metric tons	—Metallic gold	18·6	kilogrammes.
Silver ore	12,383 ,, ,,	— ,, silver	31,359	,,
Quicksilver ore	48,204 ,, ,,	— ,, mercury	398	metric tons.
Copper ore	4,445 ,, ,,	— ,, copper	481	,, ,,
Iron ore	618,963 ,, ,,	— ,, iron	379,639	,, ,,
Lead ore	13,542 ,, ,,	— ,, lead	6,385	,, ,,
		Litharge	2,996	,, ,,
Zinc ore	27 339 ,, ,,	—Metallic zinc	4,119	,, ,,
Manganese ore	9,109 ,, ,,			
Graphite	13.379 ,, ,,			
Petroleum	1,249 ,, ,,			
Lignite	8,961,498 ,, ,,			
Coal	6,343,315 ,, ,,			

Exclusive of salt, the value of the produce of the Austrian mines in 1881 was 44,693,692 florins. The total output of salt in 1881 was 267,279 metric tons, valued according to the monopoly prices at 23,000,498 florins.

Hungary in 1879[6] produced

Gold	1,593 kilogrammes.	Iron	118,321 metric tons.
Silver	18,660 ,,	Coal	674,008 ,, ,,
Copper	1,035 metric tons.	Lignite	932,475 ,, ,,
Lead	1,967 ,, ,,	Iron pyrites	56,282 ,, ,,
Mercury	22 ,, ,,		

Belgium.—Belgium is rich in coal, the output in 1881 being no less than 16,873,951 metric tons, valued at 163,704,242 francs. Though it produces iron ores, it is largely dependent upon other countries, and especially the grand-duchy of Luxemburg, for supplies for its blast furnaces. The principal lead mine is that of Bleiberg, and the calamine deposits in the neutral territory of Moresnet have long been worked with success by the celebrated Vieille Montagne Company, which also owns zinc mines in Belgium, Germany, Sweden, Sardinia, and Algeria.

Russia.—In a vast empire like Russia it is not surprising that there should be valuable deposits of a great variety of minerals. Among the most important are the auriferous alluvia of the Ural mountains and Siberia, which in 1880 yielded 115,940 troy ℔ of gold, worth more than 5 millions sterling. Platinum is found associated with the gold-bearing sands of the Urals; the output in 1880 was 7895 troy ℔. Zinc ore is largely worked in Poland. Important supplies of chromic iron ore are derived from the Urals, amounting in 1880 to more than 8000 tons. The metallic copper produced in 1880 was about 3100 tons, and the oil wells of Baku yielded in that year 346,000 tons of petroleum. Russia also possesses mines of iron ore, manganese, lead, silver, coal, and lignite. A little tin ore is furnished by Finland.

Italy.—The most important mineral in Italy[7] is sulphur, 359,540 tons (metric), worth 36,448,453 lire, having been obtained in 1880, and mainly from seams containing the native element in the Miocene rocks of Sicily and Romagna.

The celebrated iron mines of the island of Elba have been worked from very early times, and furnish a valuable ore; and the deposits of calamine, lead ore, and silver ore in Sardinia form no small proportion of the mineral wealth of the Italian kingdom. The gold mines in and near the Val Anzasca (Piedmont) are producing more than 7000 ounces of metal yearly.

Spain.—Spain is justly celebrated for its mineral wealth. It produces more cupreous pyrites than any other country in the world, and very large amounts of lead ore and quicksilver; and its iron ores are abundant and of excellent quality. The principal lead mines are in the provinces of Jaen (Andalusia) and Murcia, and the total amount of metallic lead produced in Spain or from Spanish ores is estimated to be 120,000 tons yearly.

Cinnabar, the heavy red ore of mercury, naturally attracted attention at a very early date, and the world-renowned Almaden mine has been worked from time immemorial. The output in 1880 was 1387½ tons (metric) of quicksilver.[8]

The cupreous pyrites, often known as sulphur ore, is obtained from the province of Huelva, where vast deposits occur over a belt of country nearly 100 miles long by 20 miles wide. The Rio Tinto mines are the largest in the district, and are worked on a gigantic scale. The company employs upwards of 10,000 hands, or more persons than are engaged in all the Cleveland iron mines, and the output is upwards of a million tons per annum. About one-quarter of this, containing 3½ per cent. of copper, is exported, mainly for the manufacture of sulphuric acid and subsequent treatment for copper and silver, whilst the remaining three-quarters, with 2¼ to 2½ per cent. of copper, are treated on the spot. The ore contains rather less than 1 oz. of silver to the ton, and a few grains of gold. These are profitably extracted from the burnt ore by Claudet's process, and some idea of the importance of the copper and silver will be gained by reference to the following figures.[9] During the year 1881 there were obtained from cupreous pyrites imported into the United Kingdom in 1881, mainly from Spain and Portugal, 14,000 tons of copper, 258,463 oz. of silver, and 1490 oz. of gold. The total value of the silver and gold was £64,195.

The total output of iron ore in 1880 was 3,565,338 metric tons,[10] more than two-thirds, viz., 2,683,627 tons, being obtained from the celebrated mines near Bilbao in the province of Biscay. England, France, Belgium, and Germany are all glad to draw supplies of

10 *Estadistica Minera*, &c., *ut supra*, p. 15.

excellent red and brown hæmatite from the Bilbao mines. Murcia comes next in importance to Biscay, with a production of 539,328 tons.

Portugal.—The great mineral belt of Huelva extends into Portugal, and deposits of cupreous pyrites almost identical with that of Rio Tinto have been wrought from very early ages. The principal mine, San Domingos, is close to the Spanish frontier. It is estimated that the workings had yielded up to the year 1877 no less than 3,578,745 English tons of cupreous pyrites, by far the greater part of this having been extracted in recent times. The quantity of ore raised from the mine in 1882 was 405,029 tons.

Portugal possesses notable manganese mines, but produces comparatively small quantities of iron, lead, and copper.

Norway.—The mines at Kongsberg are famous for the large quantities of native silver they produce, and enormous masses are sometimes met with. The annual output is from 10,000 to 12,000 troy ounces. Copper ore and cupreous pyrites are also mined in Norway, and there are important workings for nickel and cobalt and for apatite. Alluvial gravels have been washed for gold in Norwegian Finland.

Sweden.—The most important mineral obtained in Sweden is iron ore, much being in the form of magnetite; red hæmatite also is mined, and brown hæmatite is dredged up from some of the lakes. The principal iron-producing districts are those of Norberg, Dannemora, Nora, and Perseberg. The output of the Swedish mines in 1880 was—

Iron ore	775,205 tons.	Zinc ore	43,452 tons.
Lead ore	12,958 „	Copper ore	29,380 „

Greece.—One of the most interesting undertakings of modern times has been the re-working of the Laurium mines, which are situated in the southern extremity of Attica; and an account of them written by Cordella furnishes many curious details concerning the methods of mining, washing, and smelting employed by the ancients. The workings for lead and silver appear to have been carried on with the greatest vigour between 600 B.C. and the Peloponnesian War, and were finally abandoned in the 1st century of the Christian era. Huge piles of slag which had accumulated from the old smelting works were found to be well worth being re-worked for silver and lead, and operations were commenced in 1864. Five years later the old heaps of mine refuse began to be treated, and at last in 1875 a French company resumed working the mine. A Greek company employing some 3000 persons is now producing annually from the old mine heaps no less than 8000 to 9000 tons of pig lead, yielding 45 oz. of silver to the ton, whilst the mines of the *Compagnie française des mines du Laurium* made an output in 1881 of 36,664 tons (metric) of roasted calamine, with 40 to 60 per cent. of zinc, in addition to lead ore and mixed ores. Cordella calculates that during the three hundred years the Laurium mines were worked by the ancients the total amount of lead produced was 2,100,000 tons, with 22½ million troy lb of silver. Besides this the ancients left behind two million tons of lead slags containing on an average 10·67 per cent. of lead, 109 million tons of mine refuse with 1½ to 18 per cent. of lead, and excavations to the extent of 51 million cubic yards with lead ore still in sight. They did not touch the calamine deposits.[1] Next in importance to lead, silver, and zinc comes bay-salt, and after that emery. The island of Naxos furnished 3300 metric tons of emery in 1877, valued at £28,000.

Africa.—Algeria is rich in iron, and three-fourths of the value of its total mineral output are due to ores of this metal. In 1880 the iron mines produced 614,000 metric tons of ore, Mokta-el-hadid mine, near Bona, alone yielding about 300,000 tons. Algeria also possesses mines of copper, lead, zinc, and antimony.

The name "Gold Coast" applied to part of the shores of Africa, denotes its productiveness of the precious metal, and it is probable that very important supplies of gold will one day be derived from various districts of the Dark Continent.

Cape Colony possesses rich copper mines in the Namaqualand division, which in 1882 produced ore and metal worth £331,546; however, the most valuable and remarkable mineral deposits of Africa at the present time are the diamond mines. The first diamonds were obtained from recent gravel in the bed of the Vaal river, and it was afterwards discovered that the precious stones could be obtained from the so-called dry diggings. The most important of these, the Colesberg Kopje, now known as the Kimberley mine, produced in 1881 diamonds weighing 900,000 carats, worth £1,575,000. Three other neighbouring mines are Old De Beer's, which yielded 300,000 carats in 1881, worth £600,000, Du Toit's Pan, and Bulfontein. The value of the diamonds raised in South Africa since 1870 amounts to forty millions sterling;[2] indeed the Kimberley mine alone was estimated in 1877 to have already produced ten million pounds worth of diamonds, extracted from 4 million tons of diamantiferous rock.

Asia.—For many centuries India was regarded as possessing fabulous mineral wealth, and a strong basis for this idea may be found in the existence of traces of mining on a very extensive scale. No doubt in early days India did supply what then appeared to be very large quantities of metals, and a country that produces gold and precious stones is apt to be endowed by the popular mind with boundless riches. The actual amounts of mineral raised in India at the present day are comparatively small. Gold exists over considerable areas, but it remains to be proved that the gold mines of the Wynaad and Mysore can be profitably worked by British companies. Diamonds occur and are worked in alluvial diggings and in a conglomerate belonging to the Vindhyan formation. Sapphires and rubies are obtained from Upper Burmah. Ceylon[3] produced in 1880 no less than 10,286 tons of graphite or plumbago, valued at £192,879. Petroleum is abundant in Upper Burmah, and oil from wells has been utilized for upwards of twenty centuries. The total output in 1873 was estimated to be about 10,000 tons yearly. Tin ore occurs and is worked in Tenasserim. Passing into Siam and the Malay Peninsula we find deposits of alluvial tin ore, producing what is known in commerce as Straits tin. A little to the east are the islands of Banca and Billiton, which for many years have been a source of wealth to the Dutch Government. The sales of Banca tin in 1881 amounted to 4339 tons, and those of Billiton tin to 4735 tons, whilst 11,475 tons of Straits tin were exported from Penang and Singapore.[4] Stanniferous alluvia are also worked in Karimon, Singkep, and Sumatra, whilst the latter island possesses also valuable seams of coal.

Borneo furnishes coal, antimony ore, and some cinnabar; and river-gravels are washed for diamonds, gold, and platinum.

There is no doubt that the mineral wealth of China is enormous. In addition to important coal-fields it possesses numerous metallic mines. The province of Yunnan in the south of the empire seems to be specially favoured with regard to metalliferous wealth, for mines of gold, silver, copper, lead, tin, and iron are worked there, whilst jade and precious stones are found in the beds of rivers.

Japan produces more than 3000 tons of copper yearly, or about as much as the British Isles. The output of lead and tin is insignificant, but the quantity of silver, exceeding 300,000 oz. yearly, is worthy of notice. Gold, iron, and petroleum are other products of Japan.

The gold of Siberia has been mentioned in speaking of Russia.

Canada.—The Dominion of Canada is rich in minerals. Gold-bearing quartz veins are worked in Nova Scotia, whilst in British Columbia alluvial deposits are the main source of the supply. Silver occurs on Lake Superior, the most important mine being that of Silver Islet, which from 1869 to the spring of 1877 yielded 2½ million ounces of silver, and gave a profit of £200,000.

Rocks resembling the copper-bearing strata of the United States territory are mined in Michipoten island in Lake Superior. Iron ores, in the form of magnetite, red hæmatite, limonite, and ilmenite, are worked in various parts of Canada.

Petroleum is derived from oil wells in Western Ontario, and the quantity refined in 1875 was about 210,000 barrels, each of 40 gallons. It is in Ontario also that the veins of apatite exist from which a large amount of that useful mineral has been raised.

United States.—The mineral wealth of the United States is admirably summed up by Mr Richard P. Rothwell in his address to the American Institute of Mining Engineers.[5]

"*Production of Coal, Metal, and Petroleum in* 1881.[6]

Anthracite	30,261,940 tons (of 2240 lb).
Bituminous coal	42,417,764 „ (of 2000 lb).
Pig iron	4,144,000 „ (of 2240 lb).
Lead	105,000 „
Copper	31,000 „ „
Quicksilver	59,000 flasks (of 76½ lb. avoir
Gold	$31,870,000 (=1,541,711 oz.).
Silver	$45,078,000 (=34,865,960 oz.).
Petroleum	27,264,000 barrels (of 42 gallons).

"The statistics of other useful minerals and metals show an equally marvellous advance during the past thirty years. The production of pig iron, which in 1852 was 541,000 net tons, in 1861 was 653,000 tons, and in 1871 was 1,708,000 tons. Ten years later, in 1881, we produced no less than 4,144,000 tons, an increase in thirty years of nearly 800 per cent.

"Lead, which appears at 14,400 tons in 1852, varied but little from that figure until the construction of railroads into the argentiferous lead-mining districts of the west about 1870. Eureka, Nevada, Utah, and more recently Colorado, with its Leadville bonanzas. rapidly raised the production from 18,000 tons in 1871 to 47,000 tons in 1873, 75,000 tons in 1877, and 105,000 tons in 1881.

"Our production of copper steadily increased from 1000 tons in 1852 to 31,000 tons in 1881,—the enormous output of that unrivalled mine Calumet and Hecla steadying the production and neutralizing the fluctuations of the lesser mines.

"Quicksilver has shown wide fluctuations, due more to trade combinations than to the condition of the mines. In 1852 the output amounted to 20,000 flasks;

4 Hunt, *Min. Stat.* for 1881, p. 9.

5 *Engineering and Mining Journal*, vol. xxxiv. p. 174.

6 The total production of coal in the United States in 1882 amounted to 86,862,614 tons of 2240 lb (*Colliery Guardian* for 1883, p. 731). The quantities of metals produced in 1882 are estimated to be—pig iron 4,623,323 gross tons of 2240 lb each, lead 123,000 gross tons, copper 40,000 gross tons (*The Iron, Steel, and Allied Trades in* 1882, p. 188; *Eng. and Min. Jour.*, vol. xxxv. p. 27).

but it went as low as 10,000 flasks in 1860, and rose to 53,000 flasks five years later; from this it declined to 15,000 flasks in 1875, though in the following year it grew to 75,000 flasks. Last year we produced 59,000 flasks.

"Gold is the only metal in which our production has been declining. In 1852 it amounted to $60,000,000; but, with some fluctuations, it has now declined to less than $32,000,000 annually.

"The production of silver, on the contrary, has largely increased. Commencing in 1859 with $100,000, it has now attained $45,000,000. In 1877 only were these figures exceeded, and then only by about $1,000,000.

"The production of petroleum, that great American industry, has grown with wonderful rapidity. In 1859 it commenced with only 3000 barrels, and, after an almost uniform increase, it attained last year the enormous figures of 27,000,000 barrels. Scientific investigation has recently raised a note of warning in this industry, asserting the limited area of oil-producing territory and its approaching exhaustion."

Some valuable statistics concerning the production of the precious metals in the United States are contained in a report issued by the Census Bureau.[1] The output for the year ended 31st May 1880 is summed up as follows :—

	Gold.		Silver.		Total.
	Ounces.	Value.	Ounces.	Value.	Value.
Deep mines....	1,033,974	$21,374,152	31,717,297	$41,007,296	$62,381,418
Placers..........	580,767	12,005,511	80,177	103,661	12,109,172
All mines.......	1,614,741	33,379,663	31,797,474	41,110,957	74,490,620

The State producing the greatest value is Colorado, viz., $19,249,172, or gold 130,607 oz. and silver 12,800,119 oz. ; California comes next, having produced $18,301,828 of bullion, and then Nevada, with $17,318,909 of bullion.

The greatest gold producer among the States and Territories is California, with 829,676 oz. of gold, half from deep mines and half from placers. Next follows Nevada, with 236,468 oz. of gold, of which only about 1 per cent. came from placer mines ; then Dakota, 159,920 oz. of gold, nearly entirely produced by deep mines ; and in the fourth rank Colorado, 130,607 oz., with a placer production of less than 5000 oz.

The greatest silver producer is Colorado, with 12,800,119 oz.; then Nevada, 9,614,561 oz.; then Utah, 3,668,365 oz.; Montana, 2,246,938 oz. ; and fifthly Arizona, 1,798,920 oz.

It is useless within the limits of this article to attempt to convey an adequate idea of the enormous mineral resources of the United States. We can merely very briefly allude to some of the principal deposits, which are of commercial value on account of their magnitude, of scientific interest owing to their mode of occurrence, and of technical importance as having led to the introduction of considerable improvements in the arts of mining, milling, and dressing.

Among these may be mentioned the coal and anthracite mines and oil wells of Pennsylvania, the gold and quicksilver mines of California, the silver mines of Nevada, the lead and silver mines of Colorado, and the copper mines of Lake Superior. The articles COAL (vol. vi. p. 60) and GOLD (vol. x. p. 743) may be referred to for information concerning the occurrence of these minerals and the method of extracting gold by hydraulic mining and improved stamping machinery.

Quicksilver in the form of native mercury and cinnabar occurs in considerable abundance in California, and much of it is found in connexion with serpentine, either in the serpentine itself or in sandstone near its junction with serpentine. The most important mines are those of New Almaden in the southern part of the State near San Jose. The deposit at Sulphur Bank in Lake County is of much geological interest. It consists of native sulphur, gypsum, and cinnabar in a decomposed andesitic lava close to an extinct geyser from which boiling water still issues. The top of the bank was worked open-cast for sulphur, and then for sulphur and cinnabar, and now underground mining is carried on in stratified sandstone and shale impregnated with cinnabar and underlying the lava.

Some of the most marvellous silver mines in the world are those upon the Comstock lode in Nevada. A horizontal section of part of this great vein is shown on Plate IV., copied from the excellent and well-known report of Mr J. D. Hague.[2] The strike is nearly north and south, and the dip about 43° to the east. "The vein matter of the Comstock consists of crushed and decomposed country rock, clay, and quartz." "Up to January 1, 1880, the Comstock had yielded in twenty years about $325,000,000 worth of bullion. The total length of shafts and galleries is about 250 miles. The number of men employed in the mines in January 1880 was 2800, earning average wages of $4 a day. At the same date 340 men were at work in the amalgamating mills."[3] The heat of the Comstock lode is remarkable. On the 2700 feet level of the Yellow Jacket mine Mr Becker found the temperature of the water to be 153°, that of the air 126° ; whilst the water in the Yellow Jacket shaft at a depth of 3065 feet has a temperature of 170° Fahr.[4]

During the last few years the Comstock lode has been falling off in productiveness. In 1876 the total yield of the Comstock lode was $38,572,984 (gold, $18,002,906; silver, $20,570,078). During the census year ending May 31, 1880, the product of the whole Comstock district, including outlying veins, was $6,922,330 (gold, $3,109,156; silver, $3,813,174), showing a decline of $31,650,654, or 82·06 per cent., since 1876.[5]

Though the extraction of silver from its ores may be regarded as the business of the metallurgist rather than of the miner, we must not forget to mention that it is to the necessities of the treatment of the Nevada ores that we owe the system of pan amalgamation first developed in that State and practised since in Colorado.

Another district in Nevada which cannot be passed over in silence is that which contains the Eureka and Richmond mines, which are celebrated, not only for the silver they have produced, but also for the important trial in which the issue hinged upon the definition of the term vein or lode (p. 441). The bullion produced in the Eureka district from ore raised and treated during the census year ended May 31, 1880, was—gold, 62,893 oz.; and silver, 2,037,666 oz.; worth altogether $3,934,621.[6]

The history of Leadville in Colorado seems like a romance when we read of the rapid development of the mines, the creation of a large and important town, the erection of smelting works and the building of railways, under very adverse conditions, in the heart of the Rocky Mountains, all within the space of four or five years. It affords additional proof that the miner is the true pioneer of civilization. The main facts concerning the Leadville deposits are admirably summed up by Mr S. F. Emmons, from whose report[7] we borrow, not only the following facts, but also the geological section across the district (Plate IV.).

The principal deposits of the region are found at or near the junction of the porphyry with the Blue limestone, which is the lowest member of the Carboniferous formation. This bed is about 150 or 200 feet thick, and consists of dark blue dolomitic limestone. At the top there are concretions of black chert. The porphyry occurs in intrusive sheets which generally follow the bedding, and almost invariably a white porphyry is found overlying the Blue limestone. This porphyry is of Secondary age ; it is a white homogeneous-looking rock, composed of quartz and felspar of even granular texture, in which the porphyritic ingredients, which are accidental rather than essential, are small rectangular crystals of white felspar, occasional double pyramids of quartz, and fresh hexagonal plates of biotite or black mica. Along the plane of contact with the porphyry the limestone has been transformed, by a process of gradual replacement, into a vein consisting of argentiferous galena, cerussite, and cerargyrite mixed with the hydrous oxides of iron and manganese, chert, granular cavernous quartz, clay, heavy spar, and "Chinese talc," a silicate and sulphate of alumina. The vein seems to have been formed by aqueous solutions, which took up their contents from the neighbouring eruptive rocks and brought about the alteration of the limestone as they percolated downwards through it. In Carbonate Hill, a gradual passage may be observed from dolomite into earthy oxides of iron and manganese. The masses of workable ore are extremely irregular in shape, size, and distribution. They are often 30 to 40 feet thick vertically, and occasionally 80 feet, but only over a small area. The rich ore bodies are commonest in the upper part of the ore-bearing stratum. At Fryer Hill the Blue limestone is almost entirely replaced by vein material.

In the census year ended May 31, 1880, Lake County, Colorado, which includes the Leadville district, produced 28,226 gross tons of lead, with 3830 oz. of gold and 8,853,946 oz. of silver, of a total value of $13,032,464.[8]

The most important copper mines of the United States are those on Lake Superior, where the native metal occurs "in veins, in large masses, or scattered more or less uniformly in certain beds which are either amygdaloid or conglomerates."[9] The principal copper-producing districts are in Michigan, where the Portage Lake district, in Houghton county, contains the famous Calumet and Hecla mine, which alone produced 15,837 tons of copper in 1880, or about half the entire output of the United States. The deposit from whence this vast amount of copper was obtained is a bed of conglomerate, generally called a vein, dipping about 38° north-west. It has been worked for a depth of 2250 feet on the incline. In 1875 the stuff stamped yielded 4½ per cent. of copper.

In conclusion, we will point out that the value of the mining industry in the United States exceeds that of any other country in the world, Mr Porter estimating it for 1879–1880 at 360 million dollars, and that of Great Britain at 325 millions.[10] Germany holds

the third rank, followed by France and Russia. The United States produce 33 per cent.[1] of the gold yield of the whole world, 50 per cent. of the silver, 22 per cent. of the pig iron,[2] 29 per cent. of the steel, and about 25 per cent. of the lead.

Mexico has been renowned for its gold and silver mines ever since the Spaniards first took possession of it, and its production is still very considerable. Indeed, after the United States, it still produces far more silver than any other country in the world. The average annual output of silver during the twenty-five years 1851 to 1875 is estimated by Dr Adolf Soetbeer at 501,520 kilogrammes, or 16,124,235 oz.;[3] whilst the average annual output of gold during the same period was 1785 kilogrammes, or 57,389 oz. Tin ore occurs in considerable quantities in Mexico, and is likely to be worked on a large scale as soon as the tin district is opened up by a railway.

Central America possesses numerous gold mines.

South America.—Venezuela produces gold, copper, and a little lead. The copper is found at Aroa near the north coast, and the gold in the province of Guiana, which is now producing upwards of 100,000 oz. annually. It is highly probable that the existence of this gold was known to the Indians, who reported it to Sir Walter Raleigh, and so led him to undertake his unfortunate expedition in search of "El Dorado." French Guiana contains workable deposits of gold, and yielded 72,168 oz. in 1880.

The chain of the Andes forms a long belt of mineral-producing country. Beginning with the United States of Colombia we have a country rich in gold,—the State of Antiquoia being especially favoured in this respect. The annual yield of all the states is about 200,000 oz. Colombia has mines of rock salt, yielding 19,000 tons a year, and the emerald mine at Muzo has long been famous. Peru is renowned for its silver mines; the best-known are those of Cerro de Pasco, situated at an elevation of 14,000 feet above the sea-level. Passing into Bolivia, we must notice the silver mines of Potosi, the wealth of which is proverbial. Chili is best known as the principal copper-producing country of South America; but its silver mines are not unimportant, and beds of nitrate of soda are largely wrought.

The most remarkable gold mines of Brazil lie in the province of Minas Geraes, whilst diamonds are obtained in that of Matto Grosso. In the Argentine Republic gold, silver, and copper mines are worked, especially in the provinces on the eastern flanks of the Andes.

The total annual output of the precious metal in South America is estimated to be upwards of 300,000 oz. of gold, and 2,000,000 oz. of silver. In 1877 Chili exported 35,128 metric tons of metallic copper, in addition to ore and regulus.

Australia.—Australia is remarkably rich in minerals, especially gold (see GOLD, vol. x. p. 744), tin, and copper, and its coal deposits are likely to be largely utilized in the future.

Queensland, though a young colony, has already made itself famous for gold and tin, and it also possesses vast resources of coal and copper, in addition to the ores of other metals. The quantity of gold sent by escort from the different gold fields was 204,388 oz. in 1880, in addition to what was carried by private hands. Tin ore was first worked in 1872 near the border of the colony with New South Wales, and large quantities of stream tin have been obtained from very shallow alluvial diggings near Stanthorpe. Like gold, the tin ore is not confined to one district; it occurs and is worked at the North Palmer diggings; a little to the south is Great Western, rich in tin ore, and so is Herberton to the north-east on the other side of the Dividing range.

In 1881 New South Wales[4] produced minerals and metals worth £2,373,191, viz., 149,627 oz. of gold, 1,775,224 tons of coal, 8200 tons of tin, 5493 tons of copper, 6560 tons of iron, besides silver, oil-shale, and antimony. In addition to the facts concerning the occurrence of gold already mentioned (*loc. cit.*), it is interesting to note that auriferous conglomerates containing the precious metal in payable quantities have been discovered and worked in this colony in rocks of the age of the Coal Measures.[5] The most important tin district is that of Vegetable Creek in New England, which from 1872 to 1880 produced 20,988 tons of tin ore. The accompanying map (fig. 105[6]) shows the recent alluvium which has hitherto been

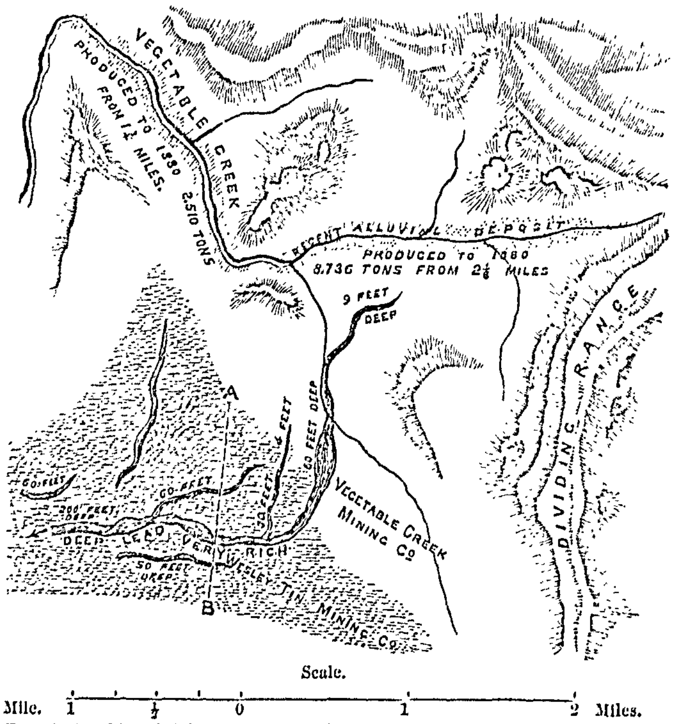

FIG. 105.—Sketch Map of Part of Vegetable Creek, New South Wales, showing recent and ancient tin deposits. The stippled part represents tin-bearing alluvium. The shaded part AB denotes basalt which has covered the lower portions of the ancient tin-bearing alluvia (deep leads), as explained in fig. 106. The rest is granite.

the main source of the supply, and the deep leads which, as far as explored at present, promise still greater riches. The section (fig. 106[6]) shows that these deep leads, like those of the gold fields

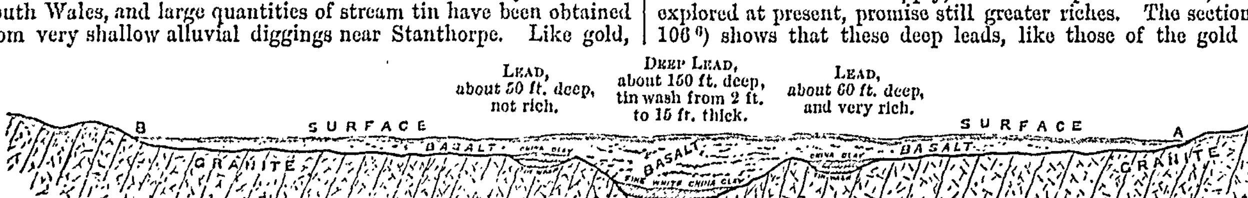

FIG. 106.—Enlarged Section (on AB of fig. 105) across Deep Leads in Vegetable Creek, New South Wales.

(GOLD, vol. x. p. 743), are old alluvia preserved under a capping of basaltic lava. There are also numerous tin lodes which are beginning to be worked.

Victoria heads the list of gold-producing British colonies, having yielded in 1882[7] as much as 864,610 oz., of which 352,078 oz. were derived from alluvial deposits, and 512,532 oz. from quartz mines. 1077 tons of tin ore were raised and 375 tons of antimony ore.

South Australia is the great copper-producing province, though the yield is not so great as it was ten years ago. The principal mines now at work are on Yorke's Peninsula. In 1881[8] South Australia produced 3824 tons of copper, worth £263,370, and 21,638 tons of copper ore, worth £154,926.

In 1881 Western Australia exported 1400 tons of lead ore, valued at £11,204.

Tasmania, like some parts of Australia, is rich in tin ore, which is now obtained principally from an alluvial deposit at Mount Bischoff. The ore is now almost entirely smelted in the colony, and in 1880 the exports were 3951 tons of metal and 3 tons of ore, worth altogether £341,736.

New Zealand furnishes a considerable amount of gold from quartz reefs and alluvial diggings. The annual exports during the ten years 1862 to 1872 were often 600,000 and even 700,000 oz. Of late years the yield has gradually diminished, and in 1880 only 303,215 oz., valued at £1,220,263, were exported. Silver is exported to the

extent of 20,000 to 30,000 oz. annually; it is mainly derived from the gold obtained in the Thames district, which contains about 30 per cent. of the less valuable metal. Coal is worked in several places, but the total output is at present comparatively small.

New Caledonia.—The discovery of nickel ore in this island by M. Garnier in 1867 was one of great mineralogical interest, and it has since borne fruits of considerable commercial importance. The New Caledonia ores are hydrous silicates of nickel and magnesium, which occur in veins in serpentine, and contain from 7 to 18 per cent. of metal. The mineral is found on the Mont d'Or not far from Noumea. Most of the ore is sent to France to be treated.

To the list of works on mining mentioned in the article COAL (vol. vi. p. 81) the following may be added:—Callon, *Cours d'exploitation des Mines*, Paris, 1874, and English translation by C. (C. L. N. F.)

MINISTRY. Ever since the introduction of monarchical institutions into England the sovereign has always been surrounded by a select body of confidential advisers to assist the crown in the government of the country. At no period could a king of England act, according to law, without advice in the public concerns of the kingdom; the institution of the crown of England and the institution of the privy council are coeval. At the era of the Norman Conquest the king's council, or as it is now called the privy council, was composed of certain select members of the aristocracy and great officers of state, specially summoned by the crown, with whom the sovereign usually advised in matters of state and government. In the earlier stages of English constitutional history the king's councillors, as confidential servants of the monarch, were present at every meeting of parliament in order to advise upon matters judicial in the House of Lords; but in the reign of Richard II. the privy council dissolved its judicial connexion with the peers and assumed an independent jurisdiction of its own. It was in the reign of Henry VI. that the king's council first assumed the name of privy council, and it was also during the minority of this sovereign that a select council was gradually emerging from out of the larger body of the privy council, which ultimately resulted in the institution of the modern cabinet. Since the Revolution of 1688, and the development of the system of parliamentary government, the privy council has dwindled into comparative insignificance when contrasted with its original authoritative position. The power once swayed by the privy council is now exercised by that unrecognized select committee of the council which we call the cabinet. The practice of consulting a few confidential advisers instead of the whole privy council had been resorted to by English monarchs from a very early period; but the first mention of the term cabinet council in contradistinction to privy council occurs in the reign of Charles I., when the burden of state affairs was intrusted to the committee of state which Clarendon says was enviously called the "cabinet council." At first government by cabinet was as unpopular as it was irregular. Until the formation of the first parliamentary ministry by William III. the ministers of the king occupied no recognized position in the House of Commons; it was indeed a moot point whether they were entitled to sit at all in the lower chamber, and they were seldom of one mind in the administration of matters of importance. Before the Revolution of 1688 there were ministers, but no ministry in the modern sense of the word; colleague schemed against colleague in the council chamber, and it was no uncommon thing to see ministers opposing one another in parliament upon measures that ought to have been supported by a united cabinet. As the exchange from government by prerogative to government by parliament, consequent upon the Revolution of 1688, developed, and the House of Commons became more and more the centre and force of the state, the advantage of having ministers in the legislature to explain and defend the measures and policy of the executive Government began gradually to be appreciated. The public authority of the crown being only exercised in acts of administration, or, in other words, through the medium of ministers, it became absolutely necessary that the advisers of the sovereign, who were responsible for every public act of the crown as well as for the general policy they had been called upon to administer, should have seats in both Houses of Parliament. The presence of ministers in the legislature was the natural consequence of the substitution of government by parliament for the order of things that had existed before 1688. Still nearly a century had to elapse before political unanimity in the cabinet was recognized as a political maxim. From the first parliamentary ministry of William III. until the rise of the second Pitt divisions in the cabinet were constantly occurring, and a prime minister had more to fear from the intrigues of his own colleagues than from the tactics of the opposition. In 1812 an attempt was made to form a ministry consisting of men of opposite political principles, who were invited to accept office, not avowedly as a coalition Government, but with an offer to the Whig leaders that their friends should be allowed a majority of one in the cabinet. This offer was declined on the plea that to construct a cabinet on "a system of counteraction was inconsistent with the prosecution of any uniform and beneficial course of policy." From that date it has been an established principle that all cabinets are to be formed on some basis of political union agreed upon by the members composing the same when they accept office together. It is now also distinctly understood that the members of a cabinet are jointly and severally responsible for each other's acts, and that any attempt to separate between a particular minister and his colleagues in such matters is unfair and unconstitutional.

The leading members of an administration constitute the CABINET (*q.v.*). The members of an administration who are sworn of the council, but who are not cabinet ministers, are the lord-lieutenant of Ireland, the vice-president of the council for education, the judge advocate general, and the chief officers of the royal household. The subordinate members of an administration who are never in the cabinet, and who are seldom raised to the distinction of privy councillors, are the junior lords of the treasury, the joint-secretaries to the treasury, the paymaster-general, the junior lords of the admiralty, the parliamentary under-secretaries of state, and the law officers of the crown.

During the present century the power of ministers has been greatly extended, and their duties more distinctly marked out. Owing to the development of the system of parliamentary government, much of the authority which formerly belonged to English sovereigns has been delegated to the hands of responsible ministers. As now interpreted, the leading principles of the British constitution are the personal irresponsibility of the sovereign, the responsibility of ministers, and the inquisitorial power of parliament. At the head of affairs is the prime minister, and the difference between theory and practice is curiously exemplified by the post he fills. The office is full of anomalies. Like the cabinet council the prime minister is unknown to the law

and the constitution, for legally and according to the fictions of the constitution no one privy councillor has as such any superiority over another, yet practically the premier is the pivot on which the whole administration turns. He is the medium of intercourse between the cabinet and the sovereign; he has to be cognizant of all matters of real importance that take place in the different departments so as to exercise a controlling influence in the cabinet; he is virtually responsible for the disposal of the entire patronage of the crown; he selects his colleagues, and by his resignation of office dissolves the ministry. Yet, though entrusted with this power, and wielding an almost absolute authority, he is in theory but the equal of the colleagues he appoints and whose opposition he can silence by the threat of dissolution. The prime minister is nominated by the sovereign. "I offered," said Sir Robert Peel on his resignation of office, "no opinion as to the choice of a successor. That is almost the only act which is the personal act of the sovereign; it is for the sovereign to determine in whom her confidence shall be placed." Yet this selection by the crown is practically limited. No prime minister could carry on the government of the country for any length of time who did not possess the confidence of the House of Commons; and royal favour, if it were ever invidiously exercised, would ultimately have to yield to a regard for the public interests. As a general rule the prime minister holds the office of first lord of the treasury, either alone or in connexion with that of chancellor of the exchequer. Before 1806 the premiership was occasionally held in connexion with different other offices,—a secretaryship of state, the privy seal, and the like,—but it is now almost invariably associated with the post of first lord of the treasury. With the exception of the premier, whose duties are more general than departmental, the work of the other members of the administration is exemplified by the title of the offices to which they are called. The lord chancellor, in addition to the jurisdiction which he exercises in his judicial capacity, is prolocutor of the House of Lords by prescription, the keeper of the sovereign's conscience, the general guardian of all infants, idiots, and lunatics, and to him belongs the appointment of all the justices of the peace throughout the kingdom. In former times the lord chancellor was frequently prime minister; the earl of Clarendon in the reign of Charles II., however, was the last who occupied that position. The lord president of the council, who is always a member of the Upper House, presides over the department of the privy council, exercises a general superintendence over the education department, and has to frame minutes of council upon subjects which do not belong to any other department of state. Subordinate to his department are separate establishments in relation to public health, the cattle plague, and quarantine. The post of lord privy seal is one of great trust, though its duties are not very onerous, since they simply consist in applying the privy seal once or twice a week to a number of patents. Ever since the days of Henry VIII. the privy seal has been the warrant of the legality of grants from the crown and the authority of the lord chancellor for affixing the great seal. The lord privy seal is always a member of the cabinet. As his official duties are light he is at liberty to afford assistance to the administration in other ways, and he has often to attend to matters which require the investigation of a member of the Government.

The secretaries of state are among the most important members of the ministry, and within the present century their number has been increased and their duties more specially consolidated. The ancient English monarchs were always attended by a learned ecclesiastic, known at first as their clerk, and afterwards as secretary, who conducted the royal correspondence; but it was not until the end of the reign of Queen Elizabeth that these functionaries were called secretaries of state. Upon the direction of public affairs passing from the privy council to the cabinet after 1688, the secretaries of state began to assume those high duties which now render their office one of the most influential of an administration. Until the reign of Henry VIII. there was generally only one secretary of state, but at the end of his reign a second principal secretary was appointed. Owing to the increase of business consequent upon the union of Scotland, a third secretary, in 1708, was created, but a vacancy occurring in this office in 1746 the third secretaryship was dispensed with until 1768, when it was again instituted to take charge of the increasing colonial business. However, in 1782 the office was again abolished, and the charge of the colonies transferred to the home secretary; but owing to the war with France in 1794 a third secretary was once more appointed to superintend the business of the war department, and seven years later the colonial business was attached to his department. In 1854 a fourth secretary of state for the exclusive charge of the war department and in 1858 a fifth secretaryship for India were created. There are therefore now five principal secretaries of state, four of whom, with their political under-secretaries, occupy seats in the House of Commons. One of these secretaries of state is always a member of the House of Lords. The secretaries of state are the only authorized channels through which the royal pleasure is signified to any part of the body politic, and the counter-signature of one of them is necessary to give validity to the sign manual; thus, while the personal immunity of the sovereign is secured, a responsible adviser for every act is provided who has to answer for whatever course the crown has pursued. The secretaries of state constitute but one office, and are coordinate in rank and equal in authority. Each is competent in general to execute any part of the duties of the secretary of state, the division of duties being a mere matter of arrangement. These duties are of the deepest importance to the welfare of the nation. The home secretary controls all matters relating to the internal affairs of the country: he is responsible for the preservation of the public peace and for the security of life and property throughout the kingdom; he exercises extensive powers over the civil and military authorities of the country, and has a direct controlling power over the administration of justice and police in the municipal boroughs, over the police in and around London, and over the county constabulary; and he is especially responsible for the exercise of the royal prerogative in the reprieve or pardon of convicted offenders or the commutation of their sentences. The foreign secretary, as his name implies, is the official organ of the crown in all communications between Great Britain and foreign powers: he negotiates all treaties or alliances with foreign states, protects British subjects residing abroad, and demands satisfaction for any injuries they may sustain at the hands of foreigners. The secretary of state for the colonies has to superintend the government of the various colonial possessions of the British crown: he appoints the governors over the different dependencies of the crown, and sanctions or disallows the enactments of the colonial legislatures. This latter power has of late years been much curtailed owing to the establishment of responsible government in most of the colonies; still it is the duty of the secretary of the colonies to correspond with the colonial governors and to offer such suggestions as may be expedient to assist the deliberations of the colonial councils and to promote the welfare of colonial subjects. Until the year 1854 the direction of military affairs was practically divided between the commander-in-chief at the horse guards, the board of ordnance, the secretary at war, and the secretary of state for war and the colonies. Upon the declaration of hostilities, however, against Russia in 1854, the duties of war minister were separated from those of colonial secretary, and a secretary of state for war appointed, in whose hands the supreme and responsible authority over the whole military business of the country formerly transacted by the various departments was placed. The actions of the commander-in-chief are subject to the approval of the secretary of state for war. The duties of the commander-in-chief embrace the discipline and patronage of the army and the direct superintendence of the *personnel* of the army; with the exception of those duties, everything connected with the management of the army in peace or war (its *matériel* and civil administration, &c.) remains in the hands of the war minister. The subordinate position of the commander-in-chief is the result of the British system of parliamentary government. The secretary of state for war is the minister of the crown and not of parliament; although he is responsible to parliament for the advice he may give to the sovereign, yet it is in the execution of the royal authority and prerogative that he is superior to the officer commanding in chief. The principle of the constitutional army is that command, preferment, and honour come to it from the crown; but the general principle is equally undisputed that for all pecuniary remuneration it is made to depend on parliament. By the constitution the crown exercises its authority only through responsible advisers, and hence it follows that the secretary of state for war is supreme over any authority in the army, including the officer commanding in chief. From 1784 to 1858 the territories belonging to the British crown in

the East Indies were governed by a department of state called the board of control in conjunction with the court of directors of the East India Company. In 1858 this double government was abolished, and the entire administration of the British empire in India was assumed by the crown, and all the powers formerly exercised by the East India Company and the board of control were transferred to a fifth principal secretary of state. The secretary for India is responsible for everything connected with the Indian Government at home and abroad; the whole of the Indian revenues are at his disposal, and the governor-general of India is subject to his control. To assist him in his labours, and to act as a check upon the exercise of his otherwise arbitrary administrative powers, this secretary has the aid of a council of state for India, consisting of fifteen persons, of which, however, he is the president. The members of the council for India cannot sit in the House of Commons.

The duties of the other members of the ministry can be briefly dismissed. The chancellor of the exchequer at present exercises all the powers which formerly devolved upon the treasury board; he has the entire control of all matters relating to the receipt and expenditure of public money; he frames the annual estimates of the sums required to defray the expenditure of government in every branch of the public service; and it is his duty to lay before the country the annual statement of the estimated expenses of government and of the ways and means by which it is proposed to defray those charges, including the imposition or remission of taxes. The first lord of the admiralty (since the abolition of the office of lord high admiral), with the aid of the junior lords who are called the lords of the admiralty, conducts the administration of the entire naval force of the empire both at home and abroad, and is responsible to parliament for all his political proceedings; as the admiralty is but an executive board, it is, however, subject on certain matters —the number of men required for the naval service, the distribution of the fleet, the strength of foreign squadrons, &c.—to the control of the cabinet. The president of the board of trade takes cognizance of all matters relating to trade and commerce, and has to protect the mercantile interests of the United Kingdom; until 1864 it was not necessary for the president to have a seat in the cabinet, but since that date he has always been a cabinet minister in order to insure for his advice on commercial matters a due consideration; in 1867 the office of vice-president of the board was abolished. The chancellor of the duchy of Lancaster exercises jurisdiction over all matters of equity relating to lands held of the crown in right of the duchy of Lancaster; the office is, however, practically a sinecure, and is usually filled by a leading statesman whose time is at the service of the Government for the consideration of such important questions as do not come within the province of other departments. In 1832 the public works and buildings of Great Britain were for the first time placed under the control of a responsible minister of the crown, and were assigned to the charge of the commissioners of woods and forests; but in 1851 the department of public works was separated from the woods and forests and erected into a board under the name of the office of her majesty's works and public buildings. The first commissioner of works is the head of the board, and in his hands is placed the custody of the royal palaces and parks and of all public buildings not specially assigned to the care of other departments. Since the establishment of his office the first commissioner has frequently had a seat in the cabinet. The duties of the postmaster-general, of the president of the local government board, and of the minor members of the administration are so obvious from the titles of the offices they hold as not to call for any special mention.

The prime minister is responsible for the distribution of the chief offices of government between the two Houses of Parliament. Owing to the development of the House of Commons within the present century it is now considered advisable that a larger proportion of cabinet ministers should have seats in that chamber than was formerly the case. In the first cabinet of George III. only one of its members was in the House of Commons and thirteen in the House of Lords. In 1783 Mr Pitt was the sole cabinet minister in the Commons. In 1801 four cabinet ministers were in the Commons and five in the Lords. In 1804 Mr Pitt and Lord Castlereagh were, out of a cabinet of twelve, the only ministers in the Commons. In the Grenville ministry ("All the Talents"), of a cabinet of eleven, seven were in the Lords and four in the Commons. In 1809, of Mr Perceval's cabinet, six were peers and four commoners. In 1812, of Lord Liverpool's cabinet, ten were peers and only two commoners. In 1818, out of a cabinet of fourteen, six were commoners; and in 1822, out of a cabinet of fifteen, nine were peers. Since the Reform Act of 1832, however, the leading members of Government have been more equally apportioned between the two Houses.

MINK. The genus *Putorius*, belonging to the family *Mustelidæ* or Weasel-like animals (see MAMMALIA, vol. xv. p. 440), contains a few species called Minks, distinguished from the rest by slight structural modifications, and especially by semiaquatic habits. They form the subgenus *Lutreola* of Wagner, the genus *Vison* of Gray. As in other members of the genus, the dental formula is $i\ \frac{3}{3}$, $c\ \frac{1}{1}$, $p\ \frac{3}{3}$, $m\ \frac{1}{2}$; total 34. They are distinguished from the Polecats, Stoats, and Weasels, which constitute the remainder of the group, by the facial part of the skull being narrower and more approaching in form that of the Martens, by the premolar teeth (especially the first of the upper jaw) being larger, by the toes being partially webbed, and by the absence of hair in the intervals between the naked pads of the soles of the feet. The two best-known species, so much alike in size, form, colour, and habits that although they are widely separated geographically some zoologists question their specific distinction, are *P. lutreola*, the *Nörz* or *Sumpf-otter* (Marsh-Otter) of eastern Europe, and *P. vison*, the Mink of North America. The former inhabits Finland, Poland, and the greater part of Russia, though not found east of the Ural mountains. Formerly it extended westward into central Germany, but it is now very rare, if not extinct, in that country. The latter is found in places which suit its habits throughout the whole of North America. Another form, *P. sibiricus*, from eastern Asia, of which much less is known, appears to connect the true Minks with the Polecats.

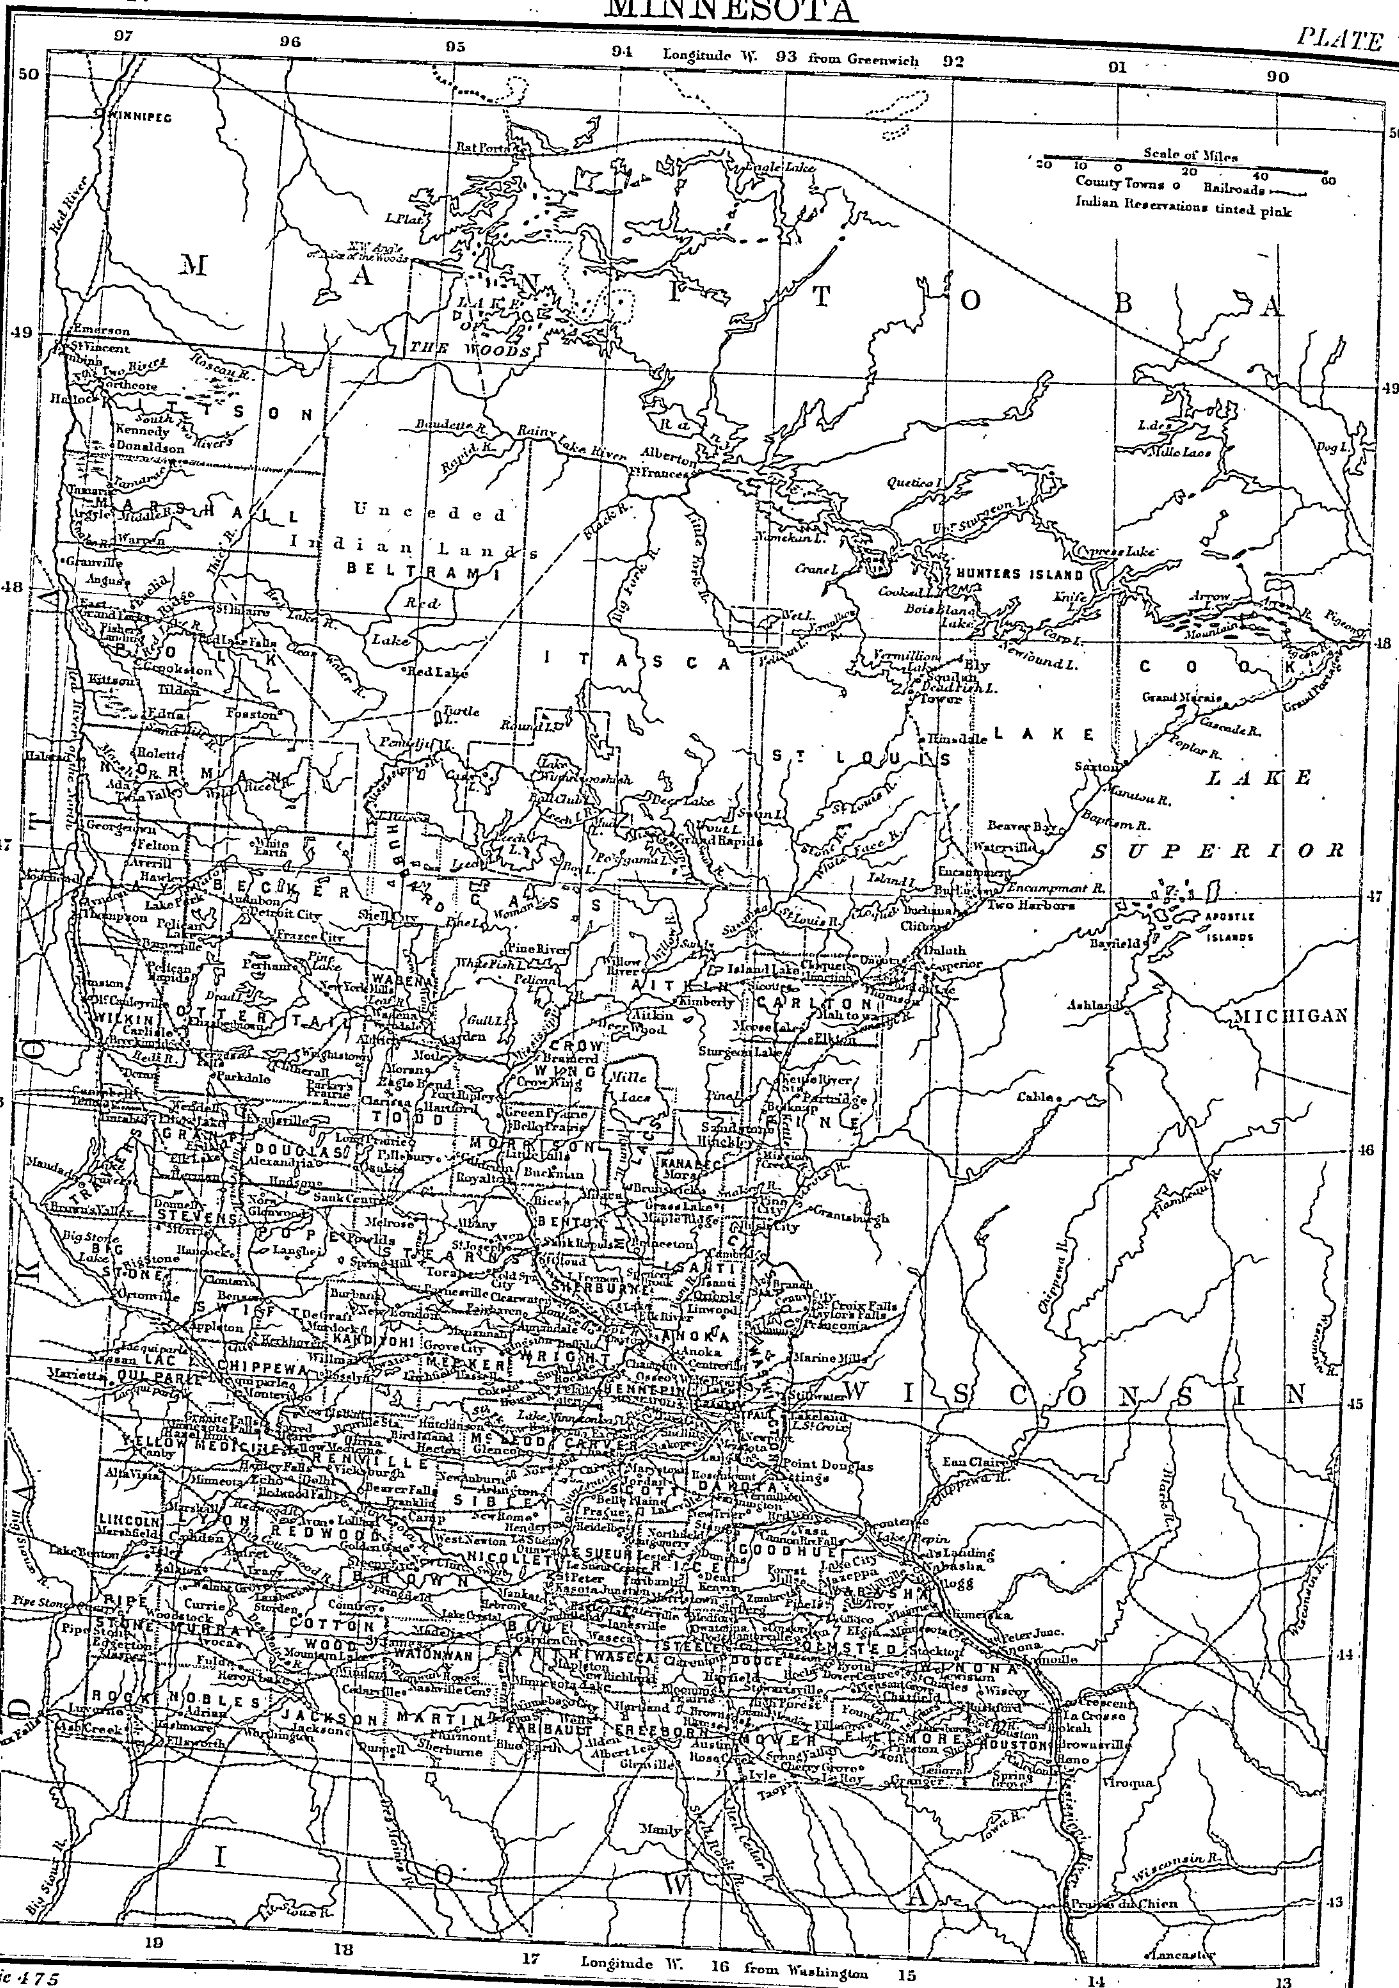
The name may have originated in the Swedish *maenk* applied to the European animal. Captain John Smith, in his *History of Virginia* (1626), at p. 27, speaks of "Martins, Powlecats, Weesels, and Minkes," showing that the animal must at that time have been distinguished by a vernacular appellation from its congeners. By later authors, as Lawson (1709) and Pennant (1784), it is often written "Minx." For the following description, chiefly taken from the American form (though almost equally applicable to that of Europe) we are mainly indebted to Elliott Coues's *Fur-bearing Animals of North America*, 1877.

In size it much resembles the English Polecat,—the length of the head and body being usually from 15 to 18 inches, that of the tail to the end of the hair about 9 inches. The female is considerably smaller than the male. The tail is bushy, but tapering at the end. The ears are small, low, rounded, and scarcely project beyond the adjacent fur. The pelage consists of a dense, soft, matted under fur, mixed with long, stiff, lustrous hairs on all parts of the body and tail. The gloss is greatest on the upper parts; on the tail the bristly hairs predominate. Northern specimens have the finest and most glistening pelage; in those from southern regions there is less difference between the under and over fur, and the whole pelage is coarser and harsher. In colour, different specimens present a considerable range of variation, but the animal is ordinarily of a rich dark brown, scarcely or not paler below than on the general upper parts; but the back is usually the darkest, and the tail is nearly black. The under jaw, from the chin about as far back as the angle of the mouth, is generally white. In the European Mink the upper lip is also white, but, as this occasionally occurs in American specimens, it fails as an absolutely distinguishing character. Besides the white on the chin, there are often other irregular white patches on the under parts of the body. In very rare instances the tail is tipped with white. The fur, like that of most of the animals of the group to which it belongs, is an important article of commerce.

The principal characteristic of the Mink in comparison with its congeners is its amphibious mode of life. It is to the water what the other Weasels are to the land, or Martens to the trees, being as essentially aquatic in its habits as the Otter, Beaver, or Musk-rat, and spending perhaps more of its time in the water than it does on land. It swims with most of the body submerged, and dives with perfect ease, remaining long without coming to the surface to breathe. It makes its nest in burrows in the banks of streams, breeding once a year about the month of April, and producing five or six young at a birth. Its food consists of frogs, fish, freshwater molluscs and crustaceans, as well as mice, rats, musk-rats, rabbits, and small birds. In common with the other animals of the genus, it has a very peculiar and disagreeable effluvium, which, according to Coues, is more powerful, penetrating, and lasting than that of any animal of the country except the Skunk. It also possesses the courage, ferocity, and tenacity of life of its allies. When taken young, however, it can be readily tamed, and lately Minks have been extensively bred in captivity in America both for the sake of their fur and for the purpose of using them in like manner as Ferrets in England, to clear buildings of rats. (W. H. F.)

MINNEAPOLIS, the county seat of Hennepin county, Minnesota, United States, and in 1880 the first city of the State as regards population, lies on both banks of the

MINNESOTA



ENCYCLOPÆDIA BRITANNICA. NINTH EDITION.

Mississippi, at the falls of St Anthony, 14 miles by river above St Paul. The east side was first settled, under the name of St Anthony, which was incorporated as a city in 1860. The west side settlement, named Minneapolis, was incorporated as a city in 1867, and soon surpassed St Anthony in population. In 1872 the two cities were united under the name of Minneapolis. The chief industries are the manufacture of flour and of lumber, for which the falls supply abundant water-power. The Mississippi here flows over a limestone bed resting upon a friable white sandstone; hence erosion is rapid, and the river banks show that the falls have receded from a position at the mouth of the Minnesota river. In 1851 90 feet of the limestone gave way at once; and, as the rock bed extends but 1200 feet above the present site of the falls, the destruction of the water-power was threatened. This has been averted by the construction of an apron, or inclined plane, of timber, with heavy cribwork at the bottom, and the building of a concrete wall in the bed of sandstone behind the falls and underneath the channel of the river. For this work the United States Government appropriated $550,000 and the citizens of Minneapolis contributed $334,500. The city has twenty-seven flour-mills, which can produce 29,272 barrels a day. The total product for the year ended September 1, 1882, was 2,301,667 barrels. The shipments of lumber for 1880 were 164,620,000 feet. The population in 1870 was 18,079; and in 1880, 46,887.

MINNESÄNGER. See GERMANY, vol. x. p. 525.

MINNESOTA, one of the north-western States of the American Union, extending from 43° 30′ N. lat. to the British Possessions (about 49° N. lat.), and from Wisconsin and Lake Superior on the east to Dakota on the west, between the meridians of 89° 39′ and 97° 5′ W. long. Its area, including half of the lakes, straits, and rivers along its boundaries, except Rainy Lake and Lake of the Woods, amounts to 83,365 square miles.

The surface of Minnesota is diversified by few elevations of any great height. In general it is an undulating plain, breaking in some sections into rolling prairie, and traversed by belts of timber. It has an average elevation above sea-level of about 1000 feet. The watershed of the north (which determines the course of the three great continental river systems) and that of the west are not ridges or hills, but elevations whose inclination is almost insensible. The southern and central portions of the State are chiefly rolling prairie, the upper part of which is crossed from N.W. to S.E. by the forest belt known as the Big Woods,—a stretch of deciduous forest trees with an area of about 5000 square miles. North of the 47th parallel, the great Minnesota pine belt reaches from Lake Superior to the confines of the Red River valley, including the region of the headwaters of the Mississippi and its upper tributaries, as well as those of the Superior streams. North of the pine region there is but a stunted growth of tamarack and dwarf pine. In the north-east are found the rugged elevations of the granite uplift of the shores of Lake Superior, rising to a considerable height; while in the north-west the surface slopes away to the level prairie reaches of the Red River valley. The surface elevation of the State varies from 800 to 2000 feet above sea-level. A short line of hills in the north-east reaches the latter altitude, while only the valleys of the Red River, the Mississippi, and the Minnesota fall below the former.

Geology and Soil.—The geology has not yet been mapped out with the precision attained in other States. The great central zone, from Lake Superior to the south-western extremity of the State, is occupied by granitic and metamorphic rocks, succeeded, in the south-east, by narrower bands of later formation. Within the great Azoic area lies the central watershed of the continent, from which the St Lawrence system sends its waters towards the Atlantic, the Mississippi towards the Gulf of Mexico, and the Red River of the North to Hudson's Bay. These primordial rocks carry back the geologic history of Minnesota to pre-Silurian times. They form in the north-east, in the neighbourhood of Lake Superior, an extremely rough and hilly country, but as they reach the central and south-western portions of the State they for the most part disappear beneath the surface drift. This central belt is succeeded, on the south and east, by a stretch of sandstone, partially the true red Potsdam and partially a similar but lighter-coloured stratum, which some have proposed to designate the St Croix Sandstone. Isolated beds of sandstone are found in various parts of the State. The north-western corner, stretching east from the Red River valley, is believed to be Cretaceous; but the great depth of drift and alluvium, disturbed by no large rivers, prevents a positive conclusion. The Lower Magnesian limestone underlies the extreme south-eastern portion of the State, and extends along the west side of the Mississippi to a point a little below St Paul; thence it takes a course almost semicircular, and finally passes out of the State at the south-western boundary. The Trenton limestone occupies a large field in the south and south-east; it comes to the surface in long irregular bands, and an island of it underlies the cities of Minneapolis and St Paul with the adjacent districts. The Galena limestone, the Masquoketa shales, the Niagara limestone, and the rocks of the Devonian age in turn prevail in the other counties of the south and east; while the existence of the St Peter sandstone would scarcely be known but for its outcropping along the bluffs of the Mississippi, and at the famous waterfall of Minnehaha. From these various formations numerous kinds of stone valuable for building purposes are obtained. The grey granite of St Cloud is extremely hard and enduring. The Lower Magnesian furnishes two especially handsome building stones,—the pink limestone known as Kasota stone, and the cream-coloured stone of Red Wing, both easily worked, and hardening by exposure to atmospheric changes. Naturally, from its location underneath the principal cities of the State, the Trenton limestone is the most widely used. Sand suitable for glass-making, and argillaceous deposits abound. The clays which make up so large a portion of the surface drift of the State are almost wholly of glacial origin. Overlying the deposits of sand, gravel, boulders, and clay is, in most portions of the State, a sandy loam, very finely divided, rich in organic matter, deep brown or black in colour, and of the greatest fertility. It is this soil which has given to the State its reputation for productiveness. Its depth varies from 2 to 5 feet in various parts of the State, and it has been described by Dr Owen as "excellent in quality, rich as well in organic matter as in those mineral salts which give rapidity to the growth of plants, while it has that durability which enables it to sustain a long succession of crops."

Rivers and Lakes.—The State holds a unique place in the great water systems of the continent. The Mississippi, which takes its rise north of the centre of the state in Lake Itaska and its contributory lakelets, leaves the state limits a great river, half a mile wide, and from 5 to 20 feet deep. It drains with its tributaries all the southern and central portions and a large area of the northern part of the State. It is navigable as far as St Paul, and at Minneapolis the falls of St Anthony afford unrivalled facilities for manufacturing. Of the many affluents of the Mississippi the most important is the Minnesota, which after a course of about 440 miles flows into the main stream at Fort Snelling, 3 miles above St Paul. The source of the Minnesota is but 1 mile from Lake Traverse, the origin of the Red River of the North, and it is navigable during the high-water season for about 238 miles. Its principal tributaries are the Blue Earth, Chippewa, Redwood, Lac qui Parle, and Pomme de Terre. The Red River system drains the north-western part of the State, and its waters

finally pass into Hudson's Bay, as also do those from the country drained by streams flowing to the Rainy Lake river and the lakes along the northern boundary line. East of this lies the region tributary to Lake Superior and the St Lawrence system. This comprises an area within the State estimated at 9000 square miles. Its principal river is the St Louis. There are altogether about 2796 miles of navigable water in Minnesota.

The number of lakes is estimated at seven thousand. They are of all sizes, and are found chiefly in the northern two-thirds of the State. They have been classified geologically into glacial or drift lakes, fluviatile or river lakes, occupying basins on river courses, and lakes having rock basins either scooped out by the action of glaciers or formed by the relative position of different geological formations. By far the greater number give evidence of glacial action in their origin. They abound over the region most deeply covered by the surface drift, and are especially prevalent in morainic districts, forming the southern fringe of the lacustrine area of North America. With the melting of the ice-sheet which once overspread Minnesota its innumerable lakes came into existence; and the gentle acclivity of its slopes, precluding rapid erosive action, has tended to give permanence to the depressions constituting their basins. The census returns give 4160 square miles of water surface within the State. Most of the lakes are exceedingly picturesque in their surroundings. Forests skirt their shores, which are seldom marshy; and their waters, abounding in various kinds of fish, are clear and cool. Besides the sanitary advantages afforded by the lakes, as supplying places for recreation and delightful summer resorts, they affect the climate to some extent, tempering the extremes commonly experienced in northern latitudes. The fact that many of the lakes are gradually drying up must be explained by agricultural operations. The largest lakes, exclusive of Superior, lying wholly or in part in Minnesota are as follows:—Lake of the Woods, 612 square miles; Red, 342; Mille Lacs, 198; Leech, 194; Rainy, 146; Winnibigoshish, 78; and Vermilion, 63.

Flora and Fauna.—The flora and fauna present no marked differences from those of other States in the same latitude. In a partial list of the birds of Minnesota, two hundred and eighty-one species are enumerated. Of winter birds fifty-two species have been classified, twenty-three of them being permanent residents.

Climate.—The State lies so far north as to have a low mean annual temperature, and so far inland as to have the characteristic continental climate. Its elevation above sea-level gives an agreeable rarefaction to the atmosphere, and makes the prevalence of fogs and damp weather unknown. Between June and January there is an annual variation from the summer heat of southern Ohio to the winter cold of Montreal. The winter, usually commencing in November, and continuing till near the end of March, is not a period of intense continued cold, but is subject to considerable variations. As a rule, the comparative dryness of the atmosphere neutralizes the severest effect of excessive cold. The snowfall is extremely light during most of the winter, but as spring approaches precipitation becomes greater, and there are frequently heavy snowfalls in February and March. The change from winter to summer is rapid, vegetation sometimes seeming to leap into full and active growth within the space of a few weeks. The summer months bring days of intense heat, but, with comparatively rare exceptions, the nights are deliciously cool. Hot days and cool nights make the ideal weather for a good wheat crop; and the forcing heats of summer produce in luxuriant growth the vegetable life which belongs to the middle States. The Smithsonian chart assigns to Minnesota an average temperature for the hottest week in summer of from 85° to 90°, and for the coldest week in winter from 10° to 20° below zero. The mean annual average, for all below 47° of latitude, it gives as 40°. Observations at St Paul, extending over a period of more than thirty-five years, show the following mean temperatures:—spring, 45°·6; summer, 70°·6; autumn, 40°·9; winter, 16°·1; average, 44°·6. The average annual rainfall is about 25·5 inches. While this is not large, it is so distributed as best to subserve the purposes of vegetable growth. No moisture is lost in superfluous spring and autumn rains, or in the cold and non-producing part of the year, the precipitation, which in winter is less than 2 inches, increasing to about 12 for the summer. To the season of vegetable growth belong 70 per cent. of the yearly measures of heat, 76 per cent. of the rainfall, and 76 per cent. of the atmospheric humidity. The prevailing winds are from the south or south-east. In 1880 rain or snow fell on 150 days, and in 1881 on 167. It is evident that the causes which mitigate the actual severity of the climate as felt, which produce so large a number of clear days, and which forbid the continued presence of a large amount of moisture in the atmosphere, are those which render a climate healthful in the highest degree. Minnesota has been for many years a favourite resort for invalids. The curative properties of its climate are especially marked in the case of pulmonary complaints.

Agriculture.—The leading industry of the State is agriculture. The character of the surface soil varies in different parts of the State with the character of the underlying strata. The fertile land comprises about three-fourths of the entire area of the State. The drift soil proper of the south and centre, including the Minnesota valley and the greater part of that of the Mississippi, contains silica and calcareous matter, and is interspersed with alluvial river bottoms. The limestone soil, in which there is a large calcareous element, lies chiefly on the western slope of the Mississippi. The Red River valley consists of an argillaceous mould, rich in organic deposits. Around Lake Superior, wherever arable land is to be found, it is marked by a rich trap soil. North of the central fertile area, and in the neighbourhood of the sources of the Mississippi, is much swampy land, susceptible of easy drainage, with a large tract of sand and other drift detritus, unfavourable to production. Maize and potatoes flourish, and the uplands, which support hardwood ridges, are suited to general agriculture. To the extreme north the surface, while indicating mineral wealth, is utterly unfit, except in occasional isolated areas, for purposes of tillage.

Wheat has hitherto been the staple product of the State. Soil and climate are such as to ensure a large average yield, while the superior quality of the grain has given it a wide reputation. The other cereals are also cultivated with success. The tendency to diversify agriculture, especially in the southern part of the State, has been stimulated by several partial failures of the wheat crop, the locust invasions, and the competition of the farther north-west.

The area of the State includes 39,791,265 acres surveyed, 10,968,575 acres not surveyed, and 2,700,000 acres of lake surface. The total sales of public and railroad lands in 1879 and 1880 were not far from 4,000,000 acres. It is estimated that the aggregate of lands yet undisposed of, three-fourths of which may be profitably cultivated, is nearly 20,000,000 acres, exclusive of the lands belonging to the State. White Earth Indian reservation has thirty-six townships of prairie and timber land; and Red Lake reservation contains 3,200,000 acres.

Forestry.—A special census bulletin estimates the amount of merchantable white pine standing, May 31, 1880, as amounting in all to 6,100,000,000 feet. The entire cut for the census year 1880 was 540,997,000 feet. Of hardwood forest 3,840,000 acres remain, capable of yielding 57,600,000 cords of wood.

Every encouragement is afforded, both by the railway corporations and the State, to tree-planting on the prairies. A quarter section is given to any one who will plant and keep in good condition 40 acres of timber for eight years. In 1880 there were planted 25,331 acres of trees, exclusive of those bordering highways and the windbreaks along the railroad lines.

Manufactures.—The manufactures of Minnesota are yet in their infancy. The abundant water-power of the State, its proximity to the coal-fields of Iowa, its superior transportation facilities, and the large demand for manufactured commodities are, however, rapidly developing this branch of industry. The most important industries are the manufacture of flour and that of lumber. The former naturally established itself in a State of immense wheat yield and abundant water-power. It received its greatest stimulus from the invention and adoption of the middlings purifying process, which produces the highest grade of flour, and to which the hard spring wheat of Minnesota is especially adapted. Among other manufacturing industries actively prosecuted are the making of brick, pottery, stoneware, and agricultural implements, and also meat-packing.

Commerce.—The geographical position of Minnesota gives it extensive commercial interests. Two continental waterways terminate within the State. The Mississippi affords continuous navigation to European ports during eight months of the year. From Duluth numerous lines of vessels traverse the chain of great lakes, and transport the products of the west to the eastern seaboard. Three great transcontinental railway lines are connected more or less directly with the railroad system of the State. Twelve lines of railway from every part of Minnesota converge at the contiguous cities of St Paul and Minneapolis, and three great trunk lines from these centres to Chicago secure the advantages of a lively competition.

Education.—The common school system is supported by land grants, a local tax, and a State tax. The superintendent of instruction is appointed by the governor. County superintendents are chosen by popular vote. Common school districts have boards of three trustees each. Six directors are appointed for independent districts. The permanent fund in 1881 was $4,850,000, and the current fund $260,835. The State university, located at Minneapolis, is governed by a board of regents, consisting of the governor of the State, the superintendent of public instruction, the president of the university, and six others; both sexes are admitted, and tuition is free. The State supports three normal schools. Forty-two academies and six colleges are sustained by denominational or private enterprise.

Administration.—The departments of Government are, as in all the States, the legislative, the executive, and the judicial. The State contains seventy-eight counties, of which some are still subject to change of boundary. From these are elected by districts forty-seven senators and one hundred and three members of the House of Representatives. The State officers are a governor, lieutenant-governor, secretary of state, treasurer, and attorney-general, all elected by the people. The term of office is two years.

The governor has power to veto separate items of a money bill. The judiciary is elective, and the term of office seven years. The State requirements for citizenship are residence in the United States one year, in the State four months, and in the election district ten days preceding an election. Women are allowed to vote for school officers and upon questions relating to the management of schools, and are also eligible to such offices. No county can contain more than 400 square miles. The legislature meets biennially. Extra sessions may be called, but no session can exceed sixty days in length. Under the last apportionment the State is entitled to five representatives in the national Congress.

The annual valuation of property for 1882, as equalized by the State board, gives the personal property as $79,219,445, the real estate $242,938,170. This represents a total actual value of not far from $750,000,000.

While Minnesota was still a Territory, but after it had adopted a State constitution, an amendment was added to the constitution authorizing the issue of a large amount of bonds in aid of railway construction. Shortly afterwards, the companies having failed to fulfil their contracts and defaulted payment, the State foreclosed its mortgage on the lands, franchises, &c., of the roads, and turned them over to other companies. By another amendment to the constitution, the payment of the bonds was made contingent upon the result of a popular vote. Several proposals having failed to receive this sanction, the necessity for it was removed in 1881 by a decision of the supreme court, declaring the amendment unconstitutional. The legislature immediately met, accepted a plan of settlement proposed by the bondholders themselves, and over $4,000,000 worth of new bonds were issued in exchange for the old. For the payment of the principal and interest of these the people have voted (November 1882) to set aside as a sinking fund the proceeds of 500,000 acres of land belonging to the State internal improvement fund, the deficit to be paid out of the tax on railroad earnings. These bonds include all the State debt except about $200,000. A tax of 3 per cent. imposed on the gross earnings of all railroads within the State will soon meet all expenses except provision for educational, penal, and charitable institutions.

Population.—The population of the State was 6077 at the census of 1850, 172,023 in 1860, 439,706 in 1870, and 780,773 (419,149 males and 361,624 females) in 1880. According to the last census 299,800 whites had been born in the State; and of the 267,676 foreign-born inhabitants of the State 107,770 came from Scandinavian countries and 68,277 from the United Kingdom and the British colonies, while 77,505 acknowledge the German as their native tongue. The increase of population in the State for the last decade of years alone was 75 per cent. The most important cities are St Paul, the capital, and Minneapolis, with 41,473 and 46,887 inhabitants respectively in 1880; Winona had 10,208 and Stillwater 9055.

History.—Missionary efforts and the trading spirit first induced white men to venture as far into the unexplored north-west as the boundaries of what is now the State of Minnesota. The earliest accounts of its natural features and native tribes appear in the Jesuit writings. The "Relations" of 1670–71 allude to the Sioux or Dakotas. In 1678 a company was formed for trading with this tribe. Du Luth was leader of this expedition, and later on went from Lake Superior to the Mississippi by canoe. But the first published account is that of Louis Hennepin, a Recollect monk, who, in 1680, visited the falls of St Anthony, and gave them their name, from that of his patron saint. For a century the only visitants of the wild region were a few missionaries, and a number of fur traders who found the profit of the journey to more than counterbalance its perils and hardships. To the latter class belong Perrot, who reached the Mississippi by way of the Fox and Wisconsin in 1684, and founded at Lake Pepin the first trading post in the State, and Le Sueur, a Canadian, who ascended the great river from its mouth, and established another post above Lake Pepin. Captain John Carver, the explorer of the country of the upper Mississippi, visited the falls of St Anthony in 1766, being the first British traveller who reached the spot. On March 20, 1804, Upper Louisiana was organized, consisting of Arkansas, Missouri, Iowa, and a large portion of Minnesota. From this time onwards the progress of exploration was rapid, and settlement followed in its train. The first really extensive exploration of any large part of what is now Minnesota was made between 1817 and 1823, by Major S. H. Long, of the United States engineer corps, in command of a Government expedition. About the same time the Red River received its first visitant. Thomas Douglas, earl of Selkirk, an Englishman of eccentric character, went, in 1817, to what is now Winnipeg, by way of York river. Having been struck with the agricultural possibilities of the region about the Red River of the North, he induced a colony of Swiss farmers to settle there. These were disappointed in the country, and unused to the severity of the climate, so that they finally removed to the vicinity of St Paul and contributed to the earliest development of the agricultural industry of the State. In 1821 Colonel Snelling built, at the junction of the Minnesota and Mississippi rivers, a stronghold which he named Fort St Anthony. The name was changed to Fort Snelling in his honour, in 1824, and the fort is still an important post as a base of supplies for the newer north-west. The first steamboat made its appearance at the head of navigation in 1823. The settlement of St Paul, one of the oldest towns as well as the capital, is commonly dated from 1846, at which time there were a few shanties on its site. Population now began to arrive in constantly increasing numbers, and on March 3, 1849, a bill passed Congress for organizing the Territory. It was proposed at one time to name it Itasca, but the name Minnesota, meaning, "sky-tinted water," and originally applied to the river bearing that title, was finally retained. The western boundary of the territory was fixed at the Missouri river. The population was but 4057, the largest town had but a few hundred inhabitants, and a large part of the soil of the State still belonged to the Indians. But progress now began in earnest. A constitution was adopted in 1857, and on May 11, 1858, Minnesota was admitted as a State, with a population, according to the last Territorial census, of 150,037.

One of the first acts of the new State was the issue of the railroad bonds noticed above. Soon after came the civil war. Within two months of Lincoln's first call for troops the first Minnesota regiment, over one thousand strong, was mustered into service. By August of 1862 ten regiments had been called for and furnished. In all, the State supplied to the armies of the Union 25,052 men, or about one-seventh of its entire population at the outbreak of the war.

In the meantime there occurred, in 1862, the horrible outbreak known as the Sioux massacre. Settlements were cut off, isolated settlers murdered, and even a strong post like Fort Ridgely was attacked. The outbreak spread over a large portion of the State; several severe engagements were fought; and it was not until the State had a thoroughly equipped military force ready for the campaign that the Indians begun to flee or to give themselves up. By this time over 700 persons had been murdered, 200, chiefly women, taken captive; eighteen counties were ravaged, and 30,000 people were homeless. The property loss was not less than $3,000,000.

During these local and national disturbances the material prosperity of the State was unabated. Notwithstanding the heavy cost of the civil war and the Sioux massacre, the census of 1865 showed a population of 250,099. Railroad construction began to be energetically carried forward; in 1870 329 miles were made and 1096 miles were in operation; a road to Lake Superior was completed, and the Northern Pacific was fairly under way. In 1873–76, and to some extent in 1877, successive visitations of locusts destroyed the crops of the south-western counties. The sufferers were relieved by the State, and no repetition of the scourge has since been experienced. (J. G. P.)

MINNOW (*Leuciscus phoxinus* or *Phoxinus lævis*) is the smallest British Cyprinoid, readily distinguished by its very small scales. It is abundant in rivers, brooks, and lakes, always swimming in schools, and shifting its ground in search of food, which consists of every kind of vegetable and animal substance. It ranges from southern Europe to Scandinavia, and from Ireland into north-eastern Asia; in the Alps it attains to a higher altitude than any other Cyprinoid, viz., to nearly 8000 feet. Its usual size varies between 2 and 3 inches; but in suitable localities, especially in Germany, it is known to reach a length of from 4 to 5 inches. The colours vary with age and season; a series of dark spots or cross-bands along the sides is always present, but the males assume in summer a nuptial dress of scarlet or purple on the lower parts of the head and body. The minnow is used as bait; it can also be introduced with facility and with great advantage into ponds in which there is otherwise a scarcity of food for more valuable fishes, such as trout, perch, and pike.

MINO DI GIOVANNI (1431–1486), called DA FIESOLE, was born at Poppi in the Casentino in 1431. He had property at Fiesole, whence his usual name. Vasari's account of him is very inaccurate and full of contradictions. Mino was a friend and fellow-worker both with D. da Settignano and Matteo Civitale, all three being about the same age. There is considerable similarity in their works, showing mutual influence. Mino's sculpture is remarkable for its gem-like finish and extreme delicacy of detail, as well as for its spirituality and strong devotional feeling. No other sculptor portrayed the virginal purity of the Madonna or the soft infant beauty of the Divine Child with greater tenderness and refinement. Of Mino's earlier works, the finest are in the duomo of Fiesole, the altarpiece

and tomb of Bishop Salutati, executed about 1464. In the Badia of Florence are some of Mino's most important sculptures—an altarpiece, and the tombs of Bernardo Giugni, 1466, and the Margrave Hugo, 1481—all sculptured in white marble, with beautiful life-sized recumbent effigies and attendant angels. The pulpit in Prato cathedral, finished in 1473, is very delicately sculptured, with bas-reliefs of great minuteness, but somewhat weakly designed. Soon after the completion of this work Mino paid a visit of some years to Rome, where he executed several fine pieces of sculpture, such as the tomb of Pope Paul II. (now in the crypt of St Peter's), the tomb of Francesco Tornabuoni in S. Maria Sopra Minerva, and a beautiful little marble tabernacle for the holy oils in S. Maria in Trastevere. There can be little doubt that he was also the sculptor of several of the very lovely monuments in S. Maria del Popolo, especially those in the sacristy of Bishop Gomiel and Archbishop Rocca, 1482, and the marble reredos, also in the sacristy, given by Pope Alexander VI. Some of Mino's portrait busts and delicate profile bas-reliefs are preserved in the Bargello at Florence; they are full of life and expression, though without the extreme realism of Verrocchio and other sculptors of his time. He died in 1486.

MINORITES. See FRANCISCANS.

MINOS, a legendary king of Crete, in whom both historical and religious elements are united. The historical element lies in the fact that an early civilization and maritime power had its seat in Crete. The Phœnician intercourse played a great part in developing this island state, and Minos is sometimes called a Phœnician. The name Minoa is often found where Phœnician influence was strongest, *e.g.*, at Megara. The laws and constitution which existed from a very early time in Crete were attributed to Minos, to whom they were revealed by Zeus. After his death he became the judge of the dead; he is one of the forms assumed by the old conception of the first man, who is after death king and god among the dead. It is therefore highly probable that the name Minos is the Greek form of the original *Manva*, *i.e.*, "endowed with thinking," which is seen in the Hindu Manu and the Germanic Mann. As in all other heroized forms of the god of the dead, there is both a terrible and a wise and beneficent side in the character of Minos. Cretan legends described him as the wild huntsman of the forests and mountains, the lover of the nymphs, though his love means death to them. His death is localized in the far west, in the land of sunset; his grave was shown at Camicus near Agrigentum, attached to a temple of Aphrodite. He pursued Dædalus thither, and the daughters of Cocalus, the king of Agrigentum, killed him by pouring boiling water over him in the bath, an obvious myth of the sun dying in the sea. Minos, the god of the dead, is, according to the usual rule, the sun-god, who goes to illumine the dead when he dies on the earth. His wife is Pasiphae, the moon-goddess, who had an oracle by dreams at Thalamæ in Laconia. The union of the sun and the moon, the bull and the cow, gave rise to many quaint and ugly legends: Pasiphae loved the bull of Minos, was aided by the stratagem of Dædalus, and gave birth to the Minotaur, half bull and half man. The Minotaur is one of those monstrous forms which were suggested to the Greek fancy by the quaint animals common in Oriental art. It was shut up in the LABYRINTH (*q.v.*), which was constructed by the skilled artist Dædalus. Now a son of Minos named Androgeus had been killed by the Athenians, and Minos as a punishment required that seven youths and seven maidens should be sent every ninth year and given up to the Minotaur to be devoured. When this sacrifice took place for the third time Theseus came as one of the hostages, and slew the Minotaur with the help of Ariadne. Throughout these legends we see the close relation of Minos to the Phœnician sun-god Melkarth, and perceive the way in which different places where Phœnician influence can be traced, Athens, Sicily, &c., are brought together in religious myths.

MINOTAUR. See MINOS.

MINSK, a western government of Russia, is bounded by Vilna, Vitebsk, and Moghileff on the N. and E., and by Tchernigoff, Kieff, Volhynia, and Grodno on the S. and W., and has an area of 35,175 square miles. The surface is undulating and hilly in the north-west, where a narrow plateau and a range of hills of the Tertiary formation runs to the north-east, separating the basin of the Niemen, which flows into the Baltic, from that of the Dnieper, which sends its waters into the Black Sea. The range, which averages from 800 to 1000 feet, culminates in Lysaya Gora (1129 feet). The remainder of the province is flat, 450 to 650 feet above the sea-level, covered with sands and clays of the glacial and post-glacial periods. Two broad shallow depressions, drained by the Berezina and the Pripet, cross the province from north to south and from west to east; and these, as well as the triangular space between them, are covered with immense marshes (often occupying 200 to 600 square miles), numberless ponds and small lakes, peat-bogs, downs, and moving sands, as well as with dense forests. This country, and especially its south-western part, is usually known under the name of Polyesie ("The Woods"). Altogether, marshes take up 15 per cent. and marshy forests no less than 55 per cent. of the entire area of the province (60 to 71 per cent. in several districts). The forests, however, consist of full-grown trees in the higher districts of the north-west only, those which occupy the marshy ground consisting of small and stunted pine, birch, and aspen. The climate of the Polyesie is harsh and extremely unhealthy; malarias and an endemic disease of the bulbs of the hair (*koltun*, *plica Polonica*) are the plagues of these tracts, the evil being intensified by the dreadful poverty of the population. Communication is very difficult. The railway from Poland to Moscow has, so far as Minsk is concerned, taken advantage of the plateau above mentioned; but still it has to cross the broad marshy depression of the Berezina. A successful attempt was recently made to drain the marshes of the Polyesie by a system of canals, and more than 4,500,000 acres have thus been rendered suitable for pasture and agriculture. Two great tributaries of the Dnieper, the Berezina and the Pripet, both navigable, with numberless subtributaries, many of which are also navigable, are the natural outlets for the marshes of the province. The Dnieper flows along its south-eastern border for 160 miles, and the Niemen on the north-western for 130 miles. The affluents of the Baltic, the Duna (Dwina), and the Vistula are connected by three canals with tributaries of the Dnieper. The population of the province (1,183,200 in 1873) may be estimated at about 1,350,000, mostly White Russians (67 per cent.); there are also Poles (about 11 per cent.), especially in the western districts, Jews (more than 10 per cent.), Little Russians (5 per cent.), and Russians (2 per cent.). About 70,000 are considered to be Lithuanians; there are also 4000 Tartars, whose presence can be traced to the raids of their ancestors on Lithuania in the 13th century, and about 2000 German agriculturists who settled in last century

The chief occupation of the inhabitants is agriculture, which is, however, very unproductive in the lowlands; in the Polyesie the peasants rarely have pure bread to eat. Only 23·8 per cent. of the

area is under crops, the average yield being 1,600,000 quarters of corn and 1,170,000 quarters of potatoes. Cattle-breeding is very imperfectly developed, the meadows being marshy throughout the lowlands. Hunting and bee-keeping are sources of income in the Polyesie, and fishing gives occupation to about twenty thousand persons. The chief source of income for the inhabitants of the lowlands is the timber trade. Timber is floated down the rivers, and tar, pitch, various products of bark, potash, charcoal, and numerous sorts of timber-ware (wooden dishes, &c.) are manufactured in villages to a great extent; and shipbuilding is carried on along the Dnieper, Pripet, and Niemen. Shipping is also an important source of income, owing to the traffic on the canals and rivers of the province. In 1877 560 boats and 1120 rafts with 170,000 cwts. of cargo left the banks of the Berezina and Pripet; and the traffic on the Dnieper and Niemen was nearly as great. The industrial arts are almost entirely undeveloped. There are, however, several distilleries and tanneries; and woollen-stuffs, candles, tobacco, and sugar are manufactured to a limited extent. Corn is exported from the western districts, but imported to the same amount into the southern parts; the chief export trade is in produce of forest industries. The province is crossed by two important railways, one of which connects Poland with Moscow, and the other Libau and Vilna with the provinces of Little-Russia; the great highway from Warsaw to Moscow crosses the province in the south, and its passage through the Berezina is protected by the first-class fortress of Bobruisk. Minsk is divided into nine districts, of which the capitals are—Minsk (43,500 inhabitants), Bobruisk (26,850), Borisoff (5650), close by the place where Napoleon I. crossed the Berezina on his retreat from Moscow, Igumen (2200), Mozyr (4200), Novogrodek (9000), Pinsk (18,000), Ryechitsa (4300), and Slutsk (17,200). The province is well provided with secondary schools, but primary education, especially in the Polyesie, is in a very backward state.

The country now occupied by the province of Minsk was, as far as historical records extend, an abode of Slavonians. That portion of it which was occupied by the Krivichi became part of the Polotsk principality and so of "White Russia"; the other portion, occupied by the Dregovichi and Drevlans, became part of the "Black Russia"; whilst the south-western portion of it was occupied by Yatvyags or Lithuanians. During the 12th, 13th, and 14th centuries it was divided among several principalities, which were incorporated with the great principality of Lithuania, and later were annexed to Poland. Russia took possession of this country in 1793. In 1812 it was invaded by the army of Napoleon I.

MINSK, the capital of the above province, is situated on the Svisloch, a tributary of the Berezina, at the junction of the Moscow and Warsaw and the Libau and Kharkoff railways, 465 miles by rail west from Moscow. It has 43,500 inhabitants, of whom one-third are Jews of the poorest class; the others are White Russians, Poles, and Tartars (about 700). The manufactures are few and insignificant. Since the introduction of railways the commercial importance of the place, which formerly was slight, has begun to increase.

Minsk is mentioned in Russian annals in the 11th century under the name of Myen'sk or Menesk. In 1066 and 1096 it was devastated, first by Izyaslav and afterwards by Vladimir. It changed rulers many times until the 13th century, when it became a Lithuanian fief. In the 15th century it became part of Poland, but as late as 1505 it was ravaged by Tartars, and in 1508 by Russians. In the 18th century it was taken several times by Swedes and Russians. Russia annexed it in 1793. Napoleon I. took it in 1812.

MINSTREL. The "minstrels," according to Bishop Percy, "were an order of men in the Middle Ages who united the arts of poetry and music, and sang verses to the harp of their own composing, who appear to have accompanied their songs with mimicry and action, and to have practised such various means of diverting as were much admired in those rude times, and supplied the want of more refined entertainments." This conception of the "minstrel" has been generally accepted in England ever since Percy published his *Reliques of Ancient Poetry*, which he gave to the world as the products of the genius of these anonymous popular poets and harpers. The name has been fixed in the language by the usage of romantic poets and novelists; Scott's "last minstrel" and Moore's "minstrel boy" were minstrels in Percy's sense of the word. The imagination was fascinated by this romantic figure, and the laborious and soured antiquary Ritson argued in vain that nobody before Bishop Percy had ever applied the word minstrel to such an order of men, that no such order of men ever did exist in mediæval England, and that the historical English "minstrels," so-called, were a much less gifted and respectable class, being really instrumental musicians, either retainers or strollers.

The dispute between Ritson and Percy was partly a dispute about a word, and partly a dispute about historical facts; and there can be little doubt that Ritson was substantially right in both respects. The romantic bishop transferred to the mediæval English minstrel the social status and brilliant gifts of the Anglo-Saxon *gleoman* or *scôp*, and the French *troubadour* in the flourishing period of Provençal poetry. That the gleemen sang to the harp verses of their own composing, that some of them travelled from court to court as honoured guests, while others were important attached court officials, and all received costly presents, is a well attested historical fact. The household bard at Heorot in the poem of *Beowulf*, a man who bore many things in mind and found skilfully linked words to express them, was one of King Hrothgar's thanes; the gleeman of the *Traveller's Song* had visited all the tribal chiefs of Europe, and received many precious gifts, rings and bracelets of gold. The incidents in these poems may not be historic, but they furnish indubitable testimony to the social position of the gleeman in those days; a successful gleeman was as much honoured as a modern poet-laureate, and as richly rewarded as a fashionable *prima donna*. Further, the strolling gleeman of a humbler class seems to have been respected as a non-combatant; this much we may infer from the stories about Alfred and Anlaff having penetrated an enemy's camp in the disguise of gleemen, whether these stories are true or not, for otherwise they would not have been invented. The position of poets and singers in Provence from the 11th to the 13th century is still clearer. The classification of them by King Alphonso of Castile in 1273, by which time honourable designations were getting mixed, may help to determine the exact position of the English "minstrel." There was first the lowest class, the *bufos*, who strolled among the common people, singing ribald songs, playing on instruments, showing feats of skill and strength, exhibiting learned dogs and goats, and so forth; then the *joglars* or *joculatores*, who played, sang, recited, conjured, men of versatile powers of entertainment, who performed at the houses of the nobility, and were liberally remunerated; then the *trobadors*, or *inventores*, whose distinction it was to compose verses, whether or not they had sufficient executive faculty to sing or recite them.

If we compare these distinctions with Percy's definition of the minstrel, we see that his minstrel would have corresponded with the *joglar*, who also wrote his own songs and recitations. Now in the palmy days of Provençal song there were many professional joglars, such as Arnaut Daniel or Perdigo, who stood high among the most brilliant troubadours, and visited on terms of social equality with nobles and princes. But long before English became the court language the fashion had disappeared, and a new division of functions had been developed. In Chaucer's time the poet of society no longer sang his verses to harp or fiddle, or amused his patrons with feats of legerdemain; the king's *gestour* (teller of *gestes*) discharged the professional duty of amusing with witty stories; and the social position of the *joglar* had very much sunk. Ritson was perfectly right in saying that no English poet of any social position was a professional reciter to the harp of verses of his own composing. The Provençal joglar, travelling from court to court, combined our modern functions of poet, society journalist, entertainer, and musician. But about the time when the word "minstrel" came to be applied to him the English joglar was rapidly sinking or had already sunk to the social position of the modern strolling mountebank, travelling showman, or music-hall singer. And the

word minstrel had had a separate history before it became synonymous (as in the *Catholicon Anglicum* of 1483) with *gesticulator, histrio, joculator*, and other names for strolling entertainers. Derived from the Low Latin *ministralis*, it was originally applied to those retainers whose business it was to play upon musical instruments for the entertainment of their lords. In Chaucer's *Squire's Tale*, the "minstralles" play before King Cambuscan as he dines in state "biforn him at the bord deliciously," and the "loude minstralcye" precedes him when he rises and withdraws to the ornamented chamber,

> Ther as they sownen diuerse instrumentz,
> That it is lyk an heuen for to here.

But even in Chaucer's time there were less respectable musicians than those of the king's household—strolling musicians, players on trumpets, clarions, taborets, lutes, rebecks, fiddles, and other instruments. These also were known by the generic name of minstrels, whether because many of them had learnt their art in noble households before they took to a vagabond life, or because the more respectable of them affected to be in the service or under the patronage of powerful nobles, as later on companies of strolling players figured as the "servants" of distinguished patrons. All the allusions to minstrels in literature from Langland's time to Spenser's point to them as strolling musicians. Some of them may have sung to the harp verses of their own composing, and some of them may have composed some of the ballads that now charm us with their fresh and simple art; but the profession of the "minstrel," properly so-called, was much less romantic than Bishop Percy painted it. It was not merely "the bigots of the iron time" that "called their harmless art a crime"; in a repressive Act passed by Henry IV. they appear with "westours, rymours, et autres vacabondes" among the turbulent elements of the community.

In a passage in Malory's *Morte Darthur*, the word minstrel is applied to a personage who comes much nearer the ideal of the Provençal *joglar*. When Sir Dinadan wished to infuriate King Mark, he composed a satirical song, and gave it to Elyot a harper to sing through the country, Tristram guaranteeing him against the consequences. When King Mark took him to task for this, the harper's answer was, "Wit you well I am a minstrel, and I must do as I am commanded of these lords that I bear the arms of." And because he was a minstrel King Mark allowed him to go unharmed. The service done by Elyot the harper in the old romance is a good illustration of the political function of the itinerant mediæval *joculator*; but even he did not sing verses of his own composing, and he was not a "minstrel" in the sense in which the word was used by romantic poets after the publication of Percy's *Reliques*. (W. M.)

MINT. The mint is the place where the coinage of a country is manufactured, and whence it is issued by sovereign authority, under special conditions and regulations. The privilege of coining has in all ages and countries belonged to the sovereign, and has, in England at least, been rarely delegated to any subject, and in any case in a restricted form, the crown always reserving the right of determining the standard, denomination, and design of the coins.

At a very early stage of civilization it was found necessary to have some definite medium of exchange, in order to avoid the great inconvenience arising from the system of payment in kind, which was the primitive and natural method. It was not long before metal came to be used as such a medium, probably from its durability and portability, and in the case of gold and silver on account of their intrinsic value. The less liable the value of a metal is to change the better is it suited for a standard of value.

Though historians assure us that metals were found in Britain at a very early period, there does not appear to be any evidence that the mines were worked until considerably later than the time at which the use of metal as a medium of exchange was introduced. It is probable therefore that the metals for exchange were imported into Britain long before the native mines were developed.

The metals chiefly used were silver and brass, which were at first simply exchanged by weight for commodities of all kinds. As commercial transactions became more numerous and more complicated, this system of payment grew troublesome, and it was found convenient to divide the mass of metal into small parts, which soon took the form of rough coins. But the principle of payment by weight was retained through many centuries, and is perpetuated, though in name only, in the word "pound."

Records of attempts to organize the coinage of England are found as far back as the Anglo-Saxon period, and it is known that on the dissolution of the Heptarchy the mints were regulated by laws framed in the witenagemot. The first monarch who appears to have dealt successfully with the organization of the coinage was Athelstan, who framed laws for the regulation of the mints, and appointed officers whose titles and duties are then first recorded. The only officers connected with the coinage of whom mention is found before this time are the "moneyers," who appear to have been alone responsible for the manufacture of the coin; but it is probable that even then there existed some officer who had authority over them. In early Saxon and Norman times the number of moneyers was considerable, mints being established in almost every important town, as might be expected at a period when communication between distant places was extremely difficult. They appear to have been the officers who actually performed the work of making the coin, the mint master in later times contracting with them, at a high rate, for the work. They were responsible for the purity and perfection of the coins produced, as appears from the fact that it was they who were punished (as traitors) in the case of any deficiency in weight or fineness. They had prescriptive rights in the coinage, and in modern times (even so late as 1850) claimed to have corporate privileges; but it is clear, on the authority of Ruding, that they never were a "corporation" separate from other officers of the mint.[1] The number of mints was greatly reduced after the Norman Conquest, but continued to be considerable until the reign of Richard I., when the work of coining for the whole kingdom was concentrated in the mint in the Tower of London. Only one provincial mint (Winchester) remained till a later date.

An important reorganization of the coinage took place in 1325 under Edward II., the regulations then framed for the manufacture and issue of the coins forming the basis of those still in force. The principal officers under these regulations were—master, warden, comptroller, king's assay master, king's clerks, and cuneator. The office of cuneator was one of great importance at a time when there existed a multiplicity of mints, since he had the sole charge of all the dies used not only at the mint in the Tower of London but also in the provinces. He chose the engravers and presented them to the barons of the exchequer in order that they might take the oath of fidelity; he superintended their work, and was generally answerable for the perfection of the dies before they were issued for use in the various mints of the country. The office, which was hereditary, ceased to exist when the provincial mints were suppressed. In its place was instituted the office of clerk of the irons,

[1] Among the special privileges which they undoubtedly enjoyed was exemption from local taxation, as appears in a writ of Henry III., which commands the mayor of London not to disturb them "by exacting tallages contrary to their privileges." Sometimes also houses were allowed to them rent free.

whose functions were more limited, and were not hereditary. This office was only recently abolished.

In the Middle Ages an important duty devolving on the officers of the mint was the collection of the seigniorage which was levied on the coining of money, not only for the purpose of covering the expenses of minting, but also as a source of revenue to the crown which the sovereign claimed by virtue of his prerogative. In former times the collection of the seigniorage was entrusted to the warden, who also superintended the manufacture of the coins, so far as to ensure the proper relations between the moneyers on the one hand and the state on the other. He does not appear, however, to have had any responsibility with regard to the fineness and weight of the coins.

The king's assay master was specially charged with all matters relating to the accuracy of the standard. The officer next in rank to him was the comptroller, who presented annually to the barons of the exchequer a report of all the gold and silver money struck in the kingdom during the year. These reports, which were always written upon parchment, constitute the chief mint records. The king's clerk exercised a general superintendence and kept an account of all the mint transactions. As the work of the mint became more extensive and more complicated, other officers were added such as the surveyor of the meltings, surveyor of the money presses, and many others.

The present arrangements with regard to the officers of the mint were made in 1870, when several important changes took place in the mint establishment. Up to that time there had been two controlling officers,—the master, who in some instances was selected on account of distinguished scientific attainments (as in the cases of Sir John Herschel and Professor Graham), and the deputy master and comptroller. A careful inquiry, however, having led to the conclusion that the control of the mint might with advantage be concentrated in the hands of a single officer of experience in the conduct of public business, it was decided, on the death of Professor Graham, to entrust the actual administration of the department to the deputy master,—the office and title of master of the mint being held by the chancellor of the exchequer for the time being, without salary. At the same time the services of a scientific officer were secured, by the appointment of a chemist of the mint. The coining and die department and the melting department were united under the name of the operative department, and placed under a single superintendent. The first deputy master appointed under the new regulations was the Hon. C. W. Fremantle, C.B., to whom the public are indebted for a series of *Annual Reports* which have given a new and increased interest to the subject of the coinage, and may be said to constitute in themselves a mint literature.

The actual operations of coining in early times were few in number and simple in character. The metals forming the alloy were melted together in the proportion necessary to bring them to the required standard, and the alloy thus obtained was cast into bars, which were reduced by hammering to the requisite thickness. They were then cut with shears into pieces more or less regular in size and form, roughly annealed, and finally impressed with the prescribed device by a blow with a hammer.

The last-named appears to have been the only part of the process which was performed with any great amount of care. The blank piece was placed by the hand upon a die fixed into a block of wood having a large heavy base to resist the oscillation caused by the blow; the die on which was engraved the device for the reverse of the coin was then placed upon the upper side of the blank and held by means of a holder, round which was placed a roll of lead to protect the hand of the operator while heavy blows were struck with a hammer by an assistant workman. One of the earliest improvements in coining was the introduction of a tool in shape resembling a pair of tongs, the two dies being placed one at the extremity of each leg. This avoided the necessity of readjusting the dies between successive strokes of the hammer, and ensured greater accuracy in the impression. It was long before the system of coining by hand was superseded by the coining press, or mill, which, even after its first introduction, was only very slowly adopted. Several attempts were made to introduce machinery for coining before it was brought into active use, the objection to it being its great expense. The mill and screw were finally introduced into the mint under Charles II., when many improvements were also made in the preliminary operations. Steam-power was first applied in 1810, when the vacuum screw-press was introduced. In 1839 Uhlhorn invented the lever-press, which still remains in use.

The subject of the design on coins, besides being interesting both from an artistic and an historical point of view, becomes very important when it is remembered that it is the impression of the coin with the authorized device which makes it legally current. The artistic merits of the design of the early Greek coins are well known, and prove that the dies from which the coins were struck must have been engraved with much skill and care. The form of the coins before being stamped was at first merely that of natural rounded nuggets of gold, or of the silver-gold alloy known as *electrum*. Such coined nuggets of gold are still to be found among the hill tribes of India. Simple nuggets were afterwards replaced by roughly-fashioned masses like half bullets, a form which rendered it easy to impart high relief to the obverse and comparatively low relief to the reverse of the coins. The early British coins [1] had for their prototype the gold "stater" of Philip of Macedon, but the design of this beautifully finished coin was so roughly imitated by a succession of British copyists that ultimately the wreath round the head of the monarch alone survived, and that in a scarcely recognizable form. It is not only in the early British coins that the influence of classical art may be seen, for it is very evident in some of the present day, the most notable instances being the reverse of the bronze coinage, and the beautiful design of St George and the dragon by Pistrucci, which is still used as an alternative design for the sovereign. It has been ascertained that the impressions on the reverse of very early Greek coins were produced by the rough surface of the anvil or the nail head on which they were placed, while the obverse was struck with the die. A little later the device on the reverse of the coins was obtained by placing the blank piece on small points of metal arranged in geometrical forms which caused corresponding indentations on the coins when struck with the hammer. The beauty and accuracy of design on coins gradually increased as art and manual skill developed, and probably culminated at the period of the Renaissance.

Although it has been the custom since the time of the Saxons to stamp coins with the head of the reigning monarch, it does not appear that any attempt at actual portraiture was made in England until the reign of Henry VII., who, "about the eighteenth or nineteenth year of his reign, did make a great alteration in the form of his coin, upon which his head was now represented in profile, and with a good resemblance of his other pictures." [2] Since then much care seems to have been taken to stamp the coins with a true likeness of the monarch. In most cases the heads bear a striking resemblance to the portraits drawn by the great artists of the respective periods, and were, indeed, generally designed by artists of eminence. Some of the Milan coinage of Louis XII. is said to have been

The weight and fineness of the coins specified in this schedule are according to what is provided by the Act 56 Geo. III. c. 68, that the gold coin of the United Kingdom of Great Britain and Ireland should hold such weight and fineness as were prescribed in the then existing mint indenture, that is to say, that there should be nine hundred and thirty-four sovereigns and one ten-shilling piece contained in 20 ℔ weight troy of standard gold, of the fineness, at the trial of the same, of 22 carats fine gold and 2 carats of alloy in the pound weight troy, and further, as regards silver coin, that there should be sixty-six shillings in every pound troy of standard silver of the fineness of 11 ounces 2 pennyweights of fine silver and 18 pennyweights of alloy in every pound weight troy.

The present standard of fineness for gold, 22 parts fine or pure gold and 2 parts of alloyed metal, was finally adopted in the reign of Charles II., and has remained unchanged up to the present time. Before the passing of the Act determining this standard considerable changes had been made from time to time, the highest degree of fineness having been reached in the reign of Henry III., when the first gold coins were struck of the standard of 24 carats pure gold. The standard of fineness for gold at some different periods may be seen from the following table, which shows the composition of some of the ancient gold trial plates, of which portions are preserved in the Mint:—

Date.	Standard prescribed by Law.		Standard found by Assay	Remedy or Permitted Variation in Carats and in Thousandths.
	In Carats and Grains.	Decimal Equivalent.

1873	Supplementary plate.		Pure gold.	...

The earliest trial plate of which there is any record was made in the seventeenth year of Edward IV. Before that time it would seem that the coins were compared with others known to be of standard fineness, since among the Cotton MSS. is preserved the account of the trial of the pyx of gold nobles in 1349, when the coins were compared with an ounce of florins of Florence kept in the Treasury as standards. The first gold coins were 24 carats fine or pure gold. Edward III. caused coins to be struck of 23 carats 3½ grains fine in 1345, but no trial plate of this standard was made until 1477. Henry VIII. lowered the standard to 22 carats, but caused coins to be struck both of that and the former standards. The greatest debasement of the standard ever reached in England was in 1546, when it sunk as low as 20 carats. It reached a low point in the early part of Edward VI.'s reign, but was raised towards the end of it to 22 carats; and it was still further raised to 23 carats 3½ grains by Elizabeth, who, however, caused gold coins of 22 carats also to be struck. Charles II. on his accession rejected the trial plates of the standard of 22 carats which had been made under the Commonwealth, and caused others to be made of the standard of 23 carats 3½ grains. No coins, however, appear to have been struck of this standard. The same monarch afterwards fixed the standard at 22 carats; and no variation in the legal standard has occurred since that time. The last new trial plates, made in 1873, were alloyed with copper only, in order that they might correspond with the composition of the British gold coins, former plates having been alloyed with silver and copper. At the same time supplementary plates of pure gold and silver were prepared in order that the greatest possible accuracy might be secured.

The present standard of fineness of silver for coinage was fixed at a very early period, but has been subject to considerable variation since the reign of Edward I., the first English monarch who debased the silver coinage. In the reign of Henry VIII. it was once reduced as low as 4 ounces of silver to 8 of alloying metal, and Edward VI. reduced it even lower. It was restored by Elizabeth to the original standard.

The following table shows the composition of some of the ancient silver trial plates of which portions have been preserved in the Mint:—

Date.	Standard prescribed by Law.		Standard found by Assay.	Remedy or Permitted Variation in Dwts. and in Thousandths.

1873	Supplementary plate.		Pure silver.	...

The alloy used for the bronze coinage is composed of 95 per cent. of copper, 4 of tin, and 1 of zinc. The bronze coinage superseded the old copper coinage in 1860, the latter having been in use since the reign of Charles II. The vicissitudes of the copper coinage were even greater than those of the superior coinages, coins for Ireland having been issued at one time of pewter and of other alloys in which scarcely any copper was contained.

The annual testing of the standard of gold and silver coins, called the trial of the pyx, from the "pyx" or chest in which the coins to be examined are kept, is a ceremony of very ancient institution. It arose from the circumstance that the mint master was originally a contractor, under the crown, for the manufacture of the coinage, and it was therefore necessary that periodical examinations of the coins should be held in order to ascertain that the terms of his contract had been complied with. At the present day, when the mint master is no longer a contractor, but an officer of the crown, the trial of the pyx has a somewhat different object; but it would appear from the description of these periodical examinations in some of the earliest mint records that but little change has taken place in the manner of conducting them. The finished coins are delivered to the mint master in weights called "journey weights,"

supposed to be the weight of coin which could be manufactured in a day when the operations of coining were performed by the hand. The journey weight of gold is 15 lb troy, coined into 701 sovereigns or 1402 half-sovereigns. The journey weight of silver is 60 lb troy. From each journey weight a coin is taken and deposited in the "pyx" or chest for the annual trial. This is made by the freemen of the goldsmiths' company under the direction of the crown in the presence of the queen's remembrancer, who administers the oath to the jury and presides over the proceedings. The coins selected for trial are compared with pieces cut from trial plates of standard fineness, which are in the keeping of the warden of the standards, these pieces being assayed against the coins under examination. If the coins are found to be of the standard fineness and weight, within certain limits, a verdict to that effect is drawn up by the jurors and presented to the Treasury.

In consequence of the impossibility of ensuring an absolutely exact admixture of metals in coining, it has been found necessary at all times to allow to the mint master a certain margin, or "remedy," within which coins may vary in weight and fineness from the fixed standard and still be considered of the current standard. The remedy of fineness for English gold coin is now fixed at 2 parts per 1000. The great importance of maintaining the standard of fineness for gold will be evident when it is stated that the variation of $\frac{1}{10}$ of a millième (or thousandth part) above or below the standard causes a gain or loss of £100 in every million sterling. Gold coins would be within the remedy of fineness permitted by law if the amount of precious metal contained in them varied from 914·6 to 918·6 parts in 1000; and, although this remedy cannot be considered to be more than would meet occasional and unavoidable deviation from the exact standard, still, in the case of gold, but a very small part of the remedy of fineness is actually used, the coins seldom falling below 916·3 parts of gold in 1000, or rising above 917·0, while the mean composition of many millions of coins issued from the mint is often of the precise legal standard, 916·66. The remedy of fineness for silver coin, which appears to have been always greater than that for gold coin, is 4 parts per 1000. The remedy of weight for gold is 1·6 per 1000 parts, that for silver 4·17, and that for bronze 20. Extreme care is taken to prevent the issue from the mint of any coins that exceed these permitted variations in weight and standard, each coin being weighed separately, and all those found to be above or below the standard being returned to the melting-house.

Since the real value of the gold coinage is the same as its nominal value, it is of the first importance that gold coins which are below the standard weight should not be allowed to circulate, otherwise holders of large quantities of gold coin are liable to considerable loss. After a certain amount of wear a gold coin in passing from hand to hand loses weight and becomes legally uncurrent. By the Coinage Act it is made compulsory for every person to "cut, break, or deface" any coin tendered to him in payment which is below the current weight, the person tendering it bearing the loss; but, as no penalty is imposed for disregard of this obligation, the law is practically without effect. The withdrawal of light coin from circulation was formerly accomplished solely by the Bank of England, the mint regulations making provision for the receipt of gold tendered for coinage only in the form of bars. The bank undertook to purchase the light gold from the public at the rate of £3, 17s. 6½d. an ounce, a price which, as compared with the mint value of £3, 17s. 10½d., entailed a loss of no less than 4d. an ounce on the seller. This loss was occasioned chiefly by the circumstance that the bank, being obliged before sending the light gold to the mint for recoinage to melt, assay, and cast it into bars, found it necessary to deduct the sum of 2½d. an ounce from the rate of £3, 17s. 9d. an ounce at which it was allowed by statute to purchase gold for coinage, in order to cover the expense of these operations and the loss incident to them. The heavy loss in price, added to that from deficient weight, occasioned constant disregard of the law requiring all light coin to be cut or defaced, and consequently a large amount of light gold continued to be circulated. After the passing of the Coinage Act in 1870, accordingly, fresh regulations were made, by which the mint authorities undertook to receive light gold coin for recoinage, returning to the importer the full mint value of £3, 17s. 10½d. an ounce, thus reducing the loss to that arising from deficiency of weight only. As the Bank of England was enabled by these regulations to raise its price for light gold to the rate of £3, 17s. 9d., the same rate at which it is bound to purchase ingots of standard gold, greater inducements were offered to the public to send in light gold for recoinage, and its withdrawal from circulation was in consequence greatly facilitated. It is evident, however, that, as the deficiency in weight must entail some loss on the holders of light gold coin, they will be disposed to keep it in circulation as long as possible; consequently only a small proportion of the light gold received by bankers finds its way to the Bank of England and thence to the mint for recoinage. The result of some careful experiments made by the late Mr Stanley Jevons, and published by him in the *Journal of the Statistical Society* (vol. xxxi. p. 426), showed that a sovereign becomes so light as to be legally uncurrent at the end of eighteen years. The last state measure taken for the withdrawal of light gold coin from circulation was the issue of a royal proclamation in 1842 calling attention to the laws and regulations relating to light gold coin, and instructing those persons whose duty it was to enforce them to see that they were carried out. From the beginning of July 1842 to the end of March 1845 £14,000,000 in light gold coin was withdrawn from circulation and recoined. This amount was estimated to represent 95 per cent. of the whole of the light gold then in circulation. In order to facilitate this withdrawal the Treasury had in June 1842 entered into arrangements with the Bank of England by which the bank was enabled to purchase light gold on behalf of the Government, at the full mint value of £3, 17s. 10½d. an ounce. Light coin, however, continued to be sent into the bank for some time after it had reverted to its original rate of payment for light gold, *i.e.*, £3, 17s. 6½d. an ounce. The expense to the state of this withdrawal, including the expenses of recoinage, was £67,816. As no important withdrawal of worn gold coin has occurred since that time, it is evident that a large amount of light gold must be at the present time in circulation, and that the loss in weight must be considerably greater than that of the coins withdrawn in 1842, the oldest of which were not more than twenty-five years old, the first issue having taken place in 1817. It has been proved by experiment that the average loss of weight in worn sovereigns and half-sovereigns now in circulation is about 3d. in each sovereign, and that the deficiency in fineness of a large proportion of the coin amounts to about £400 per million. This deficiency arises from the trial plate of 1829, which determined the standard of a portion of the coins still in circulation, being itself below the legal standard. Taking the gold circulation at £100,000,000, of which about 50 per cent. is light, it is estimated that the amount to be recoined cannot be less than £50,000,000, on which the loss from deficiency of gold, both in weight and fineness, must be reckoned at about £650,000, independent of the expenses of recoinage.

In the case of the silver coinage, the loss consequent on the

withdrawal and recoinage of silver money is now covered by the seigniorage arising from the difference between the real and the nominal value of the coins. Before the adoption of gold as the sole standard of value, the conditions attending the withdrawal and recoinage of silver were much the same as those for gold. In the period between the reign of Charles II. and the accession of William III. the condition of the silver coinage became so unsatisfactory as to demand the attention of parliament. A recommendation made at the suggestion of Sir Isaac Newton for a recoinage of silver was at first strenuously opposed, but was finally adopted. In the course of the discussion the question of raising the standard of weight and fineness arose, and this important change would probably have been made but for the representations of Locke, who warmly took up the question and convinced the Government of the desirability of preserving the established standard. In the great recoinage of silver, the loss arising from clipped and defaced coin was borne by the public, the money being raised by means of a special tax on glass windows. The silver reissued at this time amounted to £7,000,000, and the tax raised to cover loss and the expenses of coinage to £1,200,000. The work of this recoinage was so great that the resources of the mint in London were found to be unequal to the pressure put upon them, and therefore mints were either revived or established for the first time in a few of the large provincial towns. In addition to this ten furnaces were erected behind the Treasury at Whitehall to melt down the old pieces. By these means the renovation of the silver coinage was completed within the year. The new silver coins then issued were the first which had milled edges, the milling having been introduced in order to prevent clipping.

The mode in which the silver currency is distributed throughout the kingdom is explained by the late Mr George Forbes, cashier of the Bank of England, as follows:—

Every banker in the kingdom has a banker who is his agent in London. Every London banker has an account with the Bank of England. In the Bank of England there is a department devoted to the issue and receipt of silver coin. If in a district there is a deficiency of silver currency, the bankers of the district are the first to find it out. They at once write to their London agents, who draw on their account with the Bank of England, and obtain what silver is required, which they send to the country banker. On the other hand, if there is a surplus of silver in a district it accumulates in the coffers of the local bankers, who send it up to their London agents, and they send it into the Bank of England. If there is a general demand for silver currency, the stock which the Bank of England endeavours to keep on hand becomes unduly diminished, and immediate notice of the fact is conveyed to the mint authorities, who proceed with all convenient speed to coin a supply of florins, shillings, sixpences, or of all of these coins, as the nature of the demand may require.

Gold bullion for coinage is supplied to the mint almost entirely by the Bank of England, the bank being bound by law to purchase at the rate of £3, 17s. 9d. an ounce any gold bullion of the legal standard which the public may bring for sale. Private individuals are permitted to bring bullion to the mint, and to receive back the full amount (at £3, 17s. 10½d. an ounce) converted into coin, free of any charge for loss or manufacture; but, as they are subject to considerable delay, all "importations" of bullion being converted into coin in the order in which they are brought to the mint, the public practically prefer to sell their bullion to the bank, and receive its value without delay. In order to be accepted by the bank, the bullion must be cast into ingots and assayed, a guarantee being given by certain recognized assayers that the gold is of a certain standard fineness. This is known as the "trade assay." When the bank requires gold to be struck, due notice is sent to the deputy master, and on a fixed day the bullion is conveyed to the mint and delivered into his custody. It arrives in the form of ingots, each weighing about 200 ounces, the aggregate value of each importation being about £144,000. When the ingots arrive at the mint a small sample is taken from each and assayed,[1] the result being sent to the authorities of the bank in order that it may be compared with that of the trade assay. If the bank authorities find that the two assays agree, within certain limits, as to weight and fineness, the ingots are immediately sent to the operative department of the mint to be converted into coin. The mint assay affords the basis for calculating the amount of copper, the alloying metal, that must be melted with the gold in order to produce the standard prescribed by law. The case of silver is somewhat different, the bullion being purchased by the department at its market value, which varies from year to year. During the ten years ending 1881 the average price of silver bullion sank gradually from $60\frac{5}{16}$d. to $51\frac{13}{16}$d. The silver bullion arrives at the mint in the form of ingots, each of which weighs about 1000 ounces, the value of each set of ingots varying considerably. The ingots, both of gold and silver, are weighed on a balance capable of turning with 1 grain when loaded with 1200 ounces.

The operations of coining have undergone some slight changes with the introduction of new machinery and the increased extent of the Royal Mint, since the reconstruction of the operative department in 1881.[2] The plan (fig. 1) shows the present arrangement of the operative department.

The operations employed in the manufacture of gold and silver coin are as follows (incidental operations being printed in smaller type):—

I. Assaying the bullion.

II. Melting the metal.

(*a*) Addition of the amount of copper necessary to form the prescribed alloy; (*b*) pouring the metal into moulds so as to form bars; (*c*) dressing these bars to remove rough edges and hollow ends; (*d*) recovery of precious metals from crucibles and "sweep."

III. Assaying portions of metal cut from certain bars, to ascertain whether sufficient accuracy has been attained in the standard fineness.

IV. Rolling the bars into strips or "fillets."

Annealing the fillets (in some cases).

V. Adjusting the fillets by a final rolling, and in some cases by the use of the drawbench.

Testing the fillets to ascertain whether they are of sufficient accuracy as regards thickness.

VI. Cutting out disks or blanks from the fillets.

Adjusting the blanks in weight (in some mints).

VII. Edge-rolling the blanks to produce a raised rim.

Annealing the blanks and (in some cases) "blanching" or "pickling" them in dilute acid.

VIII. Coining, or stamping the device on the blanks, by means of engraved steel dies.

Milling the edges of the blanks or (in some cases) impressing a device, inscription, or ornament upon them.

IX. Weighing each coin, usually by the aid of automatic machinery.

X. Assaying and weighing pieces taken from the finished coin before it is issued to the public.

The foregoing list will make it clear that the operations of minting consist, not simply in the mechanical production of accurately adjusted disks of metal the purity alone of

[1] The assays are conducted in the manner already described in the articles ASSAYING and GOLD.

[2] In order to provide a stock of silver coin during the temporary suspension of the work of the mint, a large coinage of silver was issued, and 50 tons of bronze coins were manufactured by contract in the autumn of 1881. The governor of the Bank of England had previously reported that the stock of gold coin held by the bank was abnormally large, and that no inconvenience would arise "if the mint were to cease coining sovereigns and half-sovereigns for a period of six months or a year or even more."

which has to be guaranteed, but in the formation of an alloy composed of precious and base metals in definite proportions. The accuracy of the "standard fineness" of the alloy after melting must be absolutely ascertained; the alloy must be protected during manufacture against a change of standard, and finally its correctness must be verified after it has been converted into coin.

The precious metals are weighed on entering the mint, as well as during various stages in the manufacture of coin. The finished coins are also weighed in bulk before they are issued to the public.

The operations incidental to the coinage of bronze and silver differ from those described in relation to gold in some unimportant details only; and the weight and composition of the bronze coins are not so carefully guarded as is the case with gold and silver.

Subjoined are the details of the operations involved in the conversion of bullion into coin at the British mint.

Melting the metal.

After being assayed and weighed in the manner already described the bullion is taken to the melting-house, where the details of treatment for silver and gold respectively differ somewhat. (The subsequent operations are nearly identical for both metals.) The silver melting-house (see fig. 1) contains eight furnaces, of the kind shown at A fig. 2, the part of the furnace containing the crucibles being below the lids B, B. Crucibles of cast iron were formerly employed, but these were replaced in 1853 by wrought iron pots, which have since 1870 been in turn abandoned in favour of crucibles made of a mixture of clay and graphite, each crucible being capable of containing about 3000 oz. Such crucibles are very generally adopted throughout the Indian and Continental mints, but the form and dimensions given to them vary. The fuel employed in England is coke, about 75 lb of which are required to melt 3000 oz. of standard silver. Sufficient draught is afforded by the flue C and by a chimney about 35 feet high which communicates with it. The silver and copper are melted together;

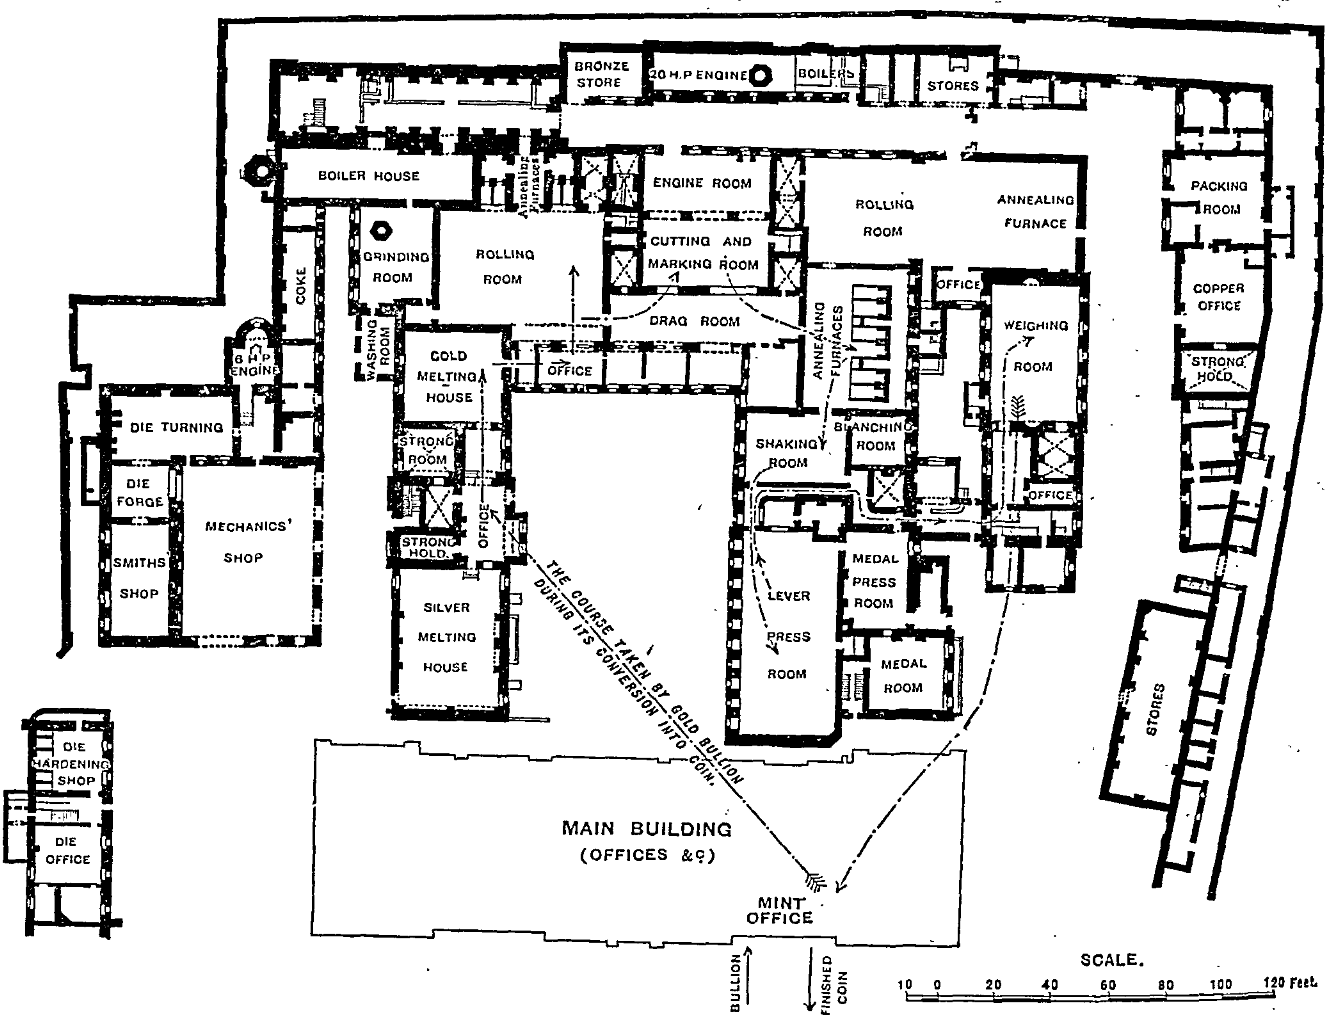

Fig. 1.—Royal Mint, Tower Hill, London. Plan showing the Operative Department as rearranged in 1881–82.

and before the metal is poured into moulds it is stirred with an iron rod having a flattened end. The surface of the molten metal is covered with a layer of charcoal to prevent oxidation of the copper. The crucible with its contents is then removed from the furnace by the aid of a crane and tongs W, and is placed in a cradle M, which can be tilted by means of a handle D. By the intervention of toothed wheels E, F, G, H, and K acting on a rack the handle turns the crucible on the fulcrum formed by a spindle, so that the contents of the crucible may be poured into the moulds N mounted on a carriage OP, running on rails Q, Q. The moulds now in use in London are of such dimensions as to enable bars to be cast 12 inches long and $\frac{3}{8}$ inch thick. The width of the bars varies, according to the coin to be produced, from $1\frac{3}{4}$ to $2\frac{5}{8}$ inches.

When the metal has solidified in the moulds it is removed, and the bars are trimmed by the aid of a revolving circular file, their ends being cut off and returned to the melting pot. Portions of metal are then cut from certain of the bars, and sent to the assay department. The bars are weighed before they pass to the subsequent operations of coinage, in order that the amount of metal retained by the crucibles or carried into the flues may be ascertained. Gold bullion is melted in a similar way, but the crucibles are smaller, and contain only 1200 oz. Their contents are poured by hand into moulds, one end of the tongs by which the crucible is grasped being supported by a chain and suspended from the roof.[1] In many Continental mints it is very generally the practice to leave the crucible containing the precious metals in the furnace, and to pour the contents into the moulds by the aid of small ladles of wrought iron lined with clay.

It has been pointed out in Gold (vol. x. p. 751) that minute quantities of certain metals render standard gold extremely brittle and unfit for coinage. If either the gold bullion or the copper used as an alloying metal should be impure, brittle bars will be the result. Should this prove to be the case, the bars are re-

[1] A new form of furnace devised by M. A. Piat of Paris has recently been introduced. In these furnaces the portion which contains the crucible may be detached from the flue, so as to admit of the molten metal being poured into moulds without removing the crucible from the incandescent fuel. Four of such furnaces have been fitted up in the gold melting-house, but have not as yet been used for gold melting; in the melting of silver and bronze, however, they are known to effect considerable economy in labour, fuel, and crucibles.

melted and chlorine gas is passed through the molten mass in the manner described in GOLD, vol. x. p. 750.

The engine-room (shown in fig. 1) contains three 60-horse-power vertical condensing engines, which are provided with Corlis valves, and are specially devised for meeting the constantly varying strain to which they are subjected by the machinery, the whole of which they are capable of driving. The central engine acts directly on either or both of the rolling rooms placed on each side of the engine-house. There is, however, an additional 20-horse-power compound beam engine usually employed, in connexion with the pumps of a deep artesian well.

Rolling. Into one or other of these rooms the bars which have been cast in the melting-house are brought, and are rolled into strips the thickness of which depends on the kind of coins to be produced. Gold is rolled in one room and silver or bronze in the other. The details of manipulation involved in the conversion of gold, silver, or bronze bars into coin, however, do not differ materially, and the coinage of sovereigns will therefore be taken as typical.

Each room contains six pairs of rolls, the diameter of the rolls varying from 10 to 14 inches. Smaller diameters are employed in most European mints, but on the other hand the use of very narrow rolls of far larger diameter has often been suggested, and there appears to be good ground for the belief that the rigidity of such rolls would enable strips or fillets of more uniform thickness to be

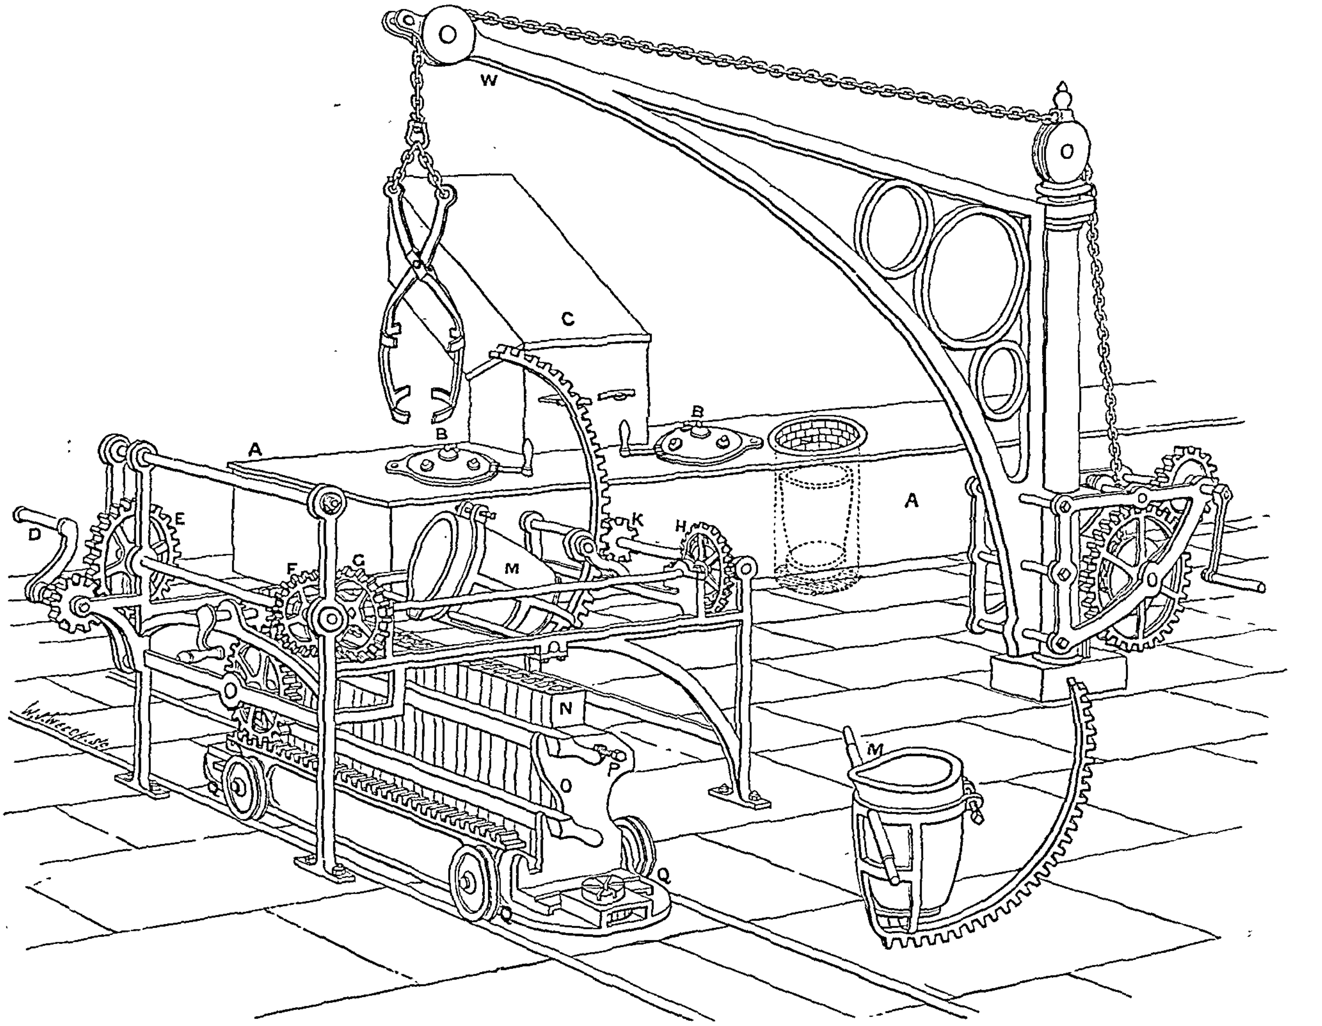

FIG. 2.—Furnace Apparatus.

produced than is the case at present. The iron frame CC (fig. 3) is firmly bolted to the stone D, which rests on a solid foundation EE. This frame supports the two rolls A, B, the lower of which B revolves, but is not, like the upper, capable of adjustment in a ver-

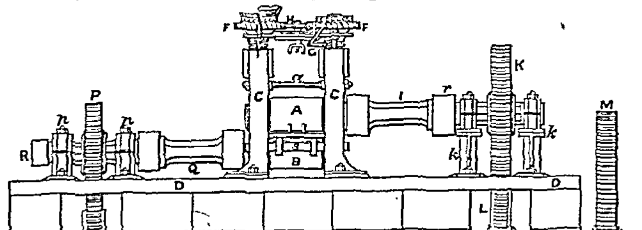

FIG. 3.—Rolls.

tical plane. The upper roll is centred in bearings, and may be raised or lowered by means of screws connected with toothed wheels F, F, which are turned by a handle G, both wheels being moved simultaneously by worms on the rod H. The bearings of the upper roll are connected by vertical rods with weights below the level of the floor; and, as it rises with the screws, it can thus be readily adjusted in a line exactly parallel with the lower roll, at a sufficient distance from it to admit the bar which is to be reduced to a strip or fillet. The rolls are turned by the shaft NN, the main wheel M, and the gearing K, L, O, P. The sockets *r* by which the upper roll is connected with the gearing by the shaft I are not rigid, as is the case with the shaft Q of the lower roll, but admit of the adjustment of the roll. The portion of the roll used is determined by a guide a little wider than the bar.[1] The rolls throughout this department are driven at the rate of about 32 revolutions in a minute. The iron frame CC is braced by rods *a*, *s*; and blocks bearing the driving shafts are shown at *k*, *k*, *p*, *p*.

The initial thickness of a sovereign bar is $\frac{5}{8}$ths of an inch. The bars are weighed out to the workmen in batches of about sixty bars, an entire batch being passed through the rolls under precisely the same conditions of adjustment. The bars are only slightly reduced in width by repeated passages through the rolls, but are successively reduced in thickness in the first stages of the rolling by $\frac{1}{10}$th of an

[1] In the second rolling room, shown in the plan on the right of the engine-house, the frames and gearing of the rolls are of newer pattern than those in the first room. In some of the six pairs the bottom rolls revolve and drive the upper ones. In the pair of "breaking-down" rolls in this room,—that is, the roll by which the fillets are first treated,—the upper roll is stationary, the lower roll alone revolving. The necessary "bite" is given to the fillet, when its end is introduced, by slightly turning the upper roll by means of a ratchet-wheel and lever.

inch, while in the later stages the reduction in thickness at each passage through the rolls is less than $\frac{1}{100}$th of an inch, and finally one or two "spring pinches" are given to the bars by simply passing them through the rolls without altering the adjustment. The testing of the fillets, to ascertain whether they are of the accurate thickness, is effected by the aid of the gauge plate (fig. 4), which consists of two steel bars set at a low angle in relation to each other and graduated to $\frac{1}{1000}$th of an inch.

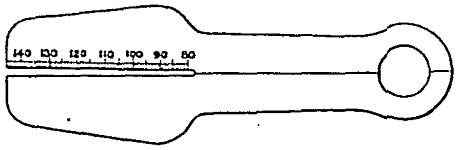

FIG. 4.—Gauge Plate.

It will be evident that the weight of the finished coin depends upon the thickness of the fillets; and to show how accurately the rolling must be performed it may be pointed out that, in the case of the half-sovereign, a variation of $\frac{1}{20000}$th of an inch above or below the accurate thickness (or a range of $\frac{1}{10000}$th of an inch) throws the coin out of "remedy."

The repeated passage through the rolls is attended by a considerable increase of hardness in the metal, and it is therefore in some cases necessary to anneal the fillets repeatedly during the rolling. In the case of fillets for sovereigns the annealing may be entirely dispensed with if the initial thickness of the bars does not exceed $\frac{3}{8}$ths of an inch. Fillets for half-sovereigns have only to be annealed once. In some European mints the fillets are annealed frequently; in one mint the operation is performed after each passage through the rolls. The furnace used for the purpose is generally so arranged as to permit the flame to play over the fillets, which are sometimes freely exposed to its action, but are more often enclosed in cases or tubes. Muffle furnaces are frequently used. The furnace used in the Royal Mint is a simple form of reverberatory furnace. The final rolling is given by a pair of finishing rolls capable of more accurate adjustment than the "breaking-down" rolls.

The fillets of gold or silver are in some cases, though not always, submitted to an appliance known as the drag bench, shown in figs. 5, 6, 7. Its object is to equalize the thickness of the fillets by drawing them between steel cylinders. The ends of the fillets are Drag bench.

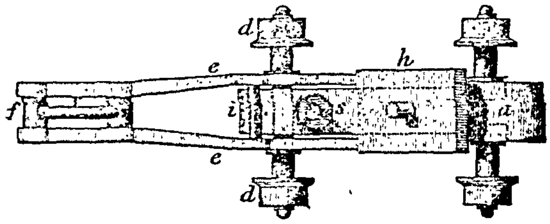

Fig. 5.

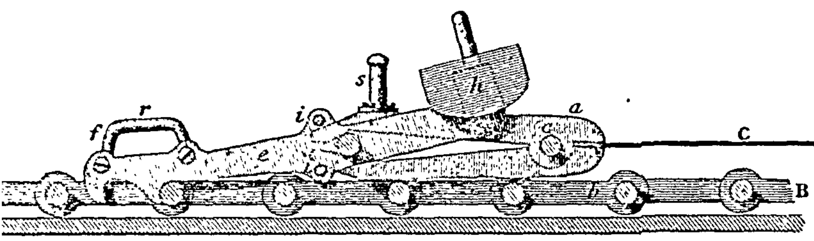

Fig. 6.

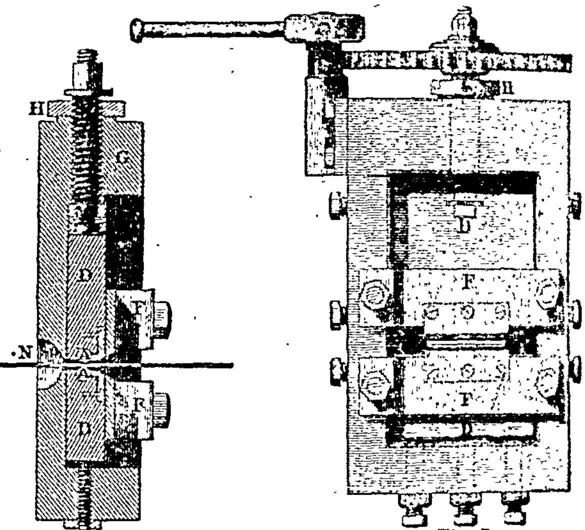

Fig. 7.

FIGS. 5, 6, 7.—Drag Bench.

first flattened in a little appliance, which need not be described. The essential feature of the machine now used in the mint consists of two small steel cylinders A, A, which do not revolve, and are held in position in the plates D, D by clamp pieces F, F screwed against them. The portions of metal may be adjusted by the aid of a wheel and screw H (figs. 6, 7), and by small adjusting screws f, f. The part of the machine containing the steel cylinders is fixed at the end of a long bench, and gearing at the other end of this bench drives an endless chain BB (fig. 6), one link or other of which catches the carriage, shown in plan in fig. 5, and drags it along as soon as its end f is depressed by the handle r. The carriage runs on the wheels d, d. The drawing of the fillet C is conducted as follows. Its flattened end is introduced between the steel cylinders, and is grasped by the jaws a. The jaws turn on the pin e, and while the fillet is being dragged through the cylinders the axle of the wheels d, d tends to increase the grip of the jaws by acting on their inclined ends. Directly the strain on the

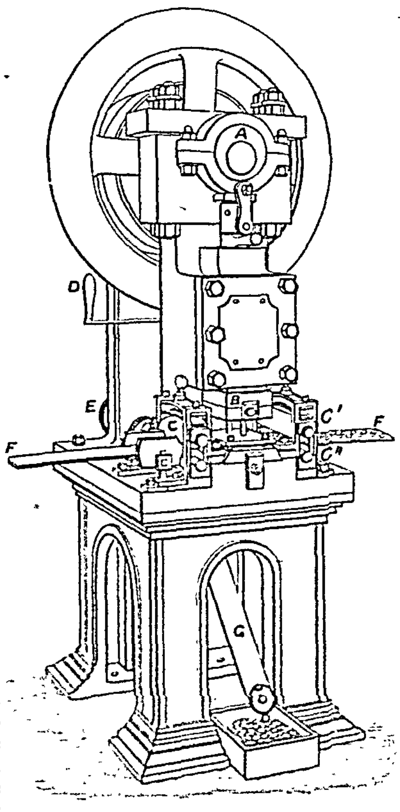

FIG. 8.—Cutting Machine.

fillet is released, the pins i, i and the weight h loosen the jaws and at the same time raise the end of the carriage so as to arrest its further progress along the bench. The carriage is then moved forward by the handle s until the jaws enter the hollowed portion N and grasp another fillet.

Formerly—when fillets were rolled from thick bars—this appliance played a more important part in coining operations than at present. It is now only used for fillets from which sovereigns and half-sovereigns are to be produced. Before fillets are passed on to the next operation—that of cutting from them the disks or blanks destined to form the coin—they are carefully tested by a skilful workman called the "tryer," who cuts one or two blanks from the sides of each fillet by the aid of a cutter worked by hand. These blanks are weighed on a delicate balance against a standard weight, and the experience of the operator enables him to determine whether the variation from the exact weight will justify his sending the fillets forward to the cutting room. In any case he divides the fillets into two or more classes for a reason that will be explained presently. Trying.

The cutters employed in the mint until quite recently were of complicated construction, but these have been replaced by a simple machine (fig. 8) which, by the revolution of an eccentric A, causes two short steel cylinders, mounted on a block of iron B suitably guided, to enter two holes firmly fixed in a plate on the bed of the machine. When the fillet FF is interposed between the short cylinders and the holes, the former force disks of metal through the holes, the fillet being advanced at each stroke of the machine by small gripping rolls C, C′, C″ actuated by a ratchet-wheel E, driven from the shaft which bears the eccentric A. The disks pass down the tube G to a receptacle placed on the floor. In the case of very large silver coins, only one disk is cut in the width of the fillet, and in some few mints disks for gold coin are also cut in this way, but it is far more usual to cut two disks in the width of the fillet, the position of the cutters being so arranged as to remove blanks in the manner shown in fig. 9. In cutting disks for bronze coin extreme precision is not necessary, and it has therefore been found possible to obtain five at each stroke of the machine. Cutting blanks.

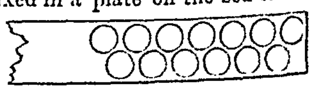

Fig. 9.

It will be evident that the rough classification of the fillets according to their thickness, to which reference has already been made, renders it easy to compensate for slight irregularities in thickness caused by rolling, by employing cutters of a slightly larger diameter than the standard size for fillets which are too thin.

The fillets after the removal of the disks present the perforated appearance shown in fig. 9. The residual metal, called "scissel," which amounts to from 25 to 30 per cent. of the metal operated upon, is returned to the melting-house in bundles weighing 180 oz. It may be mentioned here that all attempts to cut disks or blanks for coinage from the ends of rods or cylinders, and thus to avoid the production of scissel, have hitherto failed.

Adjustment of blanks.

The next operation to which the blanks are submitted varies in different mints. In some, each blank is weighed by hand or by automatic machinery, and each blank that is too heavy is adjusted either to an exact weight or to within the remedy prescribed by law. On the Continent it is very generally the practice to adjust blanks by the aid of a file, or by a machine that removes a fine shaving of metal from the surface of the blank. In mints where mechanical adjustment is adopted there is a tendency to produce "too heavy" blanks in the rolling and cutting departments, as it is impossible to adjust blanks which are too light.[1]

In the London mint finished coin alone is weighed, so that the blanks after leaving the cutting room pass directly to an edge-rolling machine, which thickens the edge of each blank so as to form a rim intended to protect the impression on the finished coin. The operation of edge-rolling is called "marking," and the method of conducting it varies considerably in different mints.

In the Royal Mint the blanks are made to pass in quick succession, at the rate of six hundred a minute, between a circular groove in the face of a revolving steel disk and a groove in a fixed block placed parallel to the face of the revolving disk. The groove in the block exactly corresponds to that on the disk; and, as the distance between the block and the disk is slightly less than the diameter of the blank submitted to the operation, the result is that before the blank escapes from the machine its edge has been thickened. The operation may be varied by admitting the blanks between a groove in the periphery of a revolving wheel and a groove in a segmented block, placed at a distance from the wheel rather less than the diameter of the blank. The wheel and block may be either vertical or horizontal.

In some cases the edges of the blanks, at the same time that they are thickened, receive the impression of a legend, or inscription, or an ornamental device. When this is the case the blank is rolled between two planes, one of which is fixed and bears the device, while the other has a reciprocating motion imparted to it, or the edge of the blank receives the impression, which may be either raised or sunk, from a collar surrounding the blank in the coining press, as will be afterwards explained.

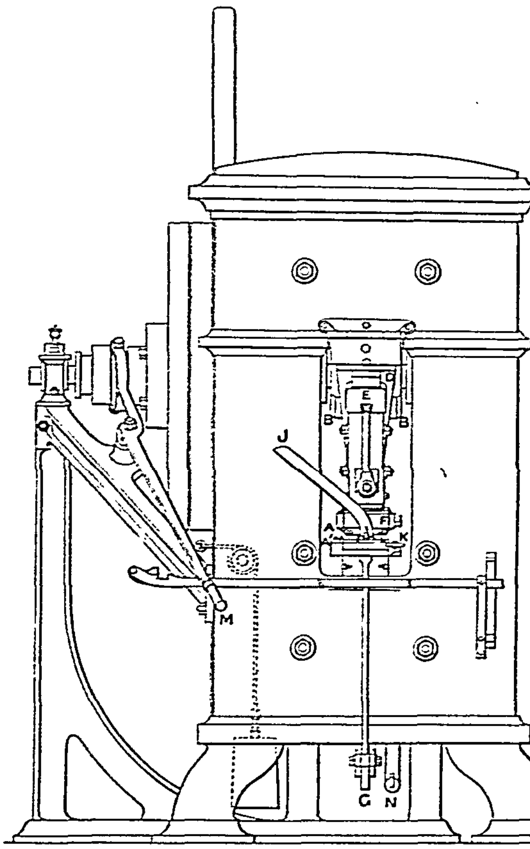

Fig. 10.

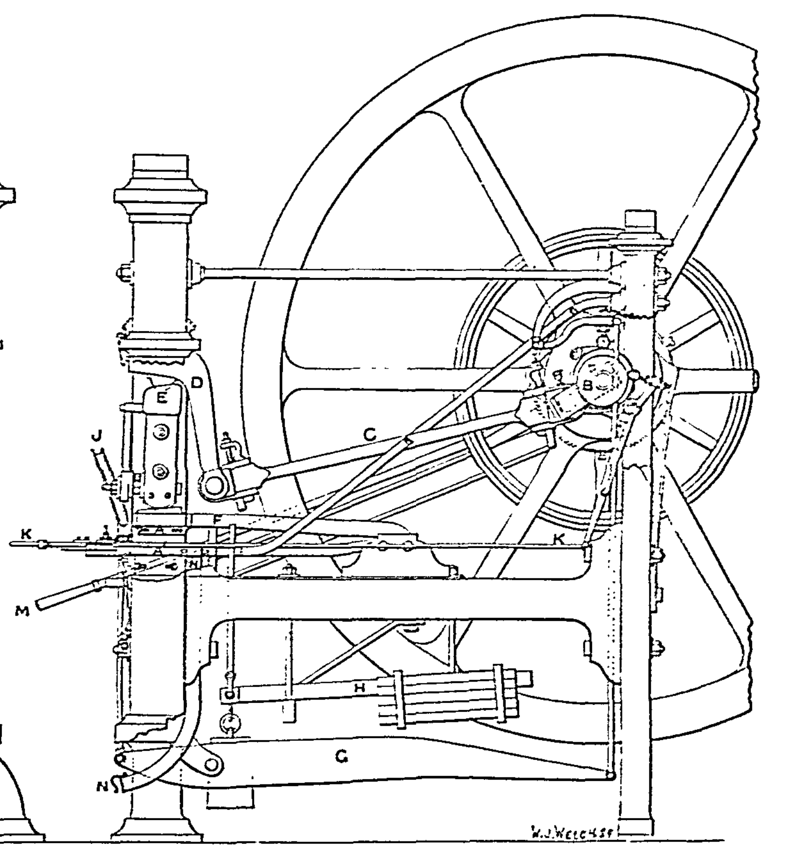

Fig. 11.

Annealing the blanks.

Before passing to the coining press the blanks either of gold or silver are annealed. In many mints the object of the heating is not only to soften the blanks before they receive the impression, but also to produce a film of oxide of copper on their surface. This is attained in various ways. In England gold blanks are placed in cylindrical crucibles of plumbago and covered with a layer of charcoal, heated in a reverberatory furnace, and when the blanks reach cherry-redness they are cooled by plunging them in water. The thin film of oxide of copper thus formed on the surface of the gold or silver blanks is readily soluble in dilute sulphuric acid, and the removal of a small portion of the alloying metal in this way constitutes "blanching" or "pickling" the coin. The method of conducting the operation varies somewhat in different mints, mainly, however, in the strength of the acid used, which varies from 3° to 5° of the hydrometer of Baumé. The solution is sometimes heated to 96° to 98° C., while in other cases the blanks are introduced into the solution while at a red heat. The latter method is, however, objectionable, as a dense layer of pure metal is found at the surface of the blank which is apt to protect the underlying oxide of copper from the action of the acid. The blanks are afterwards washed in pure water and dried either in sawdust or in copper vessels heated by steam jackets. The object of the process is to

[1] A description of a machine used for the adjustment of blanks will be found in *Dingler's Polytechnisches Journal* (1882, ccxlv. 61, pl. 6); and some years ago Mr J. M. Napier devised for the Indian mints a beautiful machine which first ascertains how much it is necessary to cut from each blank in order to reduce it to the standard weight, and then removes the necessary amount of metal and no more. The initial cost of such machinery, however, is considerable. In 1849 M. Diereck, director of the mint in Paris, endeavoured to substitute a chemical for a mechanical treatment by submitting the heavy gold blanks to aqua regia, which it was anticipated would bring them within the prescribed limits of accuracy. The results were not satisfactory, and the attempt was abandoned. In 1870 the present chemist of the mint, Professor W. Chandler Roberts, showed that gold alloyed with copper might be removed from heavy blanks with singular regularity by means of a suitable solvent aided by a battery. The blanks are arranged in a frame of wood and submitted to the action of a solution of cyanide of potassium, the heavy blanks forming the dissolving pole of the battery. The process was not used in the London mint, as it became evident that it could not profitably replace the present system, under which finished coins alone are weighed and the manufacture of good coin only is paid for. It was, however, introduced into the Bombay mint in 1870 by the late Mr L. G. Hines, who extended its usefulness by transferring the metal dissolved from the heavy blanks to blanks which are too light, the latter being by this means raised to the prescribed weight. The process has now fairly taken its place as an ordinary operation of coining, and its importance to the mints where it is used may be gathered from the fact that in the Indian mints no less than 1300 tons of silver were converted into coin in one year (1879), so that the saving effected by its introduction must be considerable.

improve the appearance of the finished coin by removing all traces of impurity from the surface of the blank. It has, however, been abandoned in the British mint except in the case of some of the smaller silver coins, mainly because the soft superficial layer of metal wears away with undue rapidity. Certain precautions suggested in 1869 by Mr Hill, the superintendent of the operative department, for avoiding oxidation or tarnishing of the metal during coinage rendered the abolition of the process possible.

Coining press. The blanks receive the impression which constitutes them coins from engraved dies. Each is placed in the lower of two dies, and the upper die is brought forcibly down upon it. The lateral escape of the metal is prevented by a collar which surrounds the blank while it is being struck. This collar may be either plain or engraved, and if the latter is the case any device or ornament it may bear will be imparted to the edge of the blank.

The coining presses used in various mints may be divided into three types:—(1) the screw press worked by atmospheric pressure, (2) the excentric press, and (3) the lever press. The first of these (see *Ency. Brit.*, 8th ed., vol. vii. p. 92) has now been abandoned. In the excentric press the power is applied to a shaft bearing an excentric which acts by means of a connecting rod upon a vertical slide holding the die which is brought down on the blank. This form of press is used in the mint at Constantinople, where the atmospheric screw press is also still retained. Of the third type, the lever press, there are two modifications, devised respectively by Thonnelier and by Uhlhorn. The details of the Uhlhorn press have been improved by Messrs R. Heaton & Sons of Birmingham; and, their superiority to the old vacuum screw press having been demonstrated by careful experiments, they have been finally adopted in the newly arranged mint, which contains fourteen of them. This press is shown in figs. 10 and 11. It is driven from below the floor of the press-room by bands which pass over fast and loose pulleys on the same shaft that bears the fly-wheel. The loose pulley, however, is only used when it is necessary to stop the machine entirely, as the fly-wheel is permitted to revolve without imparting motion to the shaft so long as a lever M, worked from the front of the machine, does not cause the fly-wheel to be connected with the driving wheel by means of two pins. The dies are placed in the front part of the machine (fig. 10). The lower one is firmly fixed to the bed, while the upper is held at A by the upper of two jaws F and A′, or levers, the fulcra of which are so close together as almost to coincide, the lower jaw A′ bearing the collar which encircles the blank while it is being converted into a coin; the upper jaw F, A, governed by the weighted lever H shown below the bed of the machine, has a tendency to rise a sufficient distance to admit the blank between the upper and lower die. A crank B on the shaft bearing the fly-wheel is connected by a rod C with the bent lever D, and this bent lever, acting through the toggle joint and a piece of metal E connected with the jaw that bears the

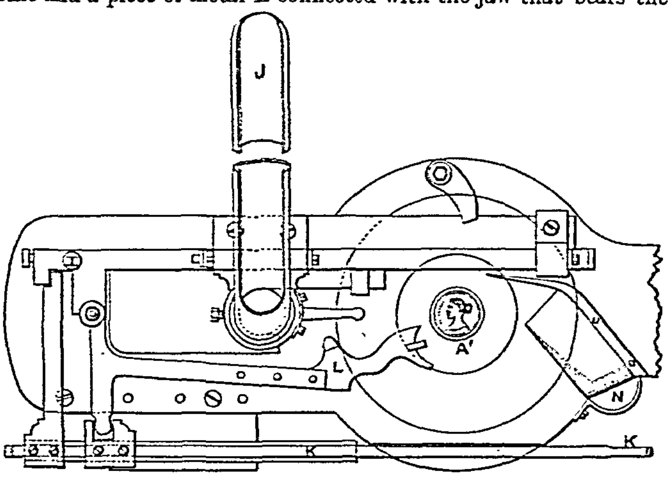

Fig. 12.

upper die, forces it down, and thus squeezes the blank between the upper and lower dies. A cam on the crank shaft acting on the lower of the two levers G shown below the bed of the machine causes the lower jaw A′ bearing the collar which surrounded the blank to be depressed sufficiently to leave the finished coin freely resting on the lower die, from whence it is driven down the shoot N by the next blank in succession. Coins are produced at rates varying from 60 to 120 a minute, 90 a minute giving the best results. The blanks to be converted into coins are placed on the slide J, and the advance of each blank in succession is regulated by the rod called the "layer on" K, the backward and forward movement of which is also regulated by an excentric on the crank shaft. The details of this part of the machine are shown in plan, fig. 12.

Automatic balance. The last operation before the finished coin is returned to the mint office for issue to the public is the weighing each gold or silver piece separately. This is effected in the American and in most Continental mints by hand, but in England automatic balances of beautiful construction are employed. They were originally devised for separating worn pieces from those of current weight, but they are now employed to distinguish between "light," "heavy," and "good" pieces, the latter alone being permitted to pass into circulation. In the newly arranged department thirty such machines are provided. Each is driven from overhead shafting by means of gut lines. The driving pulleys derive their motion from a small atmospheric engine, which is found to give more satisfactory results than would be the case if the steam-engine were employed directly. Each balance is worked by a cone pulley A (fig. 13) by a gut line passing round it from the loose pulleys B, the necessary tension being imparted to the line by means of a spring C. The tension of the line is, however, but slight, for if the action of the balance is arrested by accident the cord slides over the cone pulley A without turning it. It will be obvious that the use of the cone pulley enables the machine to be driven with varying degrees of speed. The toothed wheel D is mounted on the spindle which bears the driving pulley A, but it acts only through the intervention of a friction cheek, which is so lightly screwed against the driving wheel that it would cease to act if the machine should be accidentally deranged. The wheel D sets in motion the wheels E, E′, E″. The cam F, acting on the curved extremity of the rocking frame G, causes the slide H to bring forward one of a series of coins (arranged in the hopper I) until it rests on the plate J of the balance beam, of which beam a portion is shown in an enlarged drawing above the balance, while the plate that receives the coin is also shown in a separate drawing to the left of the machine. Another cam K then comes into play, and enables the forceps, shown at L, to release the rod M to which the balance plate J is attached. The forceps L serves to keep the rod steady while the coin is being placed on the plate J. A rod shown at N is then raised by the cam O, the lower extremity of the rod being kept steady by a pin sliding in a hole in the bottom plate of the balance, and its upper end by a pin which works into the central support of the balance beam. At the base of this rod N, and at right angles to it, there is a metallic bar QQ, the ends of which pass through stirrups in the pendants M and P from the opposite ends of the beam. The elevation of this horizontal rod by the cam O simultaneously releases both ends of the beam, and the coin placed on the beam plate has then, for the first time, a direct influence on the beam. If the coin is "too light" the counterpoise R in the cage at the end of the rod P will raise the coin, and the revolution of the machine then causes part of the cam K to permit a spring to close the forceps L and to hold the pendant M firm. An indicating finger T then falls, and by means of a horizontal lever UU′, which fits into one of three inverted steps on the bottom of the shoot V, determines over which of three orifices W, W′, W″ in the bottom plate of the balance this shoot shall stand. In the meantime the advance of the slide H brings the next piece forward, and displaces the coin which has hitherto occupied the beam plate J, forcing the coin down the shoot V, and thence through the orifice W into a receptacle, external to the balance, destined for the reception of "light coin." If this next piece should be "too heavy" it will not only raise the counterpoise R but will also elevate a little wire S, which would otherwise remain undisturbed on a support. This little wire represents the "working remedy" for the particular denomination of coin in question, which, for safety, is less by $\frac{1}{100}$th of a grain than the remedy permitted by law. The undue weight of the "heavy coin" will depress the right end of the balance beam and its pendant M to the lowest possible point, and the indicating finger T will, in this case, determine that the rod UU′ shall occupy the lowest step of the shoot V, which will consequently stand over the orifice W″ in the bottom plate of the balance which communicates with the receptacle for the "heavy" coins, and the heavy coin on the beam plate will be driven down the shoot by the next coin in succession. If the coin which is next brought forward by the slide H should be a "good" one, that is, if it is within the working "remedy," its action will be as follows. It may be slightly heavier than the counterpoise, but not sufficiently heavy to lift both the counterpoise and the remedy wire. The balance beam consequently remains approximately horizontal, and the indicating finger T will cause the rod UU′ to strike the centre step of the shoot V, which will then stand over the central orifice W′ in the bed plate which communicates with a receptacle for "good" coins, into which the coin will find its way, as soon as it is driven from the beam plate by the next coin of the series. It will be evident that this excellent appliance both weighs and classifies the coins. About twenty-three coins are passed through it in a minute.

In order to show the importance of extreme accuracy in weighing, it may be pointed out that, although by the Coinage Act of 1870 the "remedy" or allowed variation above or below the standard weight of a sovereign is only $\frac{1}{5}$th of a grain, yet in a million sterling of sovereigns the difference between the least and the greatest weight the law allows would be no less than £3244.

The manufacture of coin is not the only work which is performed in the Royal Mint. All medals issued to the

army and navy, as well as those given by the Royal Society and the university of London and some others, are struck in the mint, and their preparation forms a considerable part of the work of the die department. Since 1874 the clasps and bars for the medals have also been manufactured in the mint, whence they have been issued completely mounted. Another operation, not connected with the coinage, which is performed in the mint is the assay of the "diet" or metal scraped from the gold and silver plate manufactured at Sheffield and Birmingham under the direction of the warden of the standard of wrought plate for those towns. By Act of Parliament it is directed that this shall be brought once in each year to the mint to be assayed by the "king's assay master," under the supervision of an officer appointed by the lords of the Treasury.

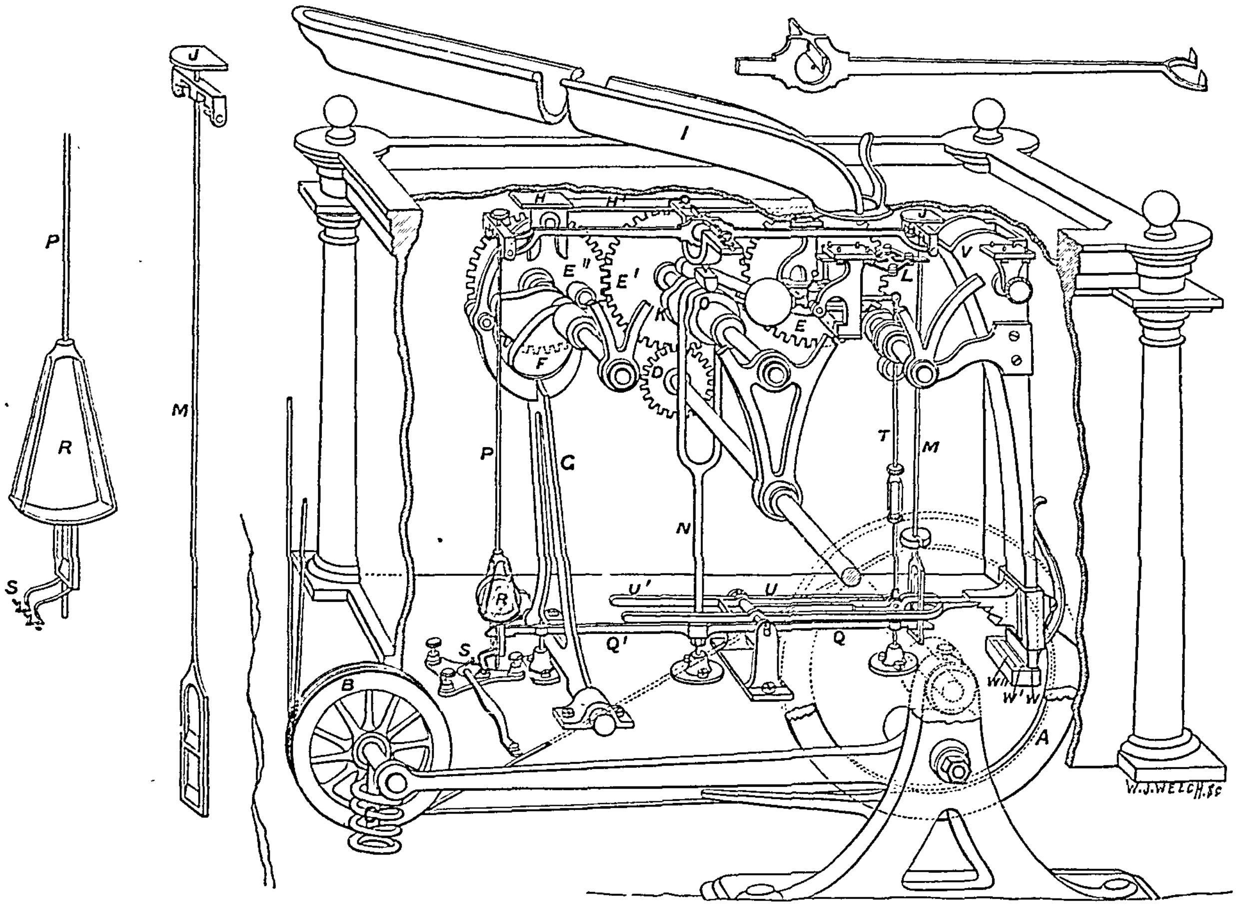

FIG. 13.—Automatic Balance.

The gold coin in circulation in Great Britain is estimated at £100,000,000. It may be well to add the following table, which gives the value of the gold and silver coinages of four of the most important foreign countries, in two recent years :—

	1880.		1881.	
	Gold.	Silver.	Gold.	Silver.
United States	£12,461,655	£5,481,941	£19,370,178	£5,587,840
Germany	1,332,430	...	326,837	...
Austria	493,605	1,674,712	485,999	1,805,734
France	...		83,646	259,910
	£14,287,690	£7,156,653	£20,266,660	£7,653,484

The value of the gold coinage of the American mints during the fiscal year ending June 1882 amounted to $89,413,447·50,—being greater than that of any previous year in their history. (W. C. R.—R. A. H.)

MINT, botanically *Mentha*, a genus of labiate plants, comprising about twenty species of perennial herbs, widely distributed throughout the temperate and sub-tropical portions of the globe. All the species are furnished with square stems, opposite, aromatic leaves, and creeping roots. The flowers are arranged in axillary cymes, which either form separate whorls or are crowded together into a terminal spike. The corolla is usually small, and of a pale purple or pinkish colour; it has four nearly equal lobes, and encloses two long and two short stamens. Great difficulty is experienced by botanists in discriminating the species of this genus by reason of the occurrence of a large number of intermediate forms, nearly three hundred of which have been named and described. Many of these varieties are permanent in consequence of being propagated by stolons.

In Britain nine of the recognized species are indigenous. *Mentha viridis*, L., or Spearmint, grows in marshy meadows, and is the species commonly used for culinary purposes; it is distinguished by its smooth, sessile leaves and lax tapering flower-spikes. *Mentha sylvestris*, L., or Horsemint, chiefly differs from the above in its coarser habit and hairy leaves, which are silky beneath, and in its denser flower-spikes. This plant is supposed to be the mint of Scripture, as it is extensively cultivated in the East, and is much used in cookery; it was one of the bitter herbs with which the paschal lamb was eaten. *M. rotundifolia* resembles the last in size and habit, but is readily distinguished by its rounded wrinkled leaves, which are shaggy beneath, and by its lanceolate bracts. The last two species usually grow on damp waste ground near roadsides. *M. aquatica*, or Capitate Mint, grows in ditches and by the side of streams, and is easily recognized by its rounded flower-spikes and stalked hairy leaves. *M. Piperita*, or Peppermint, has stalked smooth leaves and an oblong obtuse terminal spike of flowers; it is extensively culti-

vated for its volatile oil. *M. pratensis* belongs to a group of mints which, unlike the foregoing, have the flowers arranged in axillary whorls and never in terminal spikes; it otherwise bears some resemblance in foliage and habit to *M. viridis*. *M. sativa*, the Whorled Hairy Mint, grows by damp roadsides, and *M. arvensis* in cornfields; they are distinguished from *M. pratensis* by their hairy stalked leaves, which in *M. arvensis* are all equally large, but in *M. sativa* are much smaller towards the apex of the stem. *M. Pulegium*, commonly known as Pennyroyal, more rarely as Flea-mint, has small oval obtuse leaves and flowers in axillary whorls, and is remarkable for its creeping habit and peculiar odour. It differs from all the mints above described in the throat of the calyx being closed with hairs. It is met with in damp places on grassy commons, and forms a well-known domestic remedy for female disorders.

All the plants of the genus *Mentha* abound in a volatile oil, which is contained in small receptacles having the appearance of resinous dots in the leaves and stems. The odour of the oil is similar in several species, but is not distinctive, the same odour occurring in varieties of distinct species, while plants which cannot be distinguished by any botanical character possess the same odour. Thus the peppermint flavour is found in *M. Piperita*, in *M. incana*, and in Chinese and Japanese varieties of *M. arvensis*. Other forms of the last-named species growing in Ceylon and Java have the flavour of the common garden mint, *M. viridis*, and the same odour is found to a greater or less degree in *M. sylvestris*, *M. rotundifolia*, and *M. canadensis*. A bergamot scent is met with in a variety of *M. aquatica* and in forms of other species. Most of the mints may be found in blossom in August.

The name mint is also applied to plants of other genera, *Monarda punctata* being called Horsemint, *Pycnanthemum linifolium*, Mountain Mint, and *Nepeta Cataria*, Catmint.

MINTO, Sir Gilbert Elliot, First Earl of (1751–1814), was descended from an old border family, the Elliots of Minto, and was born at Edinburgh, April 23, 1751. His father, Sir Gilbert Elliot, was a member of the administration of Pitt and Grenville, and is spoken of by Horace Walpole as "one of the ablest men in the House of Commons." Young Elliot was educated by a private tutor, with whom at the age of twelve he went to Paris, where David Hume, who was then secretary of the embassy, undertook, from friendship to his father, the special charge of superintending his studies. After spending the winters of 1766 and 1767 at Edinburgh University, Elliot entered Oxford. On quitting the university he became a member of Lincoln's Inn, and was in 1774 called to the bar. He entered parliament in 1776, the year of his father's death. Although he gave a general support to Lord North's administration, he from the beginning occupied an independent position, and in 1782 supported the address of the Commons against an offensive war with America. From this time he became a declared follower of Fox and Burke, with the latter of whom he gradually came to be on terms of great intimacy. He was created Baron Minto in 1797, and after filling several diplomatic posts with great success became in 1807 governor-general of India. The character and events of his rule in India are described in vol. xii. p. 805. He was created Earl of Minto and Viscount Melgund in 1813. He returned to England in 1814, and died on June 21st of that year.

See *Life and Letters of Sir Gilbert Elliot, first Earl of Minto, from* 1751 *to* 1806, 1874; and *Life and Letters*, 1807–14, 1880. See also Mirabeau.

MINUCIUS FELIX, Marcus, one of the earliest, if not the earliest, of the Latin apologists for Christianity. Of his personal history nothing is known, and even the date at which he wrote can be only approximately ascertained. Jerome (*De Vir. Ill.*, 58) speaks of him as "Romæ insignis causidicus," but in this he is probably only improving on the expression of Lactantius (*Inst. Div.*, v. 1) who speaks of him as "non ignobilis inter causidicos loci." He is now exclusively known by his *Octavius*, a dialogue on Christianity between the pagan Cæcilius Natalis[1] and the Christian Octavius Januarius, a provincial solicitor, the friend and fellow-student of the author. The scene is pleasantly and graphically laid on the beach at Ostia on a holiday afternoon, and the discussion is represented as arising out of the homage paid by Cæcilius, in passing, to the image of Serapis. His arguments for paganism, which proceed partly upon agnostic grounds, partly upon the inexpediency of disturbing long-established religious beliefs, partly upon the known want of culture in Christians, the alleged indecency of their worship, and the inherent absurdity of their doctrines, are taken up seriatim by Octavius, with the result that the assailant is convinced, postponing, however, the discussion of some things necessary for perfect instruction to a future occasion. The form of the dialogue, modelled on the *De Natura Deorum* and *De Divinatione* of Cicero, shows much care and ability, and its style is on the whole both vigorous and elegant if at times not exempt from something of the affectations of the age. If the doctrines of the Divine unity, the resurrection, and future rewards and punishments be left out of account, the work has less the character of an exposition of Christianity than of a philosophical and ethical polemic against the absurdities of crass polytheism. Christology and the other metaphysics of distinctively Christian theology are entirely passed over, and the canonical Scriptures are not quoted, hardly even alluded to.

The *Octavius* is admittedly earlier than Cyprian's *De Idolorum Vanitate*, which borrows from it; how much earlier can be determined only by settling the relation in which it stands to Tertullian's *Apologeticum*. The argument for the priority of Minucius has been most exhaustively set forth by Ebert ("Tertullians Verhältniss zu Minucius Felix," in vol. v. of the philologico-historical series in *Abhandl. d. König. Sächs. Gesellsch. der Wissenschaften*, 1868), who has been followed by Teuffel (*Röm. Lit.*, sec. 368), Keim (*Celsus' Wahres Wort*, 1873), Kuhn, and other scholars. The opposite view is ably maintained by Professor Salmon ("Minucius Felix" in Smith's *Dict. Christ. Biogr.*, 1882). The *Octavius* was first printed (Rome, 1543) as the eighth book of Arnobius *Adv. Gentes*; Balduinus (Heidelberg, 1560) first assigned it to its proper author. There have been numerous subsequent editions, the best being that of Halm in the *Corp. Scriptor. Eccl. Lat.* (Vienna, 1867). See Kuhn's monograph, *Der Octavius des Minucius Felix* (1882).

MINUET (Fr. *Menuet*, from [*pas*] *menus*), a very graceful kind of dance, consisting of a coupee, a high step, and a balance. Its invention is universally ascribed to the inhabitants of Poitou. The melody begins with the down beat, and contains three crotchets in a bar. The music is made up of two strains, which, from being repeated, are called *reprises*, each consisting of eight or more bars, but very rarely of an odd number. Walther speaks of a minuet in Lully's opera of *Roland*, each strain of which contains ten bars, the sectional number being five,—a circumstance which renders it very difficult to be danced; but Lully's system of phrasing was remarkably irregular. Modern instrumental composers have introduced into their symphonies and quartetts, &c., minuets of rapid movement and fanciful character, followed by supplementary strains (called trios) in a different style. Some of these compositions bear but very slight resemblance to the older forms; and many of them begin with the third beat in the bar. The finest minuets we possess are those in Handel's *Samson* and Mozart's *Don Giovanni*.

MIRABEAU, Honoré Gabriel Riqueti, Comte de, (1749–1791), one of the greatest statesmen and orators

[1] This name occurs in six inscriptions of the years 211–217 found at Constantine (Cirta), North Africa (*C. I. L.*, vol. viii.).

France has ever produced, was born at Bignon, near Nemours, on March 9, 1749. M. de Loménie has shown that the family of Riquet or Riqueti came originally from the little town of Digne, that they won wealth and municipal honours as merchants at Marseilles, and that in 1570 Jean Riqueti bought the chateau and estate of Mirabeau, which had up to that time belonged to the great Provençal family of Barras, and took the title of esquire a few years later. In 1685 Honoré Riqueti obtained the title of Marquis de Mirabeau, and his son Jean Antoine brought honour to it. He served with distinction through all the later campaigns of the reign of Louis XIV., and especially distinguished himself in 1705 at the battle of Cassano, where he was so severely wounded in the neck that he had ever after to wear a silver stock; yet he never rose above the rank of colonel, owing to his eccentric habit of speaking unpleasant truths to his superiors. On retiring from the service he married Françoise de Castellane, a remarkable woman, who long survived him, and he left at his death, in 1737, three sons —Victor, Marquis de Mirabeau (see next article), Jean Antoine, Bailli de Mirabeau, and Comte Louis Alexandre de Mirabeau. The great Mirabeau was the elder surviving son of the marquis. When but three years old he had a virulent attack of confluent small-pox which left his face for ever disfigured, and contributed not a little to nourish his father's dislike to him. His early education was conducted by Lachabeaussière, father of the better known man of letters, after which, being like his father and grandfather destined for the army, then the only profession open to young men of family, he was entered at a pension militaire at Paris, kept by an Abbé Choquart. Of this school, which had Lagrange for its professor of mathematics, we have an amusing account in the life of Gilbert Elliot, first earl of Minto, who with his brother Hugh, afterwards British minister at Berlin, there made the acquaintance of Mirabeau, an acquaintance which soon ripened into friendship, and to which Mirabeau in later life owed his introduction into good English society. On leaving this school in 1767 he received a commission in the cavalry regiment of the Marquis de Lambert, which his grandfather had commanded years before. He at once began love making, and in spite of his ugliness succeeded in winning the heart of the lady to whom his colonel was attached, which led to such scandal that his father obtained a lettre de cachet, and the young scapegrace was imprisoned in the isle of Rhé. The love affairs of Mirabeau form quite a history by themselves, and a well-known history, owing to the celebrity of the letters to Sophie; and the behaviour of the marquis in perpetually imprisoning his son is equally well known, and as widely blamed. Yet it may be asserted that until the more durable and more reputable connexion with Madame de Nehra these love episodes were the most disgraceful blemishes in a life otherwise of a far higher moral character than has been commonly supposed. As to the marquis, his use of lettres de cachet is perfectly defensible on the theory of the existence of lettres de cachet at all. They were meant to be used (see Lettres de Cachet) by heads of families for the correction of their families, and Mirabeau, if any son, surely deserved such correction. Further, they did have the effect of sobering the culprit, and the more creditable part of his life did not begin till he left Vincennes. Mirabeau, it may be remarked at once, was not a statesman of the Alcibiades type, and he did not develop his great qualities of mind and character until his youthful excesses were over. These will be passed over as rapidly as possible, for it was not till 1781 that the qualities which made him great began to appear.

On being released from his first imprisonment, the young count, who had always intended to continue his military career, obtained leave to accompany as a volunteer the French expedition which was to effect the reduction of Corsica. The conquest was one of sheer numerical strength, for the whole population was on the side of Paoli, and Mirabeau, perceiving the value of public opinion, is said to have written a treatise on the oppression the Genoese had formerly exercised over the island, which the Government was ready to publish had not the Marquis de Mirabeau thought fit to destroy it because of its divergence from his own philosophical and economical views. For his services in Corsica Mirabeau was made a captain of dragoons, though not in any particular regiment, and on his return his father endeavoured to make use of the literary ability he had shown for the advancement of his own economical theories. He tried to keep on good terms with his father, though he could not advocate all his ideas, and even went so far in 1772 as to marry a rich heiress, a daughter of the Marquis de Marignane, whose alliance his father had procured for him. He did not live happily with her, and in 1774 was ordered into semi-exile in the country, at his father's request, where he wrote his earliest extant work, the *Essai sur le Despotisme*. His violent disposition now led him to quarrel with a country gentleman who had insulted his sister, and his semi-exile was changed by lettre de cachet into imprisonment in the Chateau d'If. In 1775 he was removed to the castle of Joux, to which, however, he was not very closely confined, having full leave to visit in the town of Pontarlier. Here he met Marie Therèse de Monnier, his Sophie as he called her, a married woman, for whom he conceived a violent passion. Of his behaviour nothing too strong can be said: he was introduced into the house as a friend, and betrayed his trust by inducing Madame de Monnier to fall in love with him, and all his excuses about overwhelming passion only make his conduct more despicable. The affair ended by his escaping to Switzerland, where Sophie joined him; they then went to Holland, where he lived by hack-work for the booksellers; meanwhile Mirabeau had been condemned to death at Pontarlier for *rapt et vol*, of which he was certainly not guilty, as Sophie had followed him of her own accord, and in May 1777 he was seized by the French police, and imprisoned by a lettre de cachet in the castle of Vincennes. There he remained three years and a half, and with his release ends the first and most disgraceful period of his life. During his imprisonment he seems to have learnt to control his passions from their very exhaustion, for the early part of his confinement is marked by the indecent letters to Sophie (first published in 1793), and the obscene *Erotica Biblion* and *Ma Conversion*, while to the later months belongs his first political work of any value, the *Lettres de Cachet*. The *Essai sur le Despotisme* was an ordinary but at times eloquent declamation, showing in its illustrations a wide miscellaneous knowledge of history, but the *Lettres de Cachet* exhibits a more accurate knowledge of French constitutional history skilfully applied to an attempt to show that an existing actual grievance was not only philosophically unjust but constitutionally illegal. It shows, though still in rather a diffuse and declamatory form, that application of wide historical knowledge, keen philosophical perception, and genuine eloquence to a practical purpose which was the great characteristic of Mirabeau, both as a political thinker and as a statesman.

With his release from Vincennes begins the second period of Mirabeau's life. He found that his Sophie was an idealized version of a rather common and ill-educated woman, and she speedily consoled herself with the affection of a young officer, after whose death she committed suicide. Mirabeau first set to work to get the sentence of death still hanging over him reversed, and by his eloquence not only succeeded but got M. de Monnier condemned in the costs of

the whole law proceedings. From Pontarlier he went to Aix, where he claimed the court's order that his wife should return to him. She naturally objected, but his eloquence would have won his case, even against Portalis, the leader of the Aix bar, had he not in his excitement accused his wife of infidelity, on which the court pronounced a decree of separation. He then with his usual impetuosity intervened in the suit pending between his father and mother before the parlement of Paris, and so violently attacked the ruling powers that he had to leave France and again go to Holland, and try to live by literary work. About this time began his connexion with Madame de Nehra, which sweetened the ensuing years of toil and brought out the better points of his character. She was the daughter of Zwier van Haren, a Dutch statesman and political writer, and was a woman of a far higher type than Sophie, more educated, more refined, and more capable of appreciating Mirabeau's good points and helping him to control his passions. With her the lion became a lamb, and his life was strengthened by the love of his *petite horde*, Madame de Nehra, her baby son, afterwards Lucas de Montigny, and his little dog Chico. After a period of work in Holland he betook himself to England, where his treatise on *Lettres de Cachet* had been much admired, and where he was soon admitted into the best Whig literary and political society of London, through his old schoolfellow Gilbert Elliot, who had now inherited his father's baronetcy and estates, and become a leading Whig member of parliament. Sir Gilbert introduced him freely, but of all his English friends none seem to have been so intimate with him as Lord Lansdowne, and Mr (afterwards Sir Samuel) Romilly. The latter became particularly attached to him, and really understood his character; and it is strange that his remarks upon Mirabeau in the fragment of autobiography which he left, and Mirabeau's letters to him, should have been neglected by French writers. Romilly was introduced to Mirabeau by D'Ivernois, and readily undertook to translate the *Considerations on the Order of Cincinnatus*. Romilly writes thus of him in his autobiography:—
